# Foreword

The year 1989 marks the 75th anniversary of the founding of the ARRL. The League has been the national organization for radio amateurs since 1914, and ever since 1926 the ARRL *Handbook* has been *the* book to turn to for information about radio. This is the sixty-sixth edition of the *ARRL Handbook for the Radio Amateur* and the second edition to be offered exclusively in hardcover. We think you'll agree that this edition lives up to the reputation for excellence that the *Handbook* has developed over its long history. As always, this *Handbook* contains valuable information for both the beginner and the most advanced radio hobbyist.

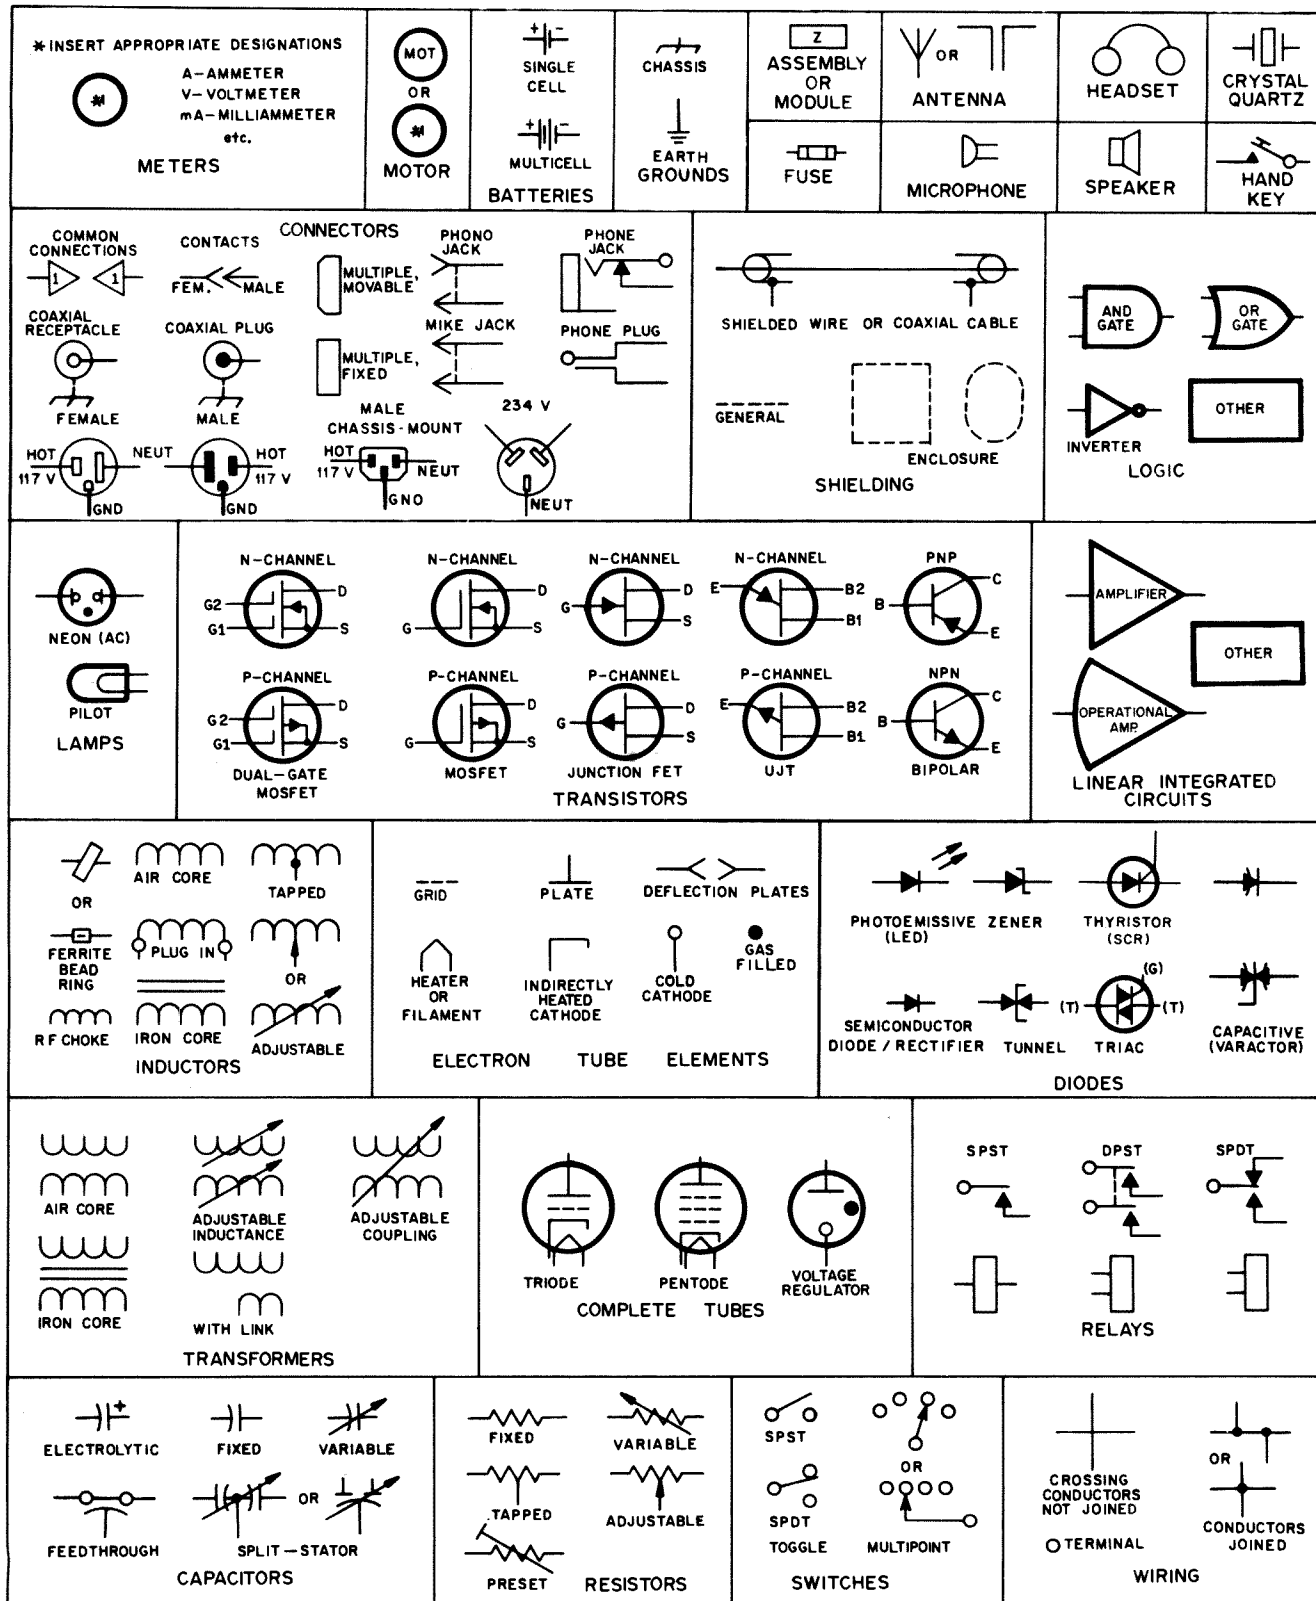

As in previous editions, the 1989 *Handbook* has been updated to keep pace with progress in electronic technology. Rather than a complete revision of a few chapters, we have made a number of more subtle changes to much of the material. There are new sections on oscilloscopes, spectrum analyzers, digital frequency synthesis and phase-noise measurement. You will find several new construction projects, including a new 500-MHz frequency counter, a microprocessor-based memory keyer, a digital audio keyer and an inductance meter. Chapter 30 contains a new 1500-W amplifier design from Dick Stevens, W1QWJ, using the 3CX1200A7 triode.

We invite your comments on the *Handbook*. If you've developed a new technique or built a new project, let us know about it so we can share it with others. This is *your* book; help us make it better.

David Sumner, K1ZZ  
Executive Vice President

Newington, Connecticut

### U.S. Customary Units

#### Linear Units

12 inches (in) = 1 foot (ft)  
36 inches = 3 feet = 1 yard (yd)  
1 rod =  $5\frac{1}{2}$  yards =  $16\frac{1}{2}$  feet  
1 statute mile = 1760 yards = 5280 feet  
1 nautical mile = 6076.11549 feet

#### Area

1 ft<sup>2</sup> = 144 in<sup>2</sup>  
1 yd<sup>2</sup> = 9 ft<sup>2</sup> = 1296 in<sup>2</sup>  
1 rod<sup>2</sup> =  $30\frac{1}{4}$  yd<sup>2</sup>  
1 acre = 4840 yd<sup>2</sup> = 43,560 ft<sup>2</sup>  
1 acre = 160 rod<sup>2</sup>  
1 mile<sup>2</sup> = 640 acres

#### Volume

1 ft<sup>3</sup> = 1728 in<sup>3</sup>  
1 yd<sup>3</sup> = 27 ft<sup>3</sup>

#### Linear

1 meter (m) = 100 centimeters (cm) = 1000 millimeters (mm)

#### Area

1 m<sup>2</sup> =  $1 \times 10^4$  cm<sup>2</sup> =  $1 \times 10^6$  mm<sup>2</sup>

#### Volume

1 m<sup>3</sup> =  $1 \times 10^6$  cm<sup>3</sup> =  $1 \times 10^9$  mm<sup>3</sup>  
1 liter (l) = 1000 cm<sup>3</sup> =  $1 \times 10^6$  mm<sup>3</sup>

#### Mass

1 kilogram (kg) = 1000 grams (g)  
(Approximately the mass of 1 liter of water)  
1 metric ton (or tonne) = 1000 kg

#### Liquid Volume Measure

1 fluid ounce (fl oz) = 8 fluidrams = 1.804 in<sup>3</sup>  
1 pint (pt) = 16 fl oz  
1 quart (qt) = 2 pt = 32 fl oz =  $57\frac{3}{4}$  in<sup>3</sup>  
1 gallon (gal) = 4 qt = 231 in<sup>3</sup>  
1 barrel =  $31\frac{1}{2}$  gal

#### Dry Volume Measure

1 quart (qt) = 2 pints (pt) = 67.2 in<sup>3</sup>  
1 peck = 8 qt

1 bushel = 4 pecks = 2150.42 in<sup>3</sup>

#### Avoirdupois Weight

1 dram (dr) = 27.343 grains (gr) or (gr a)  
1 ounce (oz) = 437.5 gr  
1 pound (lb) = 16 oz = 7000 gr  
1 short ton = 2000 lb, 1 long ton = 2240 lb

#### Troy Weight

1 grain troy (gr t) = 1 grain avoirdupois  
1 pennyweight (dwt) or (pwt) = 24 gr t  
1 ounce troy (oz t) = 480 grains  
1 lb t = 12 oz t = 5760 grains

#### Apothecaries' Weight

1 grain apothecaries' (gr ap) = 1 gr t = 1 gr a  
1 dram ap (dr ap) = 60 gr  
1 oz ap = 1 oz t = 8 dr ap = 480 gr  
1 lb ap = 1 lb t = 12 oz ap = 5760 gr

# The Amateur's Code

## ONE

***The Amateur is Considerate*** . . . He never knowingly uses the air in such a way as to lessen the pleasure of others.

## TWO

***The Amateur is Loyal*** . . . He offers his loyalty, encouragement and support to his fellow radio amateurs, his local club and to the American Radio Relay League, through which Amateur Radio is represented.

## THREE

***The Amateur is Progressive*** . . . He keeps his station abreast of science. It is well-built and efficient. His operating practice is above reproach.

## FOUR

***The Amateur is Friendly*** . . . Slow and patient sending when requested, friendly advice and counsel to the beginner, kindly assistance, cooperation and consideration for the interests of others; these are marks of the amateur spirit.

## FIVE

***The Amateur is Balanced*** . . . Radio is his hobby. He never allows it to interfere with any of the duties he owes to his home, his job, his school, or his community.

## SIX

***The Amateur is Patriotic*** . . . His knowledge and his station are always ready for the service of his country and his community.

— PAUL M. SEGAL  
ex-W3EEA, W9EEA

# Amateur Radio

**A**mateur Radio. You've heard of it. You probably know that Amateur Radio operators are also called hams. (Nobody knows quite why!) But who are these people and what do they do?

Every minute of every hour of every day, 365 days a year, radio amateurs all over the world communicate with each other. It's a way of discovering new friends while experimenting with different and exciting new ways to advance the art of their hobby. Ham radio is a global fraternity of people with common and yet widely varying interests, able to exchange ideas and learn more about each other with every on-the-air contact. Because of this Amateur Radio has the ability to enhance international relations as does no other hobby.

How is it possible to talk to an astronaut circling the earth in the Space Shuttle; a Tokyo businessman, a U.S. legislator, a Manhattan store owner, a camper in a Canadian national park, the head of state of a Mediterranean-area country, a student at a high school radio club in Wyoming, or a sailor on board a ship in the middle of the Pacific? And all without leaving your home! Only with Amateur Radio — that's how!

The way communication is accomplished is just as interesting as the people you get to meet. Signals can be sent around the world using reflective layers of the earth's ionosphere or relayed long distances via mountaintop radio repeaters. Orbiting satellites that hams built are used for two-way communication. Still other hams bounce their signals off the moon! Possibilities are almost unlimited. Not only do radio amateurs use international Morse code and voice for communication, but they also use radioteletype, facsimile and various forms of television. Many hams even have computers hooked up to their radios. As new techniques and modes of communication are developed, hams continue their long tradition of being among the first to use them.

Amateur Radio has flown two missions aboard the Space Shuttle. In the August 1985 mission, Tony England, WØORE, carried along slow-scan television (SSTV) equipment and sent images back to Earth. Tony treated hams around the world to glimpses such as this of life aboard the Space Shuttle *Challenger* on the 2-meter downlink frequency.

What's in the future? Digital voice-encoding techniques? Three-dimensional TV? One can only guess. But if there is ever such a thing as a Star Trek transporter unit that makes it possible for people to physically travel via radio waves, hams will probably have one!

Once radio amateurs make sure that their gear does work, they look for things to do with the equipment and special skills they possess. Public service is a very large and integral part of the whole Amateur Radio Service. Hams continue this tradition by

becoming involved and sponsoring various activities in their communities.

Field Day, just one of the many public service-type activities, is an annual event occurring every June when amateurs take their equipment into the great outdoors (using electricity generated at the operating site) and test it for use in case of disaster. Not only do they test their equipment, but they make a contest out of the exercise and try to contact as many other hams operating emergency-type stations as possible (along with ordinary types). Often

OSCAR (Orbiting Satellite Carrying Amateur Radio) is the name given to a series of satellites designed and built by hams.

they make Field Day a club social event while they are operating.

Traffic nets (networks) meet on the airwaves on a schedule for the purpose of handling routine messages for people all over the country and in other countries where such third-party traffic is permitted. By so doing, amateurs stay in practice for handling messages should any real emergency or disaster occur which would require operating skill to move messages efficiently. Nets also meet because the members often have common interests: similar jobs, interests in different languages, different hobbies (yes, some hams have hobbies other than ham radio!), and a whole barrelful of other reasons. It is often a way to improve one's knowledge and to share experiences with other amateurs for the good of all involved.

DX (distance) contests are popular, and awards are actively sought by many amateurs. This armchair travel is one of the more alluring activities of Amateur Radio. There are awards for Worked All States (WAS), Worked All Canadian Provinces (WAVE), Worked 100 Countries (DXCC), and many others.

Mobile operation (especially on the very high frequencies) holds a special attraction to many hams. It's always fun to keep in touch with ham friends over the local repeater (stations that receive your signal and retransmit it for better coverage of the area) or finding new friends on other frequencies while driving across the country. Mobile units are often the vital link in emergency communications, too, since they are usually first on the scene of an accident or disaster.

The OSCAR (Orbiting Satellite Carrying Amateur Radio) program is a relatively new challenge for radio amateurs. Built by hams from many countries around the world, these ingenious devices hitch rides as secondary payloads on space shots for commercial and governmental communications or weather satellites. OSCAR satellites receive

signals from the ground on one frequency and convert those signals to another frequency to be sent back down to earth. VHF (very-high frequency) and UHF (ultra-high frequency) signals normally do not bend around the earth much beyond the horizon, but when beamed to these satellites, a VHF/UHF signal's effective range is greatly increased to make global communication possible. These OSCAR satellites also send back telemetry signals either in Morse or radioteletypewriter (RTTY) code, constantly giving information on the condition of equipment aboard the satellite.

Self-reliance has always been a trademark of the radio amateur. This is often best displayed by the many hams who design and build their own equipment. Many others prefer to build their own equipment from kits. The main point is that hams want to know their equipment, how it functions, what to do with it and how to fix it if a malfunction should occur. Repair shops aren't always open during hurricanes or floods and they aren't always out in the middle of the Amazon jungle, either. Hams often come up with variations on a circuit design in common use so that it may perform a special function, or a ham may bring out a totally original electronic design, all in the interest of advancing the radio art.

### Looking Back

How did Amateur Radio become the almost unlimited hobby it is today? The beginnings are slightly obscure, but electrical experimenters around the turn of the century, inspired by the experiments of Marconi and others of the time, began duplicating those experiments and attempted to communicate among themselves. There were no regulatory agencies at that time, and much interference was caused by these amateur experimenters to other stations until governments the world over stepped in and established licensing, laws and regulations to control the problems involved in this new technology. Amateur experimenter stations were then restricted to the useless wavelengths of 200 meters and below. Amateurs suddenly found that they could communicate over longer distances than commercial stations on the longer wavelengths. Even so, signals often had to be relayed by intermediate amateur stations to get a message to the proper destination. Because of this, the American Radio Relay League was organized to establish routes of Amateur Radio communication and serve the public interest through Amateur Radio. But the dream of eventual transcontinental and even transoceanic Amateur Radio contact burned hot in the minds of radio amateur experimenters.

World War I broke out, and Amateur Radio, still in its infancy, was ordered out of existence until further notice. Many former Amateur Radio operators joined the armed services and served with distinc-

This emergency communications van, owned and operated by L'Anse Creuse Radio Club (Michigan), demonstrates the commitment Amateur Radio operators have to being prepared for any emergency that may arise.

tion as radio operators, finding their skills to be much needed.

After the close of the "War to End All Wars," Amateur Radio was still banned by law, yet there were many hundreds of formerly licensed amateurs just itching to "get back on the air." The government had tasted supreme authority over the radio services and was half inclined to keep it. Hiram Percy Maxim, one of the founders of the American Radio Relay League, called the pre-war League's officers together and then contacted all the old members who could be found in an attempt to reestablish Amateur Radio. Maxim traveled to Washington, DC, and after considerable effort (and untold red tape) Amateur Radio was opened up again on October 1, 1919.

Experiments on shorter wavelengths were then begun with encouraging results. It was found that as the wavelength dropped (that is, frequency increased) greater distances were covered. The commercial stations were not about to miss out on this opportunity. They moved their stations to the new shorter wavelengths while the battle raged over who had the right to transmit in this new area. Usually, it turned out to be the station with the stronger signal, able to blot out everyone else.

National and international conferences were called in the twenties to straighten out the tangle of wavelength allocations. Through the efforts of ARRL officials, amateurs obtained frequencies on various bands similar to what we have today: 160 through 6 meters. When the amateur operators moved to 20 meters, the dream of coast-to-coast and transoceanic communication without relay stations was finally realized. (A more detailed history of the early days of Amateur Radio is con-

Ham operators are using computers more and more to do station "housekeeping," such as keeping a log of stations contacted.

tained in the ARRL publication *Two Hundred Meters and Down* by Clinton B. DeSoto.)

### Public Service

Amateur Radio is a grand and glorious hobby, but this fact alone would hardly merit the wholehearted support given it by nearly all the world's governments at international conferences. There are other reasons. One of these is a thorough appreciation of the value of amateurs as sources of skilled radio personnel in time of war. Another asset is best described as public service.

The public service record of the amateur is a brilliant tribute to his work. These activities can be roughly divided into two classes: expeditions and emergencies. Amateur cooperation with expeditions began in 1923, when a League member, Don Mix, ITS, accompanied MacMillan to the Arctic on the schooner Bowdoin with an amateur station. Amateurs in Canada and the U.S. provided the home contacts. The success of this venture was so outstanding that other explorers followed suit. During subsequent years Amateur Radio assisted perhaps 200 voyages and expeditions, the several explorations of the Antarctic being perhaps the best known. And this kind of work is not all in the distant past, either: In 1978 Japanese explorer Naomi Uemura, JG1QFW, became the first person to trek to the North Pole alone. Amateur Radio, through member stations of the National Capital DX Association at Washington, DC and the Polar Amateur Radio Club, VE8RCS, at Alert, NWT, Canada, provided important backup communications.

Sometimes Mother Nature goes on a rampage — with earthquakes such as those in Alaska in 1964, Peru in 1970, California in 1971, Guatemala in 1976 and Italy in 1980; floods like those in Big Thompson Canyon, Colorado, in 1976, Kentucky, Virginia, West Virginia, and Johnstown, Pennsylvania in 1977, Jackson, Mississippi in 1979; the big forest fires of California, particularly in 1977; and tornadoes, hurri-

canes, blizzards and typhoons, most anywhere, any year. In each of these disasters, amateurs were ready, with equipment not needing power from the electric company, to carry on communications for police, fire departments and relief organizations. The ability of radio amateurs to help the public in emergencies is one big reason Amateur Radio has survived and prospered.

### Technical Developments

Amateurs started the hobby with spark-gap transmitters, which took up great hunks of frequency space. Then they moved on to tubes when these devices came along. Much later, transistors were used; now integrated circuits are a part of the everyday hardware in the Amateur Radio shack. This is because amateurs are constantly in the forefront of technical progress. Their incessant curiosity and eagerness to try anything new are two reasons. Another is that ever-growing Amateur Radio continually overcrowds its frequency assignments, spurring amateurs to the development and adoption of new techniques to permit the accommodation of more stations.

Amateurs have come up with ideas in their shacks while at home and then taken them to industry with surprising results. During World War II, thousands of skilled amateurs contributed their knowledge to the development of secret radio devices, both in government and private laboratories. Equally as important, the prewar technical progress by amateurs provided the keystone for the development of modern military communications equipment.

In the fifties, the U.S. Air Force was

Greg Marshall, KA1DYT, generates electricity using his bicycle. This pedal power was used to contact five Amateur Radio stations.

faced with converting its long-range communications from Morse to voice; jet bombers had no room for skilled radio operators. At the time, amateurs had been using single sideband for about a decade, and were communicating by voice at great distances with both homemade and commercially built equipment. Generals LeMay and Griswold, both radio amateurs, hatched an experiment in which ham equipment was used to keep in touch with Strategic Air Command headquarters in Omaha, Nebraska, from an airplane traveling around the world. The system worked well; the equipment needed only slight modification to meet Air Force needs, and the expense and time of normal research and development procedures was saved.

Many youngsters build an early interest in Amateur Radio into a career. Later, as professionals, they may run into ideas which they try out in ham radio. A good example is the OSCAR series of satellites, initially put together by amateurs who worked in the aerospace industry, and launched as secondary payloads with other space shots. At this writing 11 Amateur Radio satellites have been launched by Western Hemisphere hams. OSCARs 9 and 10, portions of which were built by amateurs of several different countries, are currently in space relaying the signals of amateurs as well as scientific data. OSCAR can be heard on almost any 29-MHz receiver.

Development of third-generation Phase III satellites proceeds under the guidance of the Radio Amateur Satellite Corporation (AMSAT) with the assistance of Project OSCAR, Inc., the original nonprofit group, both affiliated with ARRL. The Phase III program was temporarily set back in May of 1980 when the first satellite in the series, Phase IIIA, ended up in the

This compact Amateur Radio station in a closet has been used by Ethan Winning, WD6GKF, to contact over 100 countries using a trap dipole antenna. Close the closet door, and the station disappears.

Lunchtime at the Fontana (California) Junior High School Amateur Radio Club station involves the students making contact with other ham operators around the world. These kids have talked to places like Zaire and Finland using equipment they helped buy with money raised from candy sales and a balloon race.

Many Amateur Radio clubs hold theory and code classes to help prospective ham operators get licensed. ARRL Headquarters can provide you with the name and address of the club closest to you.

Atlantic Ocean because of a malfunctioning launch vehicle. It is a credit to its builders that up to the moment of its demise, the satellite functioned flawlessly. The thousands of hours of experience that went into the design and construction of Phase IIIA were used as the starting point for its successor, Phase IIIB. Then on June 16, 1983, Phase IIIB became OSCAR 10 when it was launched aboard a European Space Agency Ariane rocket from French Guiana. This OSCAR, placed in a highly elliptical orbit, provides a vast communications resource to amateurs throughout the world. The new Phase III satellites being built by AMSAT will continue the OSCAR program as older spacecraft are taken out of service.

The last week of November and the first week of December 1983 marked the first time a ham operator in space communicated with fellow hams in all parts of the world. Radio amateur Owen Garriott, W5LFL, made history aboard the space shuttle *Columbia's* STS-9 mission by taking an amateur 2-meter-FM station along. Amateur stations throughout the world got the thrill of working an astronaut aboard an orbiting spacecraft. The second ham-in-space mission took place in July/August 1985. Mission Specialists Tony England, W0ORE and John David Bartoe, W4NYZ beamed compatible-color SSTV signals to earth-bound stations, many of which were set up in schools.

### THE ARRL

Thanks to the hard work of a few visionaries, a national Amateur Radio organization came into being in 1914. Since then, the continued hard work of dedicated men and women — ham radio operators — have made the American Radio Relay League what it is today. The American Radio Relay League (ARRL or *the League*)

is headquartered in the Hartford, Connecticut area. Its operations are, however, national and international in scope. Through its vast network of volunteers throughout the U.S. and Canada, plus a full-time, professional staff of about 125 employees in Newington, Connecticut, the ARRL promotes the advancement of the Amateur Radio Service.

The League operates strictly as a non-profit, educational and scientific organization dedicated to the promotion and protection of the privileges that ham operators enjoy.

Of, by and for the radio amateur, ARRL numbers within its ranks the vast majority of active amateurs in North America. Approximately 120,000 licensed U.S. and Canadian amateurs are full members of the

League. An additional 11,000 foreign amateurs and unlicensed individuals are associate members. There is a place in the League for everyone who has an interest in Amateur Radio.

### League Leadership

Full membership in ARRL gives one a voice in how the affairs of the organization are governed. Each year, half of the ARRL Board of Directors stands for election by full members in those areas or divisions represented by these directors. The Board of Directors, in turn, directs the operation of the League, including the hiring of an executive vice president to run ARRL Headquarters.

The ARRL Field Organization is headed by Section Managers. The Section Managers are elected by the membership. The Field Organization provides opportunities for members to promote Amateur Radio in such areas as *public service* (message handling, emergency preparedness, resolution of radio interference problems), *regulatory matters* (state government liaison, volunteer legal counsel, volunteer examiner, volunteer monitoring), *local clubs* (affiliated club coordinator, volunteer instructor), *public information* (public information officer, bulletin manager), *technical experimentation* (technical coordinator, technical advisor), and many others. The extent of involvement depends on one's interests and available time. But even if you don't have spare time to actively volunteer your services, you can nonetheless make a positive contribution by becoming a member of the ARRL.

### ARRL Publications

A well-informed Amateur Radio community is crucial if ham radio is to continue as a trained and self-disciplined volunteer

Operating from New Hampshire, Tammy Keller, KA1HLG, is representative of the growing number of women who are becoming interested in electronics, communications and Amateur Radio.

The American Radio Relay League's station in Newington, Connecticut, W1AW, transmits bulletins of interest to radio amateurs and code practice that is heard throughout the world.

communications service worthy of the respect of federal, state and local government. At ARRL Headquarters, the League staff produces *QST*, a monthly journal that keeps the membership up to date on the technical and regulatory developments having an impact on Amateur Radio. Each month, the pages of *QST* report news of actions taken by the Federal Communications Commission (in Canada, the Department of Communications) that could have an impact on the future of Amateur Radio.

The monthly journal also keeps the membership informed of the actions the ARRL staff is taking, such as attendance at hearings and conferences. Monthly columns provide tips on contacting stations at great distances (called DXing), interfacing station equipment with computers, results of operating contests, and much more. Of course, you can also find the

latest in building and constructing techniques, plus reviews of commercial equipment now available for the Amateur Radio market. *QST* is the publication devoted entirely to Amateur Radio. ARRL membership includes a subscription to *QST*.

*QST* requires the contributions of many people. In addition to the regular writers, members from all over submit items ranging from correspondence to feature technical project articles. Not all submissions are published, but if you have an original idea or approach to an Amateur Radio problem, why not share it with your fellow hams through the pages of *QST*?

The Headquarters staff also produces several technical publications (one of these is the very book you are now reading), plus books on operating, getting a license, the FCC Rules governing Amateur Radio and specialized communications. The ARRL

*Satellite Experimenter's Handbook* is a good example of the latter. Experimentation with new or exotic modes of communications such as packet radio, spread spectrum and meteor burst is fostered by a special ARRL publication, *QEX*, *The ARRL Experimenter's Newsletter*. Volunteers in certain public service aspects of the Amateur Service can get another publication, *Field Forum*, to help prepare for their role in emergency situations.

#### Membership Services

Membership in ARRL means much more than receiving *QST* each month. Your membership dues also support many membership services. In addition to supporting the Amateur Radio Service through representation before government agencies and administrative support to the Field Organization, ARRL offers membership

services on a personal level. One of these services is the ARRL DX QSL Bureau system. Radio amateurs, as a rule, exchange small postcards called QSL cards to confirm two-way radio contacts. For U.S. and Canadian amateurs, the most convenient way of sending cards to foreign stations is to use the ARRL Outgoing Overseas QSL Bureau. For \$1 per pound (or portion thereof) of cards, ARRL members may send their cards to Headquarters for forwarding to QSL bureaus overseas.

Incoming cards destined for amateurs in the U.S. and Canada from amateurs overseas are handled by a far-ranging network of more than 400 hard-working volunteers. They are organized into call-area QSL bureaus. Each of these volunteers spends an average of 10 hours per month sorting cards, stuffing envelopes and mailing them to their destination stations in the U.S. and Canada. Out-of-pocket expenses for these incoming bureaus are borne by ARRL, but the key here is the time volunteered by sorters and handlers. This service is available to both members and non-members.

Recent cutbacks in the U.S. federal budget have led to amateurs taking over responsibility for administering Amateur Radio examinations. The ARRL Volunteer Examiner Program plays a crucial role as coordinator in the scheduling, printing and administration of amateur exams given by volunteers.

Other services performed by ARRL include low-cost insurance against equipment theft and certain other losses, assistance in resolving radio frequency interference and problems with local government restrictions on antennas, and compiling information that is useful to persons with disabilities.

Scholarships for bright, young radio amateurs and financial support for Amateur Radio satellite projects are just

Pete Demmer, KH6CTQ, has good reason to be proud of the portable windmill he designed and built. Assembled at the KH6IJ Field Day site in less than two hours, the windmill provided all the power needed to run the station.

two ways that the ARRL Foundation carries out its mission of advancing Amateur Radio. The ARRL Foundation gave financial assistance to the OSCAR 10 project and amateur efforts at WARC-79.

#### **International Involvement**

Do you plan on visiting a foreign country? ARRL Headquarters can provide you with information on how to apply for a reciprocal license to permit amateur operation from that country. ARRL serves

as the international secretariat of a worldwide federation of national Amateur Radio societies, the International Amateur Radio Union (IARU). The IARU is comprised of societies like the League in 123 countries. The IARU has official observer status at the International Telecommunication Union (ITU), which is the branch of the United Nations in charge of world conferences and agreements concerning the radio spectrum. At the most recent World Administrative Radio Conference, held in Geneva, Switzerland in 1979, the IARU successfully defended Amateur Radio frequencies against other interests. At that conference, the member-societies of the IARU, after many years of careful planning and coordination, stunned the communications community by accomplishing what was earlier thought impossible — the acquisition of three new high-frequency bands for the use of radio amateurs.

#### **Are You a Member?**

No matter what particular aspect of Amateur Radio attracts you, ARRL membership is relevant and important. It has often been said that there would be no Amateur Radio as we know it today had it not been for the ARRL. The ARRL of today needs the broad-based support of radio amateurs and others interested in the continued existence of the Amateur Radio Service. An Amateur Radio license is not required for membership in the League, although full voting membership is granted only to licensed amateurs in the U.S. and Canada. Inquiries about membership are always welcome! For more information about the American Radio Relay League and answers to any questions you may have about Amateur Radio, write or call ARRL Headquarters, 225 Main St., Newington, CT 06111. Tel. 203-666-1541. Information on how to become a ham radio operator appears in Chapter 36.

# Electrical Fundamentals

Electricity and magnetism are familiar to everyone. The effects of static electricity on a dry, wintry day, the attraction of a compass needle to the Earth's magnetic poles, and the propagation and reception of radio waves are all examples of electromagnetic phenomena. Even the radiation of light and radiant heat from a stove are forms of electromagnetic radiation, governed by many of the same physical laws that apply to the simplest electronic circuit. Knowledge of these laws is fundamental to understanding almost every subject in Amateur Radio, and electronics in general.

Electromagnetic energy exists in the form of fields, a spatial and time-dependent pattern of energy. The analysis of electromagnetic fields, their interrelationships and their interaction with matter forms the basis of all electrical laws. Once a field problem is analyzed in a specific case, it is often possible to use the results over and over again for more general purposes. The field solution can be used to derive numerical formulas for such electrical properties as resistance, inductance and capacitance. These elements in turn form the building blocks for more complex configurations called networks or circuits.

### ELECTROSTATIC FIELD AND POTENTIALS

Matter is made up of complex structures called atoms. Each atom is primarily composed of three fundamental particles called electrons, protons and neutrons. At the center of the atom is the nucleus formed by the combination of protons, particles with a positive charge, and neutrons, particles with no intrinsic charge themselves. Orbiting around the nucleus are the electrons, particles that have a negative charge. The unique combinations of these three atomic building blocks determine the chemical and electrical properties of the atom.

One of the fundamental laws of physics is the concept of electrostatic attraction and repulsion. Simply stated, particles with opposite charge (positive and negative) tend

to attract, while particles with like charge (both positive or both negative) tend to repel. If charged particles are considered to exist at points in space, the force of attraction (or repulsion if the charges have like signs) is given by Coulomb's law

$$F = \frac{k_0 Q_1 Q_2}{r^2}$$

where  $Q_1$  is the numerical value of one charge,  $Q_2$  is the other charge value,  $r$  is the distance between particles, and  $F$  is the force charge  $Q_1$  exerts on charge  $Q_2$ . The value of the proportionality constant,  $k_0$ , depends on the units used in specifying  $F$ ,  $Q$  and  $r$ . In the metric system of units (SI — Systeme International d'Unites) the basic unit of charge is the coulomb, the unit of force is the Newton, and the unit of space is the meter. In the metric system,  $k_0$  is then equal to

$$k_0 = \frac{1}{4\pi\epsilon_0}$$

where  $\epsilon_0$  has a value of

$$\frac{8.854 \times 10^{-12} \text{coul}^2}{\text{Newton m}^2}$$

(usually referred to as "the permittivity of free space"). If a number of charged particles are present, the force on any one particle is a function of the positions and magnitudes of the other charges.

The fundamental forces inside an atom can be described by Coulomb's law. In the case of a complex atom, one having a number of protons in the nucleus, the repulsive forces between protons within the nucleus tend to force the protons apart. Balancing this is the attractive force between the electrons held in orbit about the nucleus and the protons in the nucleus. Although this description is highly simplistic, it does portray the actions within an atom to a surprisingly high degree of accuracy. The electron and the proton both have charges of equal magnitude — about  $1.6 \times 10^{-19}$  coulombs. The charge on the electron is negative, while the charge on the proton is positive. These values of charge may seem too minute to account for atomic

particle interaction, but consider the distances ( $r$ ) involved. Almost all atoms have an outer diameter of approximately  $10^{-10}$  meter. It is evident that substantial forces exist within the atom.

Analyzing the forces exhibited by multiple charges is overwhelmingly cumbersome, so the concept of electrostatic or electric field strength is a useful one to introduce. If a single charged particle is moved slowly around a fixed charged particle, everywhere the moving particle moves, a force is exerted on the moving particle. The force exerted on the moving particle displays the existence of a force field. If the moving particle is assigned a value  $Q_t$  for its charge, then by Coulomb's law, the force ( $F_t$ ) on the moving particle is

$$F_t = \frac{Q_1 Q_2}{4 \pi \epsilon_0 r^2}$$

Writing this as a force per unit charge gives

$$\frac{F_t}{Q_t} = \frac{Q_1}{4 \pi \epsilon_0 r^2}$$

This expression describes the force on the moving particle totally as a function of the distance from  $Q_1$  and the magnitude of  $Q_1$ ; this is called the electric field intensity. For example, if a force of 1 newton existed on a test charge of 2 coulombs, the field intensity would be 0.5 newton/coulomb.

As described by Isaac Newton, whenever a force exists on an object, an expenditure of energy is needed to move the object against that force. In some instances, mechanical energy may be recovered (such as in a compressed spring) or the energy may be converted to another form of energy (such as heat produced by friction). In electrostatics, the energy is described in terms of potential. Potential is defined as the work required from some energy source in moving a unit positive charge between two points in an electric field. For example, if an energy expenditure of 5 newton-meters (5 joules) is needed to move a charge of 2 coulombs from a point of zero energy

Fig. 1 — Field lines (solid) and potential lines (dashed) surrounding a charged sphere.

Fig. 2 — Variation of potential with distance for the charged sphere of Fig. 1.

Fig. 3 — Variation of field strength with distance around a sphere charged to 5 volts for spheres of different radii.

to a given point, the potential at that point would be 2.5 joules/coulomb. The unit joules/coulomb is rather unwieldy, so another name is given to electrical potential: the volt. One joule per coulomb is equal to 1 volt. Notice that if the voltage is divided by length (meters), the dimensions of field intensity are obtained and a field strength of 1 newton/coulomb becomes 1 volt/meter.

The relationship between field intensity and potential is illustrated by the example shown in Fig. 1. A conductive sphere is gradually charged until its surface is at a potential of 5 volts. As charges arrive on the surface of a conductor, they tend to spread out into a uniform distribution; the outside of the sphere is said to constitute an equipotential surface. Since every point on the sphere has the same charge, and the charge spreads uniformly over the sphere's surface even as charge is added or removed, the same amount of energy is needed to bring a given amount of charge from a zero reference point to any one point on the sphere as would be required to bring the same amount of charge to any other point on the sphere. The amount of energy expended also is independent of the path traveled to get to the surface. For this particular sphere, it would require 5 joules of energy to bring a charge of 1 coulomb from a point of 0 voltage to any point on the sphere (as indicated by the dotted lines in Fig. 1).

The electromotive force applied to a charged particle at the surface of the sphere must be applied perpendicular to the surface for maximum potential to be realized. Any force applied from a direction other than normal to the surface will have two components: one is performing real work by moving the charge away from the sphere, and the other tends to pull the charge along the surface. Since the charges are free to move about the charged surface already, the energy source does no work in moving charges along the surface, only away from it; the potential difference between points on the sphere is zero. Once the charges are equally distributed along the sphere's surface, an equilibrium condition will be reached and any initial field component parallel to the surface becomes zero. The motion of charge under the influence of an electric field is a very important concept in electricity. The rate at which charge flows past a reference point is defined as the current. A rate of 1 coulomb per second is defined as 1 ampere.

In the case of the symmetrical sphere, the direction of the electromotive force and the electric field can be represented by the solid straight lines in Fig. 1. The arrows indicate the direction of the force for a positive charge. At points farther away from the sphere, less energy is required to move a charged particle from the zero reference. A series of concentric spherical shells, indicated by the dashed lines, can be used to define the equipotential surfaces around the

sphere. From the definition of potential difference, it can be shown through the use of integral calculus that the potential varies inversely to the distance from the center of the sphere. This relationship is indicated by the numbers in Fig. 1 and by the graph in Fig. 2.

The electric field defines the direction and magnitude of a force on a charged object. The field intensity is equal to the negative value of the slope of the curve in Fig. 2. The slope of a curve is the rate of change of some variable with distance; in this case the variable is the potential. This is why the electric field is sometimes called the potential gradient (gradient being equivalent to slope). In the case of a curve that varies as the inverse of the distance, the slope at any point is squared.

An examination of Fig. 1 suggests that the potential variation is dependent only on the shape of the conductor, and not its actual physical size. That is, once the value of the radius,  $a$ , of the sphere in Fig. 1 is specified, the potential at any other point a given distance from the sphere is also known. Thus, Fig. 1 can be used for any number of spheres with different radii. When it is changed by a certain percentage, all the other values would change by the same percentage, too. However, the amount of charge required to produce a given voltage, or voltage change, does depend on the size of the conductor, its shape, and its position in relation to other conductors and insulators. For a given conductor configuration, the voltage is related to the required charge by the formula

$$V = \frac{Q}{C}$$

where the entity  $C$  is defined as the capacitance. Capacitance will be discussed in more detail in a later section.

Since the electric field intensity is only related to the change in potential with distance, the rate at which it changes is unaffected by the absolute physical size of the conductor configuration. However, the exact numerical potential value at any point does depend on the dimensions of the configuration. This is illustrated in Fig. 3 for spheres with different radii. Note that for larger radii, the numerical value of the field strength at the surface of the sphere (distance equal to  $a$ ) is less than it is for smaller radii. This effect is important in the design of transmission lines and capacitors. (A capacitor is a device for storing charge. In older terminology, it was sometimes called a condenser.)

Even when identical voltages are applied across the terminals of two different sized transmission lines or capacitors, the field strength between the conductors is higher for configurations of small physical size than for larger physical sizes. When the field strength becomes too high for a particular insulating material, the material (including air) can break down, allowing a conductive arc to pass through the insulation. This

Fig. 4 — Spark gaps with sharp points break down at lower voltages than ones with blunt surfaces, even though the separation is the same.

effect is the basis for spark plugs in internal combustion engines. The gap between electrodes in the spark plug is adjusted to provide a calibrated breakdown of the insulator (the air-gas mixture) at a particular voltage. The arc is hot enough to ignite the fuel-air mixture.

Another example of high electric field breakdown is found in lightning arrestors. These are devices used to protect radio equipment connected to an antenna that might be subjected to high levels of atmospheric electricity. "Spark-gap" conductors are connected between the antenna transmission line and ground. The spark-gap conductors or electrodes are filed to sharp points. These needlepoints appear as conductors of very small radii, so the field strength between them is higher for the same applied potential than it would be for blunt electrodes (Fig. 4). For a given potential, this allows the separation between conductors to be relatively large so the radio frequency effects of the spark gap have minimal effect on normal circuit operation.

Increasing the size of a conductor reduces the electric field strength, thereby reducing the potential for insulation breakdown. A relatively common effect in high-strength electric fields is corona. Here the air insulation breaks down and actually glows. The effect is often seen on sharp tips of high power transmitting antennas. In order to reduce the localized field strength (and reduce the unwanted corona), a blunt electrode such as a sphere is often used on the sharp tip of a whip antenna.

Examination of Fig. 3 reveals that the field strength is zero for distances less than  $a$  (the sphere radius), which includes points actually inside the sphere. The implication here is that the effect of fields and charges cannot penetrate the conducting surface and disturb conditions inside the enclosure. The conducting sphere is said to form an electrostatic shield around the contents of the enclosure. The converse is not true, however. That is, charges inside the sphere do cause or induce a field on the outside surface. This is why it is very important

Fig. 5 — Potential and field strength along a current-carrying conductor.

that enclosures designed to confine the effects of charges be connected to a point of zero potential. Such a point is often called a ground.

### Fields and Currents

In the previous section, the motion of charged particles in the presence of an electric field was described in connection with charges placed on a conducting sphere, and the concept of current was introduced. In that example, it was assumed that charges could move around unimpeded on the surface of the sphere. In the real world using obtainable materials, this is not true. The movement of charge is dependent upon the transfer of energy between adjacent atoms in the conductor. Charges appear to collide with the constituent atoms as they move through the conductor while under the influence of the electric field of the conductor. The number of "collisions" depends on the chemical characteristics of the material used. Silver acts as a very good conductor with minimal opposition to the movement of charge; carbon and certain alloys of iron are rather poor conductors of charge flow. A measure of how easily charge can flow through a conductor is defined as the conductivity, and is denoted by  $\sigma$ .

The current density in a conductor,  $J$ , is the rate of charge flow or current through a given cross-sectional area. It is related to the electric field and conductivity by the formula

$$J = \sigma E$$

In general, the conductivity and electric field in a conductor do not remain constant over a large cross-sectional area. However, in order to simplify understanding of the following theoretical case, both are assumed to remain constant (Fig. 5).

A cylinder of a material with conductivity  $\sigma$  is inserted between two end caps of infinite conductivity. The end caps are connected to a voltage source, such as a bat-

tery or generator. (A battery consists of a number of cells that convert chemical energy to electrical energy, and a generator converts mechanical energy of motion to electrical energy.) The electric field is also considered to be constant along the length,  $\ell$ , of the cylinder. As a consequence, the slope of the potential variation along the cylinder is also a constant. This is indicated by the dashed lines in Fig. 5B. Since the electric field is constant, the current density is also constant; the total current entering the end caps is the product of the current density and the cross-sectional area. The value of the electric field is the quotient of the total voltage and the length of the cylinder. Combining these results and introducing two new entities gives the following set of equations:

$$J = \sigma \frac{V}{\ell} \text{ since } J = \sigma E \text{ and } E = \frac{V}{\ell}$$

$$I = J(A) = \frac{\sigma A V}{\ell}$$

$$\rho = \frac{1}{\sigma} \text{ and } V = I \left( \frac{\rho \ell}{A} \right)$$

$$R = \frac{\rho \ell}{A} \text{ and } V = IR$$

where

$\rho$  = the resistivity of the conducting material

$R$  = the resistance

The final equation, called Ohm's Law, is a very basic one in circuit theory. Configurations similar to the one shown in Fig. 5 are very common in electrical circuits and are called resistors.

It will be shown in a later section that the power dissipated in a resistor is equal to the product of the resistance and the square of the current. Resistance is often an undesirable effect (such as in a wire carrying current from one location to another one), and in these situations must be reduced as much as possible. This can be accomplished by using a conductor with a low resistivity such as silver or copper (which is close to silver in resistivity, but is not as expensive) with a large cross-sectional area and as short a length as possible. The current-carrying capability decreases as the diameter of a conductor gets smaller.

### Potential Drop and Electromotive Force

The application of the relationships between fields, potential and concepts similar to the physical configuration shown in Fig. 5 permitted the derivation of the formula that eliminated further consideration of the field problem. The idea of an electrical energy source was also introduced. A similar analysis involving mechanics and field theory would be required to determine the characteristics of an electrical generator, and an application of chemistry would be involved in designing a chemical cell. However, it will be assumed that this problem has been solved and that the energy source can be replaced with a symbol such as that used in Fig. 5.

The term electromotive force (EMF) is applied to describe a source of electrical energy, and potential drop (or voltage drop) is used for a device that consumes electrical energy. A combination of sources and resistances (or other elements) that are connected in some way is called a network or circuit.

### Charge Polarity and Electron Flow

The “+” and “-” symbols assigned to electromotive forces and potential drops are important in that they define the polarity of voltage and direction of current flow. These plus and minus symbols (representing positive and negative) were first used in the 18th century by Benjamin Franklin to describe two types of electric charge. Charged atoms (called ions) having more than the usual number of electrons have a negative charge, and those having less than the usual number are said to be positively charged. If a polarizing force is applied to some matter and then removed,

the atoms will tend to revert to their natural states. This means that atoms deficient in electrons will attract the needed particles from those atoms having excess electrons. Thus, the transfer of electrons is from negative ions to positive ions. When the path for electrons is an electrical circuit, the current flows from negative to positive around the potential generator.

The direction of electron flow is important in applications of thermionic and semiconductor devices. The cathode of a vacuum tube is heated so that it will boil off electrons. Current will flow in the tube if and only if the anode is biased positive with respect to the cathode. This is known as the Edison effect.

Most modern circuits employ a chassis or ground plane or bus as a common conductor. This practice reduces the wiring or printed circuitry required and simplifies the schematic diagram. When the negative terminal of the power source is connected to

this “ground” system, electrons flow from the negative terminal through the ground system and through the circuit elements to the positive terminal. While this is certainly a correct description of the action, it is more convenient to think of the common conductor as the return leg for all circuits. To accommodate this reasoning, electrical engineers have adopted a positive-to-negative convention. This convention is adhered to in most of the technical literature. The arrows in semiconductor schematic symbols point in the direction of this conventional current and away from actual electron flow.

In discussing network elements having one terminal connected to the “common,” “ground” or “return” leg of the circuit, engineers use the terms source and sink to describe the current flow. A device is a current source if current flows away from the ungrounded terminal, and a current sink if current flows into the ungrounded terminal.

## Alternating Currents

In considering current flow, it is natural to think of a single, constant force causing the electrons to move. When this is so, the electrons always move in the same direction through a path or circuit made up of conductors connected together in a continuous chain. Such a current is called a direct current, abbreviated dc. It is the type of current furnished by batteries and by certain types of generators.

It is also possible to have an EMF that periodically reverses. With this kind of EMF the current flows first in one direction through the circuit and then in the other. Such an EMF is called an alternating EMF, and the current is called an alternating current (abbreviated ac). The reversals (alternations) may occur at any rate from a few per second up to several billion per second. Two reversals make a cycle; in one cycle the force acts first in one direction, then in the other and then returns to the first direction to begin the next cycle. The number of cycles that occur in one second is called the frequency of the alternating current. The inverse of frequency, or the time duration of one cycle, is the period of the current.

The difference between direct current and alternating current is shown in Fig. 6. In these graphs, the horizontal axis indicates time, increasing toward the right. The vertical axis represents the amplitude or strength of the current, increasing in either the up or down direction away from the horizontal axis. If the graph is above the horizontal axis, the current is flowing in one direction through the circuit (indicated by the + sign). If it is below the horizontal axis the current is flowing in the

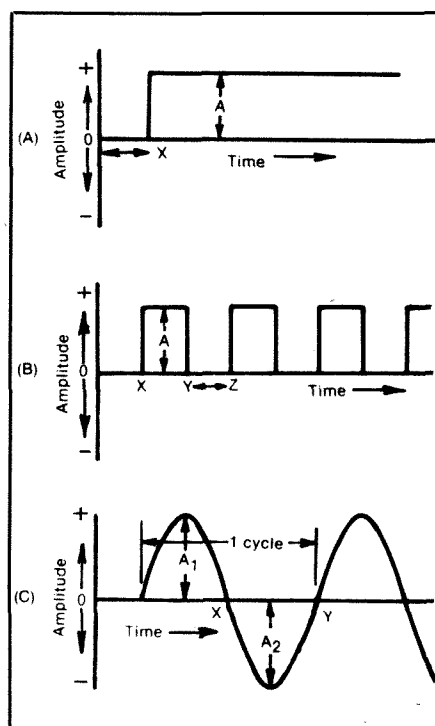

Fig. 6 — Three types of current flow. A — direct current; B — intermittent direct current; C — alternating current.

reverse direction through the circuit (indicated by the - sign). In Fig. 6A, assume that we close the circuit or make the path for the current complete at the time indicated by X. The current instantly takes the amplitude indicated by the height A. After that, the current continues at the

same amplitude as time goes on. This is an ordinary direct current.

In Fig. 6B, the current starts flowing with the amplitude A at time X, continues at that amplitude until time Y and then instantly ceases. After an interval YZ the current again begins to flow and the same sort of start-and-stop performance is repeated. This is an intermittent direct current. We could get it by alternately closing and opening a switch in the circuit. It is a direct current because the direction of current flow does not change; the amplitude is always on the + side of the horizontal axis. The intermittent direct current illustrated has an ac component, however, that can be isolated by an electrical circuit called a filter. Filtering is discussed in greater detail in later sections.

In Fig. 6C the current starts at zero, increases in amplitude as time goes on until it reaches the amplitude  $A_1$  while flowing in the + direction, then decreases until it drops to zero amplitude once more. At that time (X) the direction of the current flow reverses; this is indicated by showing the next part of the graph below the axis. As time goes on the amplitude increases, with the current now flowing in the - direction, until it reaches amplitude  $A_2$ . Then the amplitude decreases until finally it drops to zero (Y) and the direction reverses once more. This is an alternating current.

### Waveforms

The type of alternating current shown in Fig. 6C is known as a sine wave. An electrodynamic machine called an alternator generates this waveshape because the current induced in the stator winding is pro-

Fig. 7 — A complex waveform. A fundamental (top) and second harmonic (center) added together, point by point at each instant, result in the waveform shown at the bottom. When the two components have the same polarity at a selected instant, the resultant is the simple sum of the two. When they have opposite polarities, the resultant is the difference; if the negative-polarity component is larger, the resultant is negative at the instant.

Fig. 8 — Two tones of dissimilar frequency and amplitude (A) are easily recognizable in the composite waveform (B).

portional to the sine of the angle that the winding makes with the magnetic flux lines produced by the rotating field. It is also possible to generate a sine wave electronically.

The variations in many ac waves are not so smooth, nor is one half cycle necessari-

ly just like the preceding one in shape. However, these complex waves can be shown to be the sum of two or more sine waves of frequencies that are exact integral (whole-number) multiples of some lower frequency. The lowest frequency is called the fundamental, and the higher frequencies are called harmonics.

Fig. 7 shows how a fundamental and a second harmonic (twice the fundamental) might add to form a complex wave. Simply by changing the relative amplitudes of the two waves, as well as the times at which they pass through zero amplitude, an infinite number of waveshapes can be constructed from just a fundamental and second harmonic. More complex waveforms can be constructed if more harmonics are used.

When two or more sinusoidal or complex signals that are not necessarily harmonically related are applied to a common load resistor, the resultant waveform is the sum of the instantaneous voltages. If the two signals have significantly different frequencies and amplitudes, they are easily distinguishable as components of a composite wave.

The illustration in Fig. 8 is an example of this phenomenon. Two signals having equal amplitudes and nearly equal frequencies combine to produce a composite wave that is not so simply analyzed. Shown in Fig. 9 are two signals having a frequency relationship of 1.5:1. When the positive peaks coincide, the resultant amplitude is twice that of either tone. Similarly, when the maximum negative excursion of one signal corresponds with the maximum positive excursion of the other, the resultant amplitude is the algebraic sum, or zero. The negative peaks never coincide; therefore this composite waveform is not symmetrical about the zero axis. Notice the periodic variation in the amplitude or envelope of the composite waveform. This variation has a frequency equal to the difference or beat between the two tones.

## FREQUENCY AND WAVELENGTH

Frequencies ranging from about 20 to 20,000 cycles per second or hertz are called audio frequencies, because the vibrations of air particles that our ears recognize as sounds occur at a similar rate. Audio frequencies (abbreviated AF) are used to actuate loudspeakers and thus create sound waves.

Frequencies above about 20,000 hertz (Hz) are called radio frequencies (RF) because they are useful in radio transmission. Frequencies all the way up to and beyond 100,000,000,000 Hz have been used for radio purposes. At radio frequencies it becomes convenient to use a unit larger than the hertz. Three such units are the kilohertz, which is equal to 1000 Hz and is abbreviated kHz, the megahertz, equal to 1,000,000 hertz or 1000 kilohertz, and is abbreviated MHz, and the gigahertz, equal to 1,000,000,000 hertz or 1000 MHz

Fig. 9 — The graphic addition of equal-amplitude signals fairly close in frequency illustrates the phenomenon of beats. The beat-note frequency is  $1.5f - f = 0.5f$ , and is visible in the resultant waveform.

and is abbreviated GHz. Table 1 shows how to convert between the various units in common use. The prefixes attached to the basic-unit name indicate the nature of the unit. These prefixes are pico — one trillionth (abbreviated p) nano — one billionth (abbreviated n) micro — one millionth (abbreviated  $\mu$ ) milli — one thousandth (abbreviated m) kilo — one thousand (abbreviated k) mega — one million (abbreviated M) giga — one billion (abbreviated G)

Various radio frequencies are divided into classifications. These classifications constitute the frequency spectrum as far as

it extends for radio purposes at the present time.

Frequency	Classification	Abbrev.
10 to 30 kHz	Very low freq.	VLF
30 to 300 kHz	Low freq.	LF
300 to 3000 kHz	Medium freq.	MF
3 to 30 MHz	High freq.	HF
30 to 300 MHz	Very high freq.	VHF
300 to 3000 MHz	Ultrahigh freq.	UHF
3 to 30 GHz	Superhigh freq.	SHF
30 to 300 GHz	Extremely high freq.	EHF

### Wavelength

Radio waves travel at the same speed as light — about 300,000,000 meters per second or 186,000 miles per second in space. These waves can be set up by a radio-frequency current flowing in a circuit. This happens because the rapidly changing current sets up a magnetic field that changes in the same way, and the varying magnetic field in turn sets up a varying electric field. Whenever this happens, the two fields radiate at the speed of light.

Suppose an RF current has a frequency of 3,000,000 Hz. The field will go through complete reversals (one cycle) in  $1/3,000,000$  second. In that same period of time the field (the wave) moves  $300,000,000/3,000,000$  meters, or 100 meters. By the time the wave has moved that distance the next cycle has begun and a new wave has started out. In other words, the beginning of the first wave covers a distance of 100 meters before the beginning of the next, and so on. This distance is the wavelength.

The longer the time of one cycle (the lower the frequency) the greater the distance covered by each wave, and hence the longer the wavelength. The relationship between wavelength and frequency is shown by the formula

$$\lambda = \frac{300,000}{f \text{ (kHz)}}$$

where

$\lambda$  = wavelength in meters  
 $f$  = frequency in kilohertz

or

$$\lambda = \frac{300}{f \text{ (MHz)}}$$

where

$\lambda$  = wavelength in meters  
 $f$  = frequency in megahertz

Example: The wavelength corresponding to a frequency of 3650 kilohertz is

$$\lambda = \frac{300,000}{3650} = 82.2 \text{ meters}$$

### PHASE

The term phase essentially means time, or the time interval between the instant when one thing occurs and the instant when a second related thing takes place. The later event is said to lag the earlier, while the one that occurs first is said to lead. In ac circuits the current amplitude changes continuously, so the concept of phase or time becomes important. Phase can be measured in ordinary time units, such as the second, but there is a more convenient method.

Since each ac or RF cycle occupies exactly the same amount of time as every other cycle of the same frequency, we can use the cycle itself as the time unit. Using the cycle as the time unit makes the specification or measurement of phase independent of the frequency of the current, as long as only one frequency is under consideration at a time. When two or more frequencies are to be considered, as in the case where harmonics are present, the phase measurements are made with respect to the lowest, or fundamental, frequency.

The time interval or phase difference under consideration usually will be less than one cycle. With a sine wave of current, the amplitude of the current at any instant is proportional to the sine of the fraction of the cycle completed at that moment from the instant the cycle began. Phase difference could be measured in decimal parts of a cycle or radian measure, but it is often more convenient to divide the cycle into 360 parts or degrees. A phase degree is therefore  $1/360$  of a cycle (Fig. 10).

### Measuring Phase

The phase difference between two currents of the same frequency is the temporal or angular difference between corresponding parts of cycles of the two currents. This is shown in Fig. 11. The current labeled A leads the one marked B by  $45^\circ$ , since the A cycles begin  $45^\circ$  earlier in time. It is equally correct to say that B lags A by  $45^\circ$ .

Two important special cases are shown in Fig. 12. In the upper drawing B lags  $90^\circ$  behind A; that is, its cycle begins just one quarter cycle later than that of A. When one wave is passing through zero, the other is just at its maximum point.

In the lower drawing A and B are  $180^\circ$  out of phase. In this case it does not matter which one is considered to lead or lag. B is always positive while A is negative, and vice versa. The two waves are thus completely out of phase.

The waves shown in Figs. 10 and 11 could represent current, voltage or both. A and B might be two currents in separate circuits, or A might represent voltage and B current in the same circuit. If A and B represent two currents in the same circuit (or two voltages in the same circuit) the

Fig. 10 — An ac cycle is divided into 360 degrees that are used as a measure of time or phase.

Fig. 11 — When two waves of the same frequency start their cycles at slightly different times, the time difference or phase difference is measured in degrees. In this drawing wave B starts  $45^\circ$  (one eighth cycle) later than wave A, and so lags  $45^\circ$  behind A.

Fig. 12 — Two important special cases of phase difference. In the upper drawing, the phase difference between A and B is  $90^\circ$ ; in the lower drawing the phase difference is  $180^\circ$ .

total or resultant current (or voltage) also is a sine wave, because adding any number of sine waves of the same frequency always gives a sine wave also of the same frequency.

# The Decibel

It is useful to appraise signal strength in terms of relative loudness as registered by the ear. For example, if a person estimates that a signal is twice as loud when the transmitter power is increased from 10 watts to 100 watts, he or she will also estimate that a 1000-watt signal is twice as loud as a 100-watt signal. The human ear has a logarithmic response.

This fact is the basis for the use of the relative power unit called the decibel (dB). A decibel is one-tenth of a bel, the unit of sound named for Alexander Graham Bell. A change of 1 decibel in power level is just detectable as a change in loudness under ideal conditions. The number of decibels corresponding to a given power ratio is given by:

$$\text{dB} = 10 \log_{10} \left( \frac{P_2}{P_1} \right)$$

Note that the decibel is based on power ratios. Voltage or current ratios can be used, but only when the impedance is the same for both values of voltage, or current. The gain of an amplifier cannot be expressed correctly in decibels if it is based on the ratio of the output voltage to the input voltage unless both voltages are measured across the same value of impedance. When the impedance at both points of measurement is the same, the following formula may be used for voltage or current ratios:

$$\text{dB} = 20 \log \left( \frac{V_2}{V_1} \right) \text{ or } 20 \log \left( \frac{I_2}{I_1} \right)$$

where

V = voltage

I = current

If the voltage formula above is applied to an amplifier, where  $V_2$  is the output voltage and  $V_1$  is the input voltage, a positive decibel value indicates amplifier gain. On the other hand, applying the formula to a resistor network would result in a negative decibel value, signifying a loss.

When the decibel value is known, the numerical ratio can be calculated from:

$$\frac{P_2}{P_1} = \text{antilog} \left( \frac{\text{dB}}{10} \right) = 10^{\frac{\text{dB}}{10}}$$

or

$$\frac{V_2}{V_1} = \text{antilog} \left( \frac{\text{dB}}{20} \right) = 10^{\frac{\text{dB}}{20}}$$

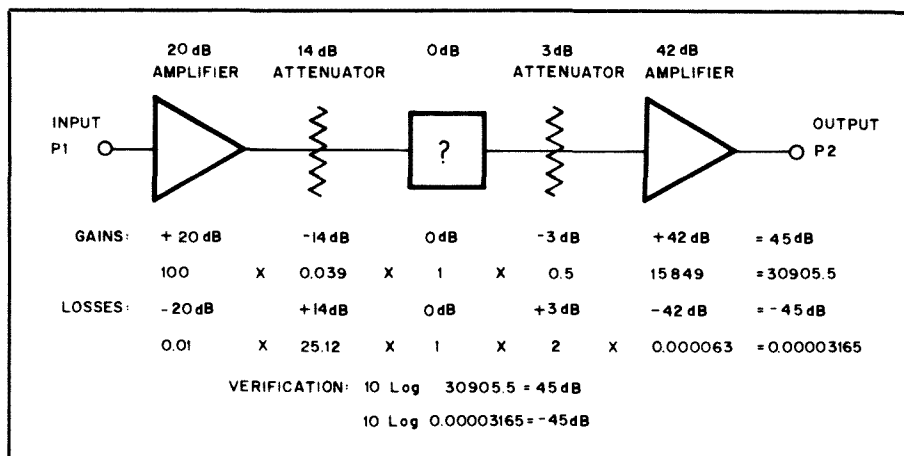

Fig. 13 — How to compute the composite gain of a system. Either numerical ratios or decibels may be used, but all must be consistent in gain or loss. The method is explained in the text.

Many mathematics textbooks contain tables of logarithms, or these numbers can be produced very quickly with a calculator. In any case, it is convenient to memorize the decibel values for a few of the common power and voltage ratios. For power changes, a numerical ratio of 2 is 3 dB, 4 is 6 dB, 10 is 10 dB, 100 is 20 dB, 1000 is 30 dB, and so on. When voltage changes are considered, doubling the voltage causes a 6-dB increase, a numerical ratio of 10 is worth 20 dB, 100 is 40 dB and so on. One can interpolate between known ratios to estimate a gain or loss within 1 decibel. Inverting a numerical ratio simply reverses the algebraic sign of the decibel value. For example, a voltage gain of 10 corresponds to 20 dB, while a gain of 1/10 (which is a loss of 10) corresponds to -20 dB.

In a system of cascaded gain and loss blocks where numerical ratios are specified for each block, the overall system gain or loss can be calculated this way: Convert the ratios to all gains or all losses (gains become fractional losses or losses become fractional gains). The overall numerical gain or loss will be the product of the individual figures, and the decibel value can be derived as before. If the individual gains and losses are given in decibels, the procedure is again to convert to all losses or gains. Only the algebraic signs need to be changed; that is, decibel losses become negative gains. Gains may also be treated as negative losses. The overall decibel gain or loss is the algebraic sum of the individual figures, and this can

be converted to a numerical ratio if desired. Fig. 13 illustrates both methods.

The decibel is a relative unit. When using decibels to specify an absolute voltage, current or power level, the decibel value must be qualified by a reference level. For example, in a discussion of sound intensity, a reference level of 1 dB corresponds to an acoustical field strength of  $10^{-16} \text{ W/cm}^2$ , the normal human hearing threshold at 600 Hz. A lion's roar at 20 feet might have a sound intensity of 90 dB, and the threshold of pain occurs at 130 dB. Thus, the human ear/brain has a dynamic range of 130 dB, or a ratio of 10 trillion to one.

In radio work, power is often rendered in dBW (decibels referenced to 1 watt) or dBm (decibels referenced to 1 milliwatt). With this system, 2 kilowatts equals +63 dBm or +33 dBW, and 5 microwatts equals -23 dBm or -53 dBW. Voltages are sometimes given as decibel values with respect to 1 volt or 1 microvolt; 2 millivolts equals +66 dB $\mu$ V or -54 dBV. Antenna gain is specified with respect to some standard reference element such as isotropic radiator or a dipole. The measurement units are the dBi (gain over isotropic) and dBd (gain over a half-wave dipole). In spectrum analysis, noise, spurious signals and distortion products can be referenced to the carrier (if one exists), dBc. A certain frequency synthesizer might have a phase-noise specification of -40 dBc, 100 Hz removed from the carrier.

## Resistance and Conductance

Given two conductors of the same size and shape, but of different materials, the amount of current that will flow when a given EMF is applied will be found to vary with the resistance of the material. The

lower the resistance, the greater the current for a given value of EMF.

Resistance is measured in ohms ( $\Omega$ ). A circuit has a resistance of 1 ohm when an applied EMF of 1 volt causes a current of

1 ampere to flow. The resistivity of a material is the resistance, in ohms, of a cube of the material measuring 1 centimeter on each edge. One of the best conductors is copper, and in making resistance calcula-

**Table 2****Relative Resistivity of Metals**

Material	Resistivity Compared to Copper
Aluminum (pure)	1.60
Brass	3.7-4.90
Cadmium	4.40
Chromium	1.80
Copper (hard-drawn)	1.03
Copper (annealed)	1.00
Gold	1.40
Iron (pure)	5.68
Lead	12.80
Nickel	5.10
Phosphor bronze	2.8-5.40
Silver	0.94
Steel	7.6-12.70
Tin	6.70
Zinc	3.40

tions it is frequently convenient to compare the resistance of the material under consideration with that of a copper conductor of the same size and shape. Table 2 gives the ratio of the resistivity of various conductors to that of copper.

The longer the physical path, the higher the resistance of that conductor. For direct current and low-frequency alternating currents (up to a few thousand hertz) the resistance is inversely proportional to the cross-sectional area of the path the current must travel; that is, given two conductors of the same material and having the same length, but differing in cross-sectional area, the one with the larger area will have the lower resistance.

**RESISTANCE OF WIRES**

The problem of determining the resistance of a round wire of given diameter and length — or its converse, finding a suitable size and length of wire to provide a desired amount of resistance — can be solved easily with the help of the copper wire table given in Chapter 35. This table gives the resistance, in ohms per thousand feet, of each standard wire size.

Example: Suppose a resistance of 3.5 ohms is needed and some no. 28 wire is on hand. The wire table in Chapter 35 shows that no. 28 wire has a resistance of 66.17 ohms per thousand feet. Since the desired resistance is 3.5 ohms, the length of wire required is

$$\frac{3.5}{66.17} \times 1000 = 52.89 \text{ ft}$$

Suppose that the resistance of wire in a circuit must not exceed 0.05 ohm and that the length of wire required for making the connections totals 14 feet. Then

$$\frac{14}{1000} \times R = 0.05 \text{ ohm}$$

where  $R$  is the maximum allowable resistance in ohms per thousand feet. Rearranging the equation gives

$$R = \frac{0.05 \times 1000}{14} = 3.57 \text{ ohms/1000 ft}$$

The wire table shows that no. 15 is the smallest size having a resistance less than this value.

When the wire in question is not made of copper, the resistance values given in the wire table should be multiplied by the ratios given in Table 2 to obtain the resulting resistance.

Example: If the wire in the first example were made from nickel instead of copper, the length required for 3.5 ohms would be

$$\frac{3.5}{66.17 \times 5.1} \times 1000 = 10.37 \text{ ft}$$

**Temperature Effects**

The resistance of a conductor changes with its temperature. The resistance of practically every metallic conductor increases with increasing temperature. Carbon, however, acts in the opposite way; its resistance decreases when its temperature rises. It is seldom necessary to consider temperature in making resistance calculations for amateur work. The temperature effect is important when it is necessary to maintain a constant resistance under all conditions. Special materials that have little or no change in resistance over a wide temperature range are used in that case.

**Resistors**

A package of material exhibiting a certain amount of resistance made up into a single unit is called a resistor. Different resistors having the same resistance value may be considerably different in physical size and construction (Fig. 14). Current flowing through a resistance causes the conductor to become heated; the higher the resistance and the larger the current, the greater the amount of heat developed. Resistors intended for carrying large currents must be physically large so the heat can be radiated quickly to the surrounding air. If the resistor does not dissipate the heat quickly it may get hot enough to melt or burn.

**Skin Effect**

A conductor's effective resistance is not the same for alternating current as it is for direct current. With alternating current, other effects tend to force the current to flow mostly in the outer parts of the conductor. This decreases the effective cross-sectional area of the conductor, with the result that the resistance increases.

At low audio frequencies the increase in resistance is insignificant, but at radio frequencies above about 1 MHz, this "skin effect" is so pronounced that practically all the current flows within a few thousandths of an inch of a copper conductor surface. Above 10 MHz, only about the outer 0.0008 inch of the surface is used, and above 100 MHz the depth is less than 0.0003 inch. The RF resistance is consequently many times the dc resistance, and increases with frequency. In the RF range

Fig. 14 — Examples of various resistors. In the right foreground are 1/4-, 1/2- and 1-watt composition resistors. The three larger cylindrical components at the center are wire-wound power resistors. The remaining two parts are variable resistors, PC-board mount at the lower left and panel mount at the upper center.

a conductor of thin tubing will have just as low resistance as a solid conductor of the same diameter, because material not close to the surface carries practically no current.

**Conductance**

The reciprocal of resistance ( $1/R$ ) is conductance. It is usually represented by the symbol  $G$ . A circuit having high conductance has low resistance, and vice versa. In radio work the term is used chiefly in connection with electron-tube and field-effect-transistor characteristics. The unit of conductance is the siemens, abbreviated  $S$ . A resistance of 1 ohm has a conductance of 1 siemens, a resistance of 1000 ohms has a conductance of 0.001 siemens, and so on. A unit frequently used in connection with electron devices is the microsiemens or one-millionth of a siemens. It is the conductance of a 1-million-ohm resistance.

**OHM'S LAW**

One of the simplest forms of electric circuit is a battery with a resistance connected to its terminals, as shown by the symbols in Fig. 15. A complete circuit must have an unbroken path so current can flow out of the battery, through the apparatus connected to it, and back into the battery. If a connection is removed at any point, the

Fig. 15 — A simple circuit consisting of a battery and resistor.

circuit is broken, or open. A switch is a device for making and breaking connections and thereby closing or opening the circuit, either allowing current to flow or preventing it from flowing.

The values of current, voltage and resistance in a circuit are by no means independent of each other. The relationship between them is known as Ohm's Law. It can be stated as follows: The current flowing in a circuit is directly proportional to the applied EMF and inversely proportional to the resistance. Expressed as an equation, it is

$$I \text{ (amperes)} = \frac{E \text{ (volts)}}{R \text{ (ohms)}}$$

The equation gives the value of current when the voltage and resistance are known. It may be transposed so that each of the three quantities may be found when the other two are known:

$$E = IR$$

(that is, the voltage is equal to the current in amperes multiplied by the resistance in ohms) and

$$R = \frac{E}{I}$$

(or the resistance of the circuit is equal to the applied voltage divided by the current).

All three forms of the equation are used often in radio work. It must be remembered that the quantities are in volts, ohms and amperes; other units cannot be used in the equations without first being converted. For example, if the current is in milliamperes it must be changed to the equivalent fraction of an ampere before the value can be substituted in the equations.

The following examples illustrate the use of Ohm's Law:

The current flowing through a resistance of 20,000 ohms is 150 milliamperes. What is the voltage? Since the voltage is to be found, the equation to use is  $E = IR$ . The current must first be converted from milliamperes to amperes, and reference to Table 1 shows that to do so it is necessary to divide by 1000. Therefore,

$$E = \frac{150}{1000} \times 20,000 = 3000 \text{ volts}$$

When a voltage of 150 is applied to a circuit, the current is measured at 2.5 amperes. What is the resistance of the circuit? In this case  $R$  is the unknown, so

$$R = \frac{E}{I} = \frac{150}{2.5} = 60 \text{ ohms}$$

No conversion was necessary because the voltage and current were given in volts and amperes.

How much current will flow if 250 volts is applied to a 5000-ohm resistor? Since  $I$  is unknown

$$I = \frac{E}{R} = \frac{250}{5000} = 0.05 \text{ ampere}$$

Milliampere units would be more con-

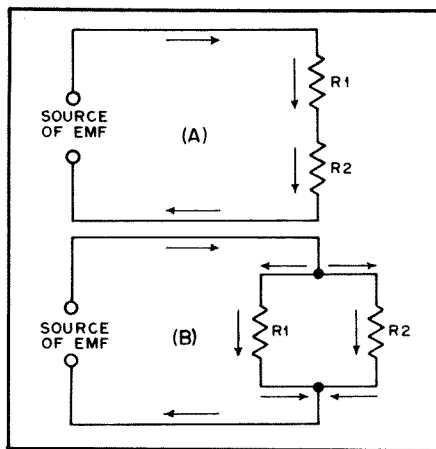

Fig. 16 — Resistors connected in series, A, and in parallel, B.

venient for the current, and 0.05 ampere  $\times 1000 = 50$  milliamperes.

### SERIES AND PARALLEL RESISTANCES

Very few actual electric circuits are as simple as Fig. 15. Commonly, resistances are found connected in a variety of ways. The two fundamental methods of connecting resistances are shown in Fig. 16. In the upper drawing, the current flows from the source of EMF (in the direction shown by the arrow, let us say) down through the first resistance,  $R_1$ , then through the second,  $R_2$ , and then back to the source. These resistors are connected in series. The current everywhere in the circuit has the same value.

In the lower drawing, the current flows to the common connection point at the top of the two resistors and then divides, one part of it flowing through  $R_1$  and the other through  $R_2$ . At the lower connection point these two currents again combine; the total is the same as the current that flowed into the upper common connection. In this case the two resistors are connected in parallel.

#### Resistors in Parallel

In a circuit with resistances in parallel, the total resistance is less than that of the lowest value of resistance present. This is because the total current is always greater than the current in any individual resistor. The formula for finding the total resistance of resistances in parallel is

$$R = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} + \dots}$$

where the dots again indicate that any number of resistors can be combined by the same method. For only two resistances in parallel (a very common case), the formula becomes

$$R = \frac{R_1 \times R_2}{R_1 + R_2}$$

Fig. 17 — An example of resistors in parallel. The solution is worked out in the text.

Example: If a 500-ohm resistor is paralleled with one of 1200 ohms, the total resistance is

$$R = \frac{R_1 \times R_2}{R_1 + R_2} = \frac{500 \times 1200}{500 + 1200}$$

$$R = \frac{600,000}{1700} = 353 \text{ ohms}$$

#### Kirchhoff's First Law

There is another solution to the problem. Suppose the three resistors of the previous example are connected in parallel as shown in Fig. 17. The same EMF, 250 volts, is applied to all three of the resistors. The current in each can be found from Ohm's Law as shown below,  $I_1$  being the current through  $R_1$ ,  $I_2$  the current through  $R_2$  and  $I_3$  the current through  $R_3$ .

For convenience, the resistance will be expressed in kilohms so the current will be in milliamperes.

$$I_1 = \frac{E}{R_1} = \frac{250}{5} = 50 \text{ mA}$$

$$I_2 = \frac{E}{R_2} = \frac{250}{20} = 12.5 \text{ mA}$$

$$I_3 = \frac{E}{R_3} = \frac{250}{8} = 31.25 \text{ mA}$$

The total current is

$$\begin{aligned} I &= I_1 + I_2 + I_3 \\ I &= 50 + 12.5 + 31.25 \\ I &= 93.75 \text{ mA} \end{aligned}$$

This example illustrates Kirchhoff's current law: The current flowing into a node or branching point is equal to the sum of the individual currents leaving the node or branching point. The total resistance of the circuit is therefore

$$R = \frac{E}{I} = \frac{250}{93.75} = 2.667 \text{ kilohms}$$

$$R = 2667 \text{ ohms}$$

#### Resistors in Series

When a circuit has a number of resistances connected in series, the total resistance of the circuit is the sum of the individual resistances. If these are numbered  $R_1$ ,  $R_2$ ,  $R_3$  and so on, then

$$R \text{ (total)} = R_1 + R_2 + R_3 + R_4 + \dots$$

where the dots indicate that as many

resistors as necessary may be added.

Example: Suppose that three resistors are connected to a source of EMF as shown in Fig. 18. The EMF is 250 volts. R1 is 5000 ohms, R2 is 20 kilohms (20,000 ohms) and R3 is 8000 ohms. The total resistance is then

$$\begin{aligned} R &= R_1 + R_2 + R_3 \\ R &= 5000 + 20,000 + 8000 \\ R &= 33,000 \text{ ohms.} \end{aligned}$$

The current flowing in the circuit is then

$$\begin{aligned} I &= \frac{E}{R} = \frac{250}{33,000} = 0.00758 \text{ ampere} \\ I &= 7.58 \text{ mA.} \end{aligned}$$

(We need not carry calculations beyond three significant figures; often, two will suffice because the accuracy of measurements is seldom better than a few percent.)

### Kirchhoff's Second Law

Ohm's Law applies in any portion of a circuit as well as to the circuit as a whole. Although the current is the same in all three of the resistances in the example of Fig. 18, the total voltage divides among them. The voltage appearing across each resistor (the voltage drop) can be found from Ohm's Law.

Example: If the voltage across R1 is called E1, that across R2 is called E2, and that across R3 is called E3, then

$$\begin{aligned} E_1 &= IR_1 = 0.00758 \times 5000 = 37.9 \text{ volts} \\ E_2 &= IR_2 = 0.00758 \times 20,000 \\ &= 151.5 \text{ volts} \\ E_3 &= IR_3 = 0.00758 \times 8000 \\ &= 60.6 \text{ volts} \end{aligned}$$

Kirchhoff's second law accurately describes the situation in the circuit: The sum of the voltages in a closed current loop is equal to zero. The resistors are sinks of power, while the battery is a source of power, so the sign conversion described earlier causes the voltage potentials across the resistors to be opposite in sign from the battery voltage. Adding all the voltages yields zero. In the simple case of a single voltage source, simple algebraic manipulation implies that the sum of the individual voltage drops in the circuit must be equal to the applied voltage.

Fig. 18 — An example of resistors in series. The solution of the circuit is worked out in the text.

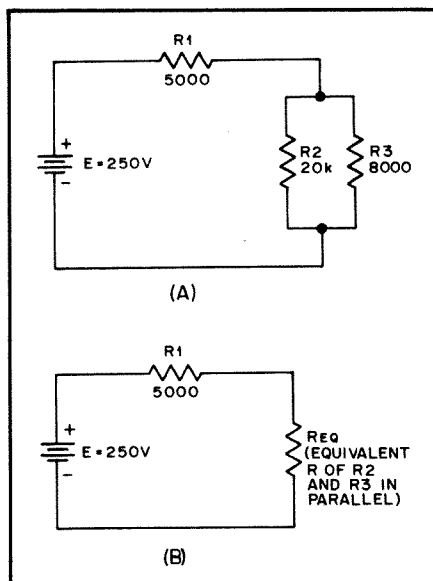

Fig. 19 — At A, an example of resistors in series-parallel. The equivalent circuit is shown at B. The solution is worked out in the text.

$$\begin{aligned} E &= E_1 + E_2 + E_3 \\ E &= 37.9 + 151.5 + 60.6 \\ E &= 250 \text{ volts} \end{aligned}$$

In problems such as this, when the current is small enough to be expressed in milliamperes, considerable time and trouble can be saved if the resistance is expressed in kilohms rather than in ohms. When the resistance in kilohms is substituted directly in Ohm's Law, the current will be milliamperes if the EMF is in volts.

### Resistors in Series-Parallel

A circuit may have resistances both in parallel and in series, as shown in Fig. 19A. The method for analyzing such a circuit is as follows: Consider R2 and R3 to be the equivalent of a single resistor,  $R_{eq}$ , whose value is equal to R2 and R3 in parallel.

$$\begin{aligned} R_{eq} &= \frac{R_2 \times R_3}{R_2 + R_3} = \frac{20,000 \times 8000}{20,000 + 8000} \\ R_{eq} &= 5.71 \text{ k}\Omega \end{aligned}$$

This resistance in series with R1 forms a simple series circuit, as shown in Fig. 19B. The total resistance in the circuit is then

$$\begin{aligned} R &= R_1 + R_{eq} = 5 \text{ k}\Omega + 5.71 \text{ k}\Omega \\ R &= 10.71 \text{ k}\Omega \end{aligned}$$

The current is

$$I = \frac{E}{R} = \frac{250 \text{ V}}{10.71 \text{ k}\Omega} = 23.3 \text{ mA}$$

The voltage drops across R1 and  $R_{eq}$  are

$$\begin{aligned} E_1 &= I \times R_1 = 23.3 \times 5 = 117 \text{ volts} \\ E_2 &= I \times R_{eq} = 23.3 \text{ mA} \times 5.71 \text{ k}\Omega \\ E_2 &= 133 \text{ volts} \end{aligned}$$

with sufficient accuracy. These two voltage drops total 250 volts, as described by

Kirchhoff's first law. E2 appears across both R2 and R3 so,

$$12 = \frac{E_2}{R_2} = \frac{133 \text{ V}}{20 \text{ k}\Omega} = 6.67 \text{ mA}$$

$$13 = \frac{E_2}{R_3} = \frac{133 \text{ V}}{8 \text{ k}\Omega} = 16.67 \text{ mA}$$

where

12 = current through R2

13 = current through R3.

The sum of 12 and 13 is equal to 23.3 mA, conforming to Kirchhoff's second law.

### Thevenin's Theorem

A useful tool for simplifying electrical networks is Thevenin's Theorem, which states that any two-terminal network of resistors and voltage or current sources can be replaced by a single voltage source and a series resistor. Such a transformation can simplify the calculation of current through a parallel branch. Thevenin's Theorem can be readily applied to the circuit of Fig. 19A, to find the current through R3.

In this example, R1 and R2 form a voltage divider circuit, with R3 as the load (Fig. 20A). The current drawn by the load (R3) is simply the voltage potential across R3, divided by its resistance. Unfortunately, the value of R2 affects the voltage potential across R3, just as the presence of R3 affects the potential appearing across R2. Some means of separating the two is needed; hence the Thevenin-equivalent circuit.

The voltage of the Thevenin-equivalent battery is the open circuit voltage as measured when no current is flowing from either terminal A or B. Without a load connected between A and B, the total current through the circuit is (from Ohm's Law)

$$I = \frac{E}{R_1 + R_2}$$

and the voltage between terminals A and B ( $E_{ab}$ ) is

$$E_{ab} = I \times R_2$$

By substituting the first equation into the second, a simplified expression for  $E_{ab}$  can be found to be

$$E_{ab} = \frac{R_2}{R_1 + R_2} \times E$$

Using the actual values, this becomes

$$\begin{aligned} E_{ab} &= \frac{20,000}{5,000 + 20,000} \times 250 = 200 \text{ volts} \end{aligned}$$

when nothing is connected to terminals A or B. With no current drawn, E then is equal to  $E_{ab}$ .

The Thevenin-equivalent resistance is the total net resistance between terminals A and B. The ideal voltage source, by definition, has zero internal resistance. As-

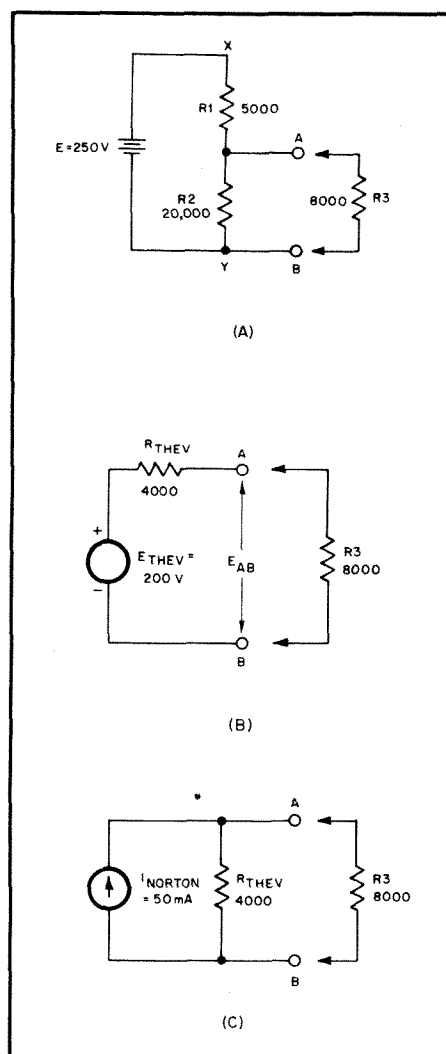

Fig. 20 — Thevenin-equivalent circuit for the circuit in Fig. 19.

Assuming the battery to be a close approximation of an ideal source, put a short between points X and Y in the circuit of Fig. 20A. R1 and R2 are then effectively placed in parallel, as viewed from terminals A and B. The Thevenin-equivalent resistance is then

$$R_{\text{th}} = \frac{R_1 \times R_2}{R_1 + R_2} = 4000 \text{ ohms}$$

This gives the Thevenin-equivalent circuit as shown in Fig. 20B. The circuits of Figs. 19A and 19B as far as R3 is concerned are equivalent.

Once R3 is connected to terminals A and B, current will flow through R<sub>th</sub>, causing a voltage drop across R<sub>th</sub>, and reducing E<sub>ab</sub>. However, the current through R3 is equal to

$$I = \frac{E_{\text{th}}}{R_{\text{total}}} = \frac{E_{\text{th}}}{R_{\text{th}} + R_3}$$

Substituting actual values gives

$$I = \frac{200}{4000 + 8000} = 16.67 \text{ mA}$$

This agrees with the value calculated earlier.

### Norton's Theorem

Another tool for analyzing electrical networks is Norton's Theorem, which states that any two-terminal network of resistors and current or voltage sources can be replaced by a single current source and a parallel resistor. Norton's Theorem is to current sources what Thevenin's Theorem is to voltage sources. In fact, the Thevenin resistance as calculated previously is used as the equivalent resistance when using Norton's Theorem.

The circuit just analyzed by means of Thevenin's Theorem can be analyzed just as easily by Norton's Theorem. The equivalent Norton circuit is shown in Fig. 20C. The current I<sub>sc</sub> of the equivalent current source is the short circuit current through terminals A and B. In the case of the voltage divider shown in Fig. 20A, the short circuit current is

$$I_{\text{sc}} = \frac{E}{R_1} = \frac{250}{5000} = 50 \text{ mA}$$

The resulting Norton-equivalent circuit consists of a 50-mA current source placed in parallel with a 4000-ohm resistor. When R3 is connected to terminals A and B, by Kirchhoff's second law one third of the supply current flows through R3 and the remainder through R<sub>th</sub>. This gives a current through R3 of 16.67 mA, again agreeing with previous conclusions.

A Norton-equivalent circuit can be transformed into a Thevenin-equivalent circuit and vice versa. The equivalent resistor stays the same in both cases; it is placed in series with the voltage source in the case of a Thevenin-equivalent circuit, and in parallel with the current source in the case of a Norton-equivalent circuit. The voltage for a Thevenin-equivalent source is equal to the no load voltage appearing across the resistor in the Norton-equivalent circuit. The current for a Norton-equivalent source is equal to the short circuit current provided by the Thevenin source.

### POWER AND ENERGY

Power, the rate of doing work, is equal to voltage multiplied by current. The unit of electrical power, called the watt, is equal to 1 volt multiplied by 1 ampere. The equation for power therefore is

$$P = EI$$

where

P = power in watts

E = EMF in volts

I = current in amperes.

Common fractional and multiple units for power are the milliwatt, one thousandth of a watt, and the kilowatt, or 1000 watts.

Example: The plate voltage on a transmitting vacuum tube is 2000 volts and the plate current is 350 milliamperes. (The

current must be changed to amperes before substitution in the formula, and so is 0.35 ampere.) Then

$$P = EI = 2000 \times 0.35 = 700 \text{ watts}$$

By substituting the Ohm's Law equivalent for E and I, the following formulas are obtained for power:

$$P = \frac{E^2}{R}$$

$$P = I^2R$$

These formulas are useful in power calculations when the resistance and either the current or voltage (but not both) are known.

Example: How much power will be used up in a 4000-ohm resistor if the potential applied to it is 200 volts? From the equation

$$P = \frac{E^2}{R} = \frac{200^2}{4000} = \frac{40,000}{4000}$$

$$P = 10 \text{ watts}$$

Now, suppose a current of 20 milliamperes flows through a 300-ohm resistor. Then

$$P = I^2R = 0.02^2 \times 300$$

$$P = 0.0004 \times 300$$

$$P = 0.12 \text{ watt}$$

Note that the current was changed from milliamperes to amperes before substitution in the formula.

Electrical power in a resistance is turned into heat. The greater the power, the more rapidly the heat is generated. Resistors for radio work are made in many sizes, the smallest being rated to dissipate (or carry safely) about 1/10 watt. The largest resistors commonly used in amateur equipment will dissipate about 100 watts.

When electrical energy is converted into mechanical energy, and vice versa, the following relationship holds: 1 horsepower = 746 watts. This formula assumes lossless transformation; practical efficiency is taken up shortly.

### GENERALIZED DEFINITION OF RESISTANCE

Electrical power is not always turned into heat. The power used in running a motor, for example, is converted to mechanical motion. The power supplied to a radio transmitter is largely converted into radio waves. Power applied to a loudspeaker is changed into sound waves. But in every case of this kind, the power is completely used up — it cannot be recovered. Also, for proper operation of the device the power must be supplied at a definite ratio of voltage to current. Both of these features are characteristics of resistance, so it can be said that any device that dissipates power has a definite value of resistance.

This concept of resistance as something that absorbs power at a definite voltage-to-current ratio is very useful; it permits substituting a simple resistance for the load

or power-consuming part of the device receiving power, often with considerable simplification of calculations. Of course, every electrical device has some resistance of its own in the more narrow sense, so a part of the power supplied to it is dissipated in that resistance and hence appears as heat even though the major part of the power may be converted to another form.

### Efficiency

In devices such as motors and vacuum tubes, the objective is to obtain power in some form other than heat. Therefore power used in heating is considered to be a loss, because it is not useful power. The efficiency of a device is the useful power output (in its converted form) divided by the power input to the device. In a vacuum-tube transmitter, for example, the objective is to convert power from a dc source into ac power at some radio frequency. The ratio of the RF power output to the dc input is the efficiency of the tube. That is,

$$\text{Eff.} = \frac{P_o}{P_i}$$

where

Eff. = efficiency (as a decimal)

$P_o$  = power output (watts)

$P_i$  = power input (watts).

Example: If the dc input to the tube is 100 watts, and the RF power output is 60 watts, the efficiency is

$$\text{Eff.} = \frac{P_o}{P_i} = \frac{60}{100} = 0.6$$

Efficiency is usually expressed as a percentage; that is, it tells what percent of the input power will be available as useful output. The efficiency in the above example is 60%.

Suppose a mobile transmitter has an RF power output of 100 W at an efficiency of 52 percent at 13.8 V. The vehicular alternator system charges the battery at a 5-A rate at this voltage. Assuming an alternator efficiency of 68 percent, how much horsepower must the engine produce to operate the transmitter and charge the battery? Solution: To charge the battery, the alternator must produce  $13.8 \text{ V} \times 5 \text{ A} = 69 \text{ W}$ . The transmitter dc input power is  $100 \text{ W} / 0.52 = 192.3 \text{ W}$ . Therefore, the total electrical power required from the alternator is  $192.3 + 69 = 261.3 \text{ W}$ . The engine load then is

$$\frac{261.3}{746 \times 0.68} = 0.515 \text{ horsepower}$$

### Energy

In residences, the power company's bill is for electrical energy, not for power. What you pay for is the work that electricity does for you, not the rate at which that work is done. Electrical work is equal to power multiplied by time; the common unit is the watt-hour, which means that a power

of 1 watt has been used for one hour. That is,

$$W = PT$$

where

$W$  = energy in watt-hours

$P$  = power in watts

$T$  = time in hours.

Other energy units are the kilowatt-hour and the watt-second (joule). These units are self-explanatory.

Energy units are seldom used in amateur practice, but it is obvious that a small amount of power used for a long time can eventually result in a power bill that is just as large as though a large amount of power had been used for a very short time.

### AC Waveform Measurements

The time dependence of alternating current raises questions about defining and measuring values of voltage, current and power. Because these parameters change from one instant to the next, one might wonder, for example, which point on the cycle characterizes the voltage or current for the entire cycle. When you are viewing a single-tone signal (that is, a pure sine wave) on an oscilloscope, the easiest dimension to measure is the total vertical displacement, or peak-to-peak voltage.

This value, abbreviated P-P, is important in evaluating the signal-handling capability of a linear processing device such as an electronic amplifier or ferromagnetic transformer. If the steepest part of the waveform has a potential of zero, the signal has equal positive and negative excursions and no dc bias. The oscilloscope measurement of the maximum positive or negative excursion, or maximum instantaneous potential, is called the peak voltage, and in a symmetrical waveform it has half the value of the peak-to-peak amplitude. Insulators, air gaps and capacitor dielectrics must withstand the peak value of an ac voltage. In a well-designed ac-to-dc power supply the rectified dc output voltage will be nearly equal to the peak ac voltage.

When an ac voltage is applied to a resistor, the resistor will dissipate energy in the form of heat, just as if the voltage were dc. The dc voltage that would cause identical heating in the ac-excited resistor is the root-mean-square (RMS) value of the ac voltage. The RMS voltage of any waveform can be determined with the use of integral calculus, but for a pure sine wave the following relationships hold:

$$V_{\text{peak}} = V_{\text{RMS}} \times \sqrt{2} \approx V_{\text{RMS}} \times 1.414$$

and

$$V_{\text{RMS}} = \frac{V_{\text{peak}}}{\sqrt{2}} \approx V_{\text{peak}} \times 0.707$$

Unless otherwise specified or obvious from context, ac voltage is rendered as an RMS value. For example, the household

Fig. 21 — Ac voltage and current measurements. The sine-wave parameters are illustrated at A, while B shows the peak envelope voltage (PEV) for a composite waveform.

117-V ac outlet provides 117  $V_{\text{RMS}}$ , 165.5  $V_{\text{peak}}$  and 331  $V_{\text{P-P}}$ .

An electrodynamic instrument such as a meter movement responds to the average value of an ac waveform. Again, integral calculus is required for computation of the average value of the general (complex) wave, but for a sinusoidal signal the peak, RMS and average voltages are related by the formulas:

$$V_{\text{avg}} = V_{\text{peak}} \times \frac{2}{\pi} \approx 0.63662 V_{\text{peak}} \\ \approx 0.9003 V_{\text{RMS}}$$

and

$$V_{\text{peak}} = \frac{V_{\text{avg}}}{0.636} = 1.5708 V_{\text{avg}}$$

Thus, our 117-V ac outlet provides an average voltage of 105.2.

Fig. 21A illustrates the four voltage parameters of a sine wave. The most accurate way to determine the RMS voltage of a complex wave is to measure the heat produced by applying the complex voltage to a known resistance and measure the dc voltage required to produce the same heat. However, some modern electronic voltmeters provide accurate RMS readings by performing mathematical operations on the waveform. The ratio of peak voltage to RMS voltage of an ac signal is called the crest factor. From the relationships presented earlier, the crest factor of a sine wave is the square root of 2.

The significant dimension of a multitone signal is the peak envelope voltage, shown in Fig. 21B. PEV is important in calculating the power in a modulated signal, such as that from an amateur SSB voice transmitter.

All that has been said about voltage measurements applies also to current (pro-

vided the load is resistive) because the waveshapes are identical. However, the terms RMS, average and peak have different meanings when they refer to ac power. The reason is that while voltage and current are sinusoidal functions of time, power is the product of voltage and current, and this product is a sine squared function. The mathematical operations that define RMS, average, and so on will naturally yield different results when applied to this new function. The relationships between ac voltage, current and power follow:

$\text{RMS voltage} \times \text{RMS current} = \text{average power} \neq \text{RMS power}$ . The average power used to heat a resistor is equal to the dc power required to produce the same heat. RMS power is a mathematical curiosity only and has no physical significance.

$\text{Peak voltage} \times \text{peak current} = 2 \times \text{average power}$ . Unfortunately, the definition given above for peak power conflicts with the meaning of the term when it is used in radio work. The peak power output of a radio transmitter is the power averaged over the RF cycle having the greatest amplitude. Modulated signals are

not purely sinusoidal because they are composites of two or more tones. However, the cycle-to-cycle variation is small enough that sine-wave measurement techniques produce accurate results. In the context of radio signals, then, peak power means maximum average power. Peak envelope power (PEP) is the parameter most often used to express the maximum signal-handling capability of a linear amplifier. To compute the PEP of a waveform such as that sketched in Fig. 21B, multiply the PEV by 0.707 to obtain the RMS value, square the result and divide by the load resistance.

## Capacitance

Suppose two flat metal plates are placed close to each other (but not touching) and are connected to a battery through a switch, as illustrated in Fig. 22. At the instant the switch is closed, electrons are attracted from the upper plate to the positive terminal of the battery, and the same number are repelled into the lower plate from the negative battery terminal. Enough electrons move into one plate and out of the other to make the EMF between them the same as the EMF of the battery.

If the switch is opened after the plates have been charged in this way, the top plate is left with a deficiency of electrons and the bottom plate with an excess. Since there is no current path between the two, the plates remain charged despite the fact that the battery no longer is connected. If a wire is touched between the two plates (short-circuiting them), the excess electrons on the bottom plate flow through the wire to the upper plate, restoring electrical neutrality. The plates are discharged.

These two plates are representative of an electrical capacitor, a device possessing the property of storing electricity in the electric field between its plates. During the time the electrons are moving — that is, while the capacitor is being charged or discharged — a current flows in the circuit even though the circuit apparently is broken by the gap between the capacitor plates. However, the current flows only during the time of charge and discharge, and this time is usually very short. There can be no continuous flow of direct current through a capacitor. However, alternating current can “pass through” a capacitor. As fast as one plate is charged positively by the positive excursion of the alternating current, the other plate is being charged negatively. Positive current flowing into one plate causes a current to flow out of the other plate during one half of the cycle, while the reverse occurs during the other half of the cycle.

Fig. 22 — A simple capacitor.

The charge or quantity of electricity that can be held in the electric field between the capacitor plates is proportional to the applied voltage and to the capacitance of the capacitor:

$$Q = CV$$

where

$Q$  = charge in coulombs  
 $C$  = capacitance in farads  
 $V$  = potential in volts

The energy stored in a capacitor is also a function of potential and capacitance:

$$W = \frac{V^2C}{2}$$

where

$W$  = energy in joules (watt-seconds)  
 $V$  = potential in volts  
 $C$  = capacitance in farads

The numerator of this expression can be derived easily from the definitions given earlier for charge, capacitance, current, power and energy. However, the denominator is not so obvious. It arises because the voltage across a capacitor is not constant, but is a function of time; the average voltage over the time interval determines the energy stored. The time dependence of the capacitor voltage is

Table 3

Dielectric Constants and Breakdown Voltages

Material	Dielectric Constant*	Puncture Voltage**
Air	1.0	21
Alsimag 196	5.7	240
Bakelite	4.4-5.4	300
Bakelite, mica filled	4.7	325-375
Cellulose acetate	3.3-3.9	250-600

Teflon	2.1	1000-2000

\*At 1 MHz    \*\*In volts per mil (0.001 inch)

discussed in the section on time constant.

The larger the plate area and the smaller the spacing between the plates, the greater the capacitance. The capacitance also depends on the kind of insulating material between the plates; it is smallest with air insulation, and substitution of other insulating materials for air may increase the capacitance many times. The ratio of the capacitance with some material other than air between the plates to the capacitance of the same capacitor with air insulation is called the dielectric constant of that particular insulating material. The material itself is called a dielectric. The dielectric constants of a number of materials commonly used as dielectrics in capacitors are given in Table 3. If a sheet of polystyrene is substituted for air between the plates of

Fig. 23 — A multiple-plate capacitor. Alternate plates are connected together.

a capacitor, for example, the capacitance will be increased 2.6 times.

### Units of Capacitance

The basic unit of capacitance is the farad, but this unit is much too large for practical work. Capacitance is usually measured in microfarads (abbreviated  $\mu\text{F}$ ) or picofarads (pF). The microfarad is one millionth of a farad ( $10^{-6}$  F), and the picofarad is one millionth of a microfarad ( $10^{-12}$  F). Capacitors nearly always have more than two plates, the alternate plates being connected together to form two sets, as shown in Fig. 23. This makes it possible to attain a fairly large capacitance in a small space, since several plates of smaller individual area can be stacked to form the equivalent of a single large plate of the same total area. Also, all plates except the two on the ends are exposed to plates of the other group on both sides, and so are twice as effective in increasing the capacitance.

The formula for calculating capacitance is

$$C = \frac{0.224 \text{ KA}}{d} (n - 1)$$

where

$C$  = capacitance in pF

$K$  = dielectric constant of material between plates

$A$  = area of one side of one plate in square inches

$d$  = separation of plate surfaces in inches

$n$  = number of plates

If the plates in one group do not have the same area as the plates in the other, use the area of the smaller plates.

### Capacitors in Radio

The types of capacitors used in radio work differ considerably in physical size, construction and capacitance. Representative types are shown in Fig. 24. In variable capacitors (almost always constructed with air for the dielectric) one set of plates is made movable with respect to the other set so the capacitance can be varied. Fixed capacitors (those having a single, nonadjustable value of capacitance) can also be made with metal plates and with air as the dielectric. However, fixed capacitors usually are constructed from plates of metal foil with a thin solid or liquid dielectric sandwiched between, so that a relatively large capacitance can be obtained in a small unit. The solid dielectrics commonly used are mica, paper and special ceramics. An example of a liquid dielectric is mineral oil. The electrolytic capacitor uses aluminum-foil plates with a semiliquid conducting chemical compound between them. The actual dielectric is a very thin film of insulating material that forms on one set of plates through electrochemical action when a dc voltage is applied to the capacitor. The capacitance obtained with a given plate area in an electrolytic capacitor is very large, compared with capacitors having other dielectrics, because the film is so thin — much less than any thickness practical with a solid dielectric.

The use of electrolytic and oil-filled

capacitors is confined to power-supply filtering and audio-bypass applications because their dielectrics have high losses at the higher frequencies. Mica and ceramic capacitors are used throughout the frequency range from audio to several hundred megahertz.

### Voltage Breakdown

When high voltage is applied to the plates of a capacitor, considerable force is exerted on the electrons and nuclei of the dielectric. The dielectric is an insulator; the electrons do not become detached from atoms the way they do in conductors. If the force is great enough the dielectric will break down. Usually failed dielectrics will puncture and offer a low resistance current path between the two plates.

The breakdown voltage a dielectric can withstand depends on the chemical composition and thickness of the dielectric, as shown in Table 3. Breakdown voltage is not directly proportional to the thickness; doubling the thickness does not quite double the breakdown voltage. Gas dielectrics break down, as evidenced by a spark or arc between the plates. Once the voltage is removed, the arc ceases and the capacitor is ready for use again. Solid dielectrics are permanently damaged by dielectric breakdown, and often will totally short out and melt or explode. Breakdown occurs at a lower voltage between pointed or sharp-edged surfaces than between rounded and polished surfaces; consequently, the breakdown voltage between metal plates of given spacing in air can be increased by buffing the edges of the plates.

A thick dielectric must be used to withstand high voltages, and since the capacitance is inversely proportional to dielectric thickness (plate spacing) for a given plate area, a high-voltage capacitor must have more plate area than a low-voltage one of the same capacitance. High-voltage, high-

(A)

Fig. 24 — Fixed-value capacitors are shown at A. A large computer-grade unit is at the upper left. This 40- $\mu\text{F}$  unit is an electrolytic capacitor. The smaller pieces are silver-mica, disc-ceramic, tantalum, polystyrene and ceramic-chip capacitors. The small black unit (cylindrical) is a PC board-mount electrolytic. Variable capacitors are shown at B. A vacuum variable is at the upper left.

capacitance capacitors are physically large.

### Capacitors in Series and Parallel

The terms parallel and series when applied to capacitance have a similar meaning as with resistances. When a number of capacitors are connected in parallel, as in Fig. 25A, the total capacitance of the group is equal to the sum of the individual capacitances:

$$C_{\text{total}} = C_1 + C_2 + C_3 + C_4 + \dots$$

When two or more capacitors are connected in series, as in Fig. 25B, the total capacitance is less than that of the smallest capacitor in the group. The rule for finding the capacitance of a number of series-connected capacitors is the same as that for finding the resistance of a number of parallel-connected resistors. That is,

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \frac{1}{C_4} + \frac{1}{C_5} + \dots}$$

and, for only two capacitors in series,

$$C_{\text{total}} = \frac{C_1 \times C_2}{C_1 + C_2}$$

The same units must be used throughout; that is, all capacitances must be expressed in either  $\mu\text{F}$  or  $\text{pF}$ ; both kinds of units cannot be used in the same equation.

Capacitors are usually connected in parallel to obtain a larger total capacitance than is available in one unit. The largest voltage that can be applied safely to a group of capacitors in parallel is the voltage that can be applied safely to the one having the lowest voltage rating.

When capacitors are connected in series, the applied voltage is divided up among them according to Kirchhoff's first law, and the situation is much the same as when resistors are in series and there is a voltage drop across each. The voltage that appears across each capacitor of a group connected in series is in inverse proportion to its capacitance, as compared with the capacitance of the whole group.

Example: Three capacitors having capacitances of 1, 2 and 4  $\mu\text{F}$ , respectively, are connected in series as shown in Fig. 26. The total capacitance is

$$C = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}} = \frac{1}{\frac{1}{1} + \frac{1}{2} + \frac{1}{4}}$$

$$C = \frac{1}{\frac{7}{4}} = \frac{4}{7} = 0.571 \mu\text{F}$$

The voltage across each capacitor is proportional to the total capacitance divided by the capacitance of the capacitor in question, so the voltage across  $C_1$  is

$$E_1 = \frac{0.571}{1} \times 2000 = 1143 \text{ volts}$$

Fig. 25 — Capacitors in parallel, A, and in series, B.

Similarly, the voltages across  $C_2$  and  $C_3$  are

$$E_2 = \frac{0.571}{2} \times 2000 = 571 \text{ volts}$$

$$E_3 = \frac{0.571}{4} \times 2000 = 286$$

The sum of these three voltages equals 2000 volts, the applied voltage.

Capacitors are frequently connected in series to enable the group to withstand a larger voltage (at the expense of decreased total capacitance) than any individual capacitor is rated to stand. As shown by the previous example, the applied voltage does not divide equally among the capacitors (except when all the capacitances are precisely the same) and care must be taken to ensure that the voltage rating of no capacitor in the group is exceeded.

### RC TIME CONSTANT

Connecting a source of EMF directly to the terminal of a capacitor charges the capacitor to the full EMF almost instantaneously. Any resistance added to the circuit as in Fig. 27A limits the amount of current flow, lengthening the time required for the EMF between the capacitor plates to build up to the same value as the EMF of the source. During this charging period, the current flowing from the source into the capacitor gradually decreases from its initial value; the increasing EMF stored in the capacitor's electric field offers increasing opposition to the steady EMF of the source.

The voltage potential between the terminals of the capacitor while being charged is an exponential function of time, and is given by

$$V(t) = E \left( 1 - e^{-\frac{t}{RC}} \right)$$

where

$V(t)$  = capacitor EMF in volts at  $t$   
 $E$  = potential of charging source in volts  
 $t$  = time in seconds after initiation of charging current  
 $e$  = natural logarithmic base = 2.718  
 $R$  = circuit resistance in ohms  
 $C$  = capacitance in farads

Theoretically, the charging process is never really finished, but eventually the charging current drops to an unmeasurable value. When  $t = RC$ , the above equation becomes

$$V(RC) = E(1 - e^{-1}) \approx 0.632E$$

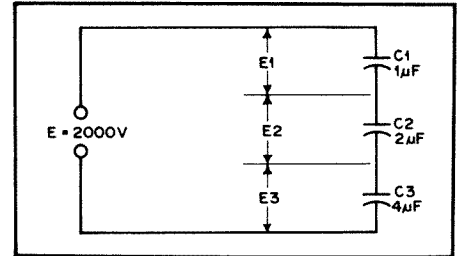

Fig. 26 — An example of capacitors connected in series. Finding the voltage drops,  $E_1$  through  $E_3$ , is worked out in the text.

Fig. 27 — Illustrating the time constant of an RC circuit.

Fig. 28 — At A, how the voltage across a capacitor rises, with time, when charged through a resistor. The curve at B shows the way in which the voltage decreases across the capacitor terminals on discharging through the same value of resistance. From a practical standpoint, a capacitor may be considered as charged (or discharged) after 5RC times.

The product of  $R$  in ohms times  $C$  in farads is called the time constant of the circuit and is the time in seconds required to charge the capacitor to 63.2% of the supply voltage. After two time constants ( $t = 2RC$ ) the capacitor charges another 63.2% of the difference between the capacitor voltage at one time constant and the supply voltage, for a total charge of 86.5%. After three time constants the capacitor reaches 95% of the supply voltage, and so on, as illustrated in the curve of Fig. 28A.

If a charged capacitor is discharged through a resistor, as indicated in Fig. 27B, the same time constant applies for the decay of the capacitor voltage. A direct short circuit applied between the capacitor's terminals would discharge instantly.  $R$  limits the current flow, so the capacitor voltage decreases only as rapidly as the capacitor can discharge itself through  $R$ . A capacitor discharging through a resistance exhibits the same time constant characteristics (calculated in the same way as above) as a charging capacitor. The voltage as a function of time while the capacitor is being discharged is given by

$$V(t) = E \left( e^{\frac{-t}{RC}} \right)$$

where  $t$  = time in seconds after initiation of discharge.

#### Alternating Current in Capacitance

In Fig. 29 a sine-wave ac voltage having a maximum value of 100 is applied to a capacitor. In the period  $OA$ , the applied voltage increases from 0 to 38; at the end of this period the capacitor is charged to that voltage. In interval  $AB$  the voltage increases to 71; that is, 33 volts additional. In this interval a smaller quantity of charge has been added than in  $OA$ , because the voltage rise during interval  $AB$  is smaller. Consequently the average current during  $AB$  is smaller than during  $OA$ . In the third interval,  $BC$ , the voltage rises from 71 to 92, an increase of 21 volts. This is less than the voltage increase during  $AB$ , so the quantity of electricity added is less; in other words, the average current during interval  $BC$  is still smaller. In the fourth interval,  $CB$ , the voltage increases only 8 volts; the charge added is smaller than in any preceding interval and therefore the current also is smaller.

By dividing the first quarter cycle into a very large number of intervals, it could be shown that the current charging the capacitor has the shape of a sine wave, just as the applied voltage does. The current is largest at the beginning of the cycle and becomes zero at the maximum value of the voltage, so there is a phase difference of  $90^\circ$  between the voltage and the current.

Fig. 29 — Voltage and current phase relationships when an alternating voltage is applied to a capacitor.

During the first quarter cycle the current is flowing in the normal direction through the circuit, since the capacitor is being charged. Hence the current is positive, as indicated by the dashed line in Fig. 29.

In the second quarter cycle — that is, in the time from  $D$  to  $H$  — the voltage applied to the capacitor decreases. During this time the capacitor loses its charge. Applying the same reasoning, it is evident that the current is small in interval  $DE$  and continues to increase during each succeeding interval. However, the current is flowing against the applied voltage because the capacitor is discharging into the circuit. The current flows in the negative direction during this quarter cycle.

The third and fourth quarter cycles repeat the events of the first and second, respectively, with this difference — the polarity of the applied voltage has reversed, and the current changes to correspond. In other words, an alternating current flows in the circuit because of the alternate charging and discharging of the capacitance. As shown in Fig. 29, the current starts its cycle  $90^\circ$  before the voltage, so the current in a capacitor leads the applied voltage by  $90^\circ$ .

#### Capacitive Reactance

The quantity of electric charge that can be placed on a capacitor is proportional to the applied EMF and the capacitance. This amount of charge moves back and forth in the circuit once each cycle, and so the rate of movement of charge (the current) is

proportional to voltage, capacitance and frequency. When the effects of capacitance and frequency are considered together, they form a quantity that plays a part similar to that of resistance in Ohm's Law. This quantity is called reactance. The unit for reactance is the ohm, just as in the case of resistance. The formula for reactance is

$$X_C = \frac{1}{2\pi fC}$$

where

$X_C$  = capacitive reactance in ohms

$f$  = frequency in hertz

$C$  = capacitance in farads

$\pi = 3.1416$

Although the unit of reactance is the ohm, there is no power dissipation in reactance. The energy stored in the capacitor in one portion of the cycle is simply returned to the circuit in the next.

The fundamental units for frequency and capacitance (hertz and farads) are too cumbersome for practical use in radio circuits. However, if the capacitance is specified in microfarads ( $\mu F$ ) and the frequency is in megahertz (MHz), the reactance calculated from the previous formula retains the unit ohms.

Example: The reactance of a capacitor of 470 pF (0.00047  $\mu F$ ) at a frequency of 7.15 MHz is

$$X = \frac{1}{2\pi fC} = \frac{1}{2\pi \times 7.15 \times 0.00047}$$

$$X = 47.4 \text{ ohms}$$

# Inductance

It is possible to show that the flow of current through a conductor is accompanied by magnetic effects; a compass needle brought near the conductor will deflect from its normal north-south position. The current sets up a magnetic field.

The transfer of energy to a magnetic field represents work performed by the source of EMF. Power is required for doing work, and since power is equal to current multiplied by voltage, there must be a voltage drop in the circuit while energy is being stored in the field. This voltage drop, exclusive of any voltage drop caused by resistance in the circuit, is the result of an opposing voltage induced in the circuit while the field is building up to its final value. Once the field becomes constant the induced EMF or back EMF disappears, since no further energy is being stored. The induced EMF opposes the EMF of the source and tends to prevent the current from rising rapidly when the circuit is closed. The amplitude of the induced EMF is proportional to the rate at which the current changes and to a constant associated with the circuit itself; the inductance of the circuit.

Inductance depends on the physical configuration of the conductor. If a conductor is formed into a coil, its inductance is increased. A coil of many turns will have more inductance than one of few turns, if both coils are otherwise physically similar. Furthermore, if a coil is placed around an iron core its inductance will be greater than it was without the magnetic core.

The polarity of an induced EMF is always such as to oppose any change in the current in the circuit. This means that when the current in the circuit is increasing, work is being done against the induced EMF by storing energy in the magnetic field. If the current in the circuit tends to decrease, the stored energy of the field returns to the circuit, and thus adds to the energy being supplied by the source of EMF. This tends to keep the current flowing even though the applied EMF may be decreasing or be removed entirely. The energy stored in the magnetic field of an inductor is given by

$$W = \frac{I^2 L}{2}$$

where

W = energy in joules  
I = current in amperes  
L = inductance in henrys

The unit of inductance is the henry. Values of inductance used in radio equipment vary over a wide range. In radio-frequency circuits, the inductance values used will be measured in millihenrys (a mH is one thousandth of a henry) at low frequencies, and in microhenrys ( $\mu\text{H}$ , one millionth of a henry) at medium frequencies and higher. Although coils for radio

frequencies may be wound on special iron cores (ordinary iron is not suitable), many RF coils made and used by amateurs are of the air-core type, that is, wound on an insulating support consisting of non-magnetic material (Fig. 30).

Every conductor passing current has a magnetic field associated with it, and therefore inductance, even though the conductor is not formed into a coil. The inductance of a short length of straight wire is small, but it may not be negligible — if the current through it changes rapidly, the induced voltage may be appreciable. This is the case in even a few inches of wire when an alternating current having a frequency of the order of 100 MHz or higher is flowing. At much lower frequencies the inductance of the same wire could be ignored because the induced voltage would be negligible.

## Calculating Inductance

The approximate inductance of a single-layer air-core coil may be calculated from the simplified formula

$$L (\mu\text{H}) = \frac{d^2 n^2}{18d + 40\ell}$$

where

L = inductance in microhenrys  
d = coil diameter in inches  
 $\ell$  = coil length in inches  
n = number of turns

The notation is explained in Fig. 31. This formula is a close approximation for coils having a length equal to or greater than  $0.4d$ .

Example: Assume a coil has 48 turns wound at 32 turns per inch and a diameter of  $\frac{3}{4}$  inch. Thus,  $d = 0.75$ ,  $\ell = 48/32 = 1.5$ , and  $n = 48$ . Substituting,

$$L = \frac{0.75^2 \times 48^2}{18 \times 0.75 + 40 \times 1.5}$$

$$L = \frac{1296}{73.5} = 17.6 \mu\text{H}$$

To calculate the number of turns of a single-layer coil for a required value of inductance

$$n = \frac{\sqrt{L(18d + 40\ell)}}{d}$$

Example: Suppose an inductance of  $10 \mu\text{H}$  is required. The form on which the coil is to be wound has a diameter of one inch and is long enough to accommodate a coil of  $1\frac{1}{4}$  inches. Then  $d = 1$ ,  $\ell = 1.25$  and  $L = 10$ . Substituting,

$$n = \frac{\sqrt{10[(18 \times 1) + (40 \times 1.25)]}}{1}$$

$$n = \sqrt{680} = 26.1 \text{ turns}$$

A 26-turn coil would be close enough in practical work. Since the coil will be 1.25 inches long, the number of turns per inch

Fig. 30 — Assorted inductors. A rotary (continuously variable) coil is shown at the upper left. Slug-tuned inductors are visible in the lower foreground. An RF choke (three pl windings) is visible at the lower right.

Fig. 31 — Coil dimensions used in the inductance formula. The wire diameter does not enter into the formula. The spacing has been exaggerated in this illustration for clarity. The formula is for closewound coils.

will be  $26.1 / 1.25 = 20.9$ . Consulting the wire table in Chapter 35, we find that no. 17 enameled wire (or anything smaller) can be used. The proper inductance is obtained by winding the required number of turns on the form and then adjusting the spacing between the turns to make a uniformly spaced coil 1.25 inches long.

## Inductance Charts

Most inductance formulas lose accuracy when applied to small coils (such as are used in VHF work and in low-pass filters built for reducing harmonic interference to television) because the conductor thickness is no longer negligible in comparison with the size of the coil. Fig. 32 shows the measured inductance of VHF coils, and may be used as a basis for circuit design. Two curves are given; curve A is for coils wound to an inside diameter of  $\frac{1}{2}$  inch; curve B is for coils of  $\frac{3}{4}$  inch inside diameter. In both curves the wire size is no. 12, winding pitch is eight turns to the inch ( $1/8$  inch center-to-center turn spacing). The inductance values given include leads  $\frac{1}{2}$  inch long.

Machine-wound coils with the diameters and turns per inch given in Tables 4 and 5 are available in many radio stores, under the trade names of B&W Miniductor, Airdux and Polycoll. Figs. 33 and 34 are used with Tables 4 and 5.

Fig. 32 — Measured Inductance of coils wound with no. 12 bare wire, eight turns to the inch. The values include half-inch leads.

Fig. 33 — Factor to be applied to the Inductance of coils listed in Table 4 for coil lengths up to 5 inches.

Forming a wire into a solenoid increases its inductance, and also introduces distributed capacitance. Since each turn is at a slightly different ac potential, each pair of turns effectively forms a parasitic capacitor. At some frequency the effective capacitance will have a reactance equal to that of the inductance, and the inductor will show self-resonance. (Reactance and resonance are treated later in this chapter.) Above the self-resonant frequency, a coil takes on the reactive properties of a capacitor instead of an inductor. The behavior of a coil with respect to frequency is illustrated in Fig. 35.

Fig. 34 — Factor to be applied to the Inductance of coils listed in Table 5, as a function of coil length. Use curve A for coils marked A, and curve B for coils marked B.

At low frequencies the inductance of a straight, round, nonmagnetic wire in free space is given by

$$L = 0.0002b \left[ \left( \ln \frac{2b}{a} \right) - 0.75 \right]$$

where

$L$  = inductance in  $\mu\text{H}$

$a$  = wire radius in mm

$b$  = wire length in mm

$\ln$  = natural logarithm =  $2.303 \times$  common logarithm (base 10)

If the dimensions are expressed in inches instead of mm, the equation may still be

used, except replace the 0.0002 value with 0.00508. Skin effect reduces the inductance at VHF and above. As the frequency approaches infinity, the 0.75 constant within the brackets approaches unity. As a practical matter, the skin effect doesn't reduce the inductance by more than a few percent.

As an example, find the inductance of

a wire that is 4 mm in diameter and 100 mm long. For the calculations,  $a = 2$  mm (radius) and  $b = 100$ . Using the natural logarithm function, the problem is formulated as follows:

$$L = 0.0002 (100) \left[ \ln \left( \frac{2 \times 100}{2} \right) - 0.75 \right]$$

$$L = 0.02 [\ln (100) - 0.75]$$

$$L = 0.02 (4.605 - 0.75)$$

$$L = (0.02) (3.855) = 0.077 \mu\text{H}$$

Fig. 36 is a graph of the inductance for wires of various radii as a function of length.

A VHF or UHF tank circuit can be fabricated from a wire parallel to a ground plane, with one end grounded. A formula for the inductance of such an arrangement is given in Fig. 37.

Suppose it is desired to find the inductance of a wire 100 mm long and 2 mm in radius, suspended 40 mm above a ground plane. (The inductance is measured between the free end and the ground plane, and the formula includes the inductance of the 40-mm grounding link.) A person skilled in the use of a sophisticated calculator could produce the answer with only a few keystrokes, but to demonstrate the use of the formula, begin by evaluating these quantities:

$$b + \sqrt{b^2 + a^2} = 100 + \sqrt{100^2 + 2^2} \\ = 100 + 100.02 = 200.02$$

$$b + \sqrt{b^2 + 4h^2} \\ = 100 + \sqrt{100^2 + 4 \times 40^2} \\ = 100 + 128.06 \\ = 228.06$$

$$\frac{2h}{a} = \frac{2 \times 40}{2} = 40$$

$$\frac{b}{4} = \frac{100}{4} = 25$$

Substituting these figures into the formula yields:

$$L = 0.0004605 \times 100 \times$$

$$\log \left( \frac{2 \times 40}{2} \times \frac{200.02}{228.06} \right)$$

$$+ 0.0002 (128.06 - 100.02 + 25 - 80 + 2) = 0.066 \mu\text{H}$$

(A)

(B)

Fig. 35 — The proximity of the turns on a solenoid forms parasitic capacitors, as sketched in A. The net effect of the capacitors is called the distributed capacitance, and causes the coil to exhibit a self-resonance, illustrated in B.

Fig. 36 — Inductance of various conductor sizes as straight wires.

$$L = 0.0004605b \left\{ \log_{10} \left[ \frac{2h}{a} \left( \frac{b + \sqrt{b^2 + a^2}}{b + \sqrt{b^2 + 4h^2}} \right) \right] \right\} + 0.0002 \left( \sqrt{b^2 + 4h^2} - \sqrt{b^2 + a^2} + \frac{b}{4} - 2h + a \right)$$

where

$L$  = inductance in  $\mu\text{H}$

$a$  = wire radius in mm

$b$  = wire length parallel to ground plane in mm

$h$  = wire height above ground plane in mm

Fig. 37 — Equation for determining the inductance of a wire parallel to a ground plane, with one end grounded. If the dimensions are in inches, the numerical coefficients become 0.0117 for the first term and 0.0508 for the second term.

Another conductor configuration that is frequently used for inductors is the flat strip. This arrangement has lower skin-effect loss at high frequencies than round wire because it has a higher surface-area to volume ratio. The inductance of such a strip can be found from

$$L = 0.00508b \left( \ln \frac{2b}{w + h} + 0.5 + 0.2235 \frac{w + h}{b} \right)$$

where

L = inductance in microhenrys  
b = length in inches  
w = width in inches  
h = thickness in inches

### Permeability of Iron-Core Coils

Suppose the coil in Fig. 38 is wound on an iron core having a cross-sectional area of 2 square inches. When a certain current is sent through the coil, it is found that there are 80,000 lines of force in the core. Since the area is 2 square inches, the magnetic flux density is 40,000 lines per square inch. Now suppose that the iron core is removed and the same current is maintained in the coil. Also suppose the flux density without the iron core is found to be 50 lines per square inch. The ratio of these flux densities, iron core to air, is 40,000/50 or 800. This is called the permeability of the core. The inductance of the coil is increased 800 times by inserting the iron core, since the inductance will be proportional to the magnetic flux through the coils, other things being equal.

The permeability of a magnetic material varies with the flux density. At low flux densities (or with an air core), increasing the current through the coil will cause a proportionate increase in flux. But at very high flux densities, increasing the current may cause no appreciable change in the flux. When this is so, the iron is said to be saturated. Saturation causes a rapid

decrease in permeability, because it decreases the ratio of flux lines to those obtainable with the same current and an air core. Obviously, the inductance of an iron-core inductor is highly dependent on the current flowing in the coil. In an air-core coil, the inductance is independent of current because air does not saturate.

Iron-core coils such as the one sketched in Fig. 38 are used chiefly in power supply equipment. They usually have direct current flowing through the winding, and the variation in inductance with current is usually undesirable. It may be overcome by keeping the flux density below the saturation point of the iron. This is done by opening the core so there is a small air gap, indicated by the dashed lines in Fig. 38. The magnetic resistance introduced by such a gap is very large compared with that of the iron, even though the gap is only a small fraction of an inch. Therefore the gap, rather than the iron, controls the flux density. This reduces the inductance, but holds the value practically constant regardless of the magnitude of the current.

For radio-frequency work, the losses in iron cores can be reduced to a more useful level by grinding the iron into a powder and then mixing it with a "binder" of insulating material in such a way that the individual iron particles are insulated from each other. Using this approach, cores can be made that function satisfactorily even into the VHF range.

Because a large part of the magnetic path is through a nonmagnetic material (the "binder"), the permeability of the iron is low compared with the values obtained at power supply frequencies. The core is usually shaped in the form of a slug or cylinder for fit inside the insulating form on which the coil is wound. Despite the fact that the major portion of the magnetic path for the flux is in air, the slug is quite effective in increasing the coil inductance. By pushing the slug in and out of the coil, the inductance can be varied over a considerable range.

### Eddy Currents and Hysteresis

When alternating current flows through a coil wound on an iron core an EMF is induced, as previously explained. Since iron is a conductor, a current flows in the core. Such currents are called eddy currents. Eddy currents represent lost power because they flow through the resistance of the iron and generate heat. Losses caused by eddy currents can be reduced by laminating the core (cutting the core into thin strips). These strips or laminations are then insulated from each other by painting them with some insulating material such as varnish or shellac.

Another type of energy loss is found in loaded inductors. Iron tends to resist any change in its magnetic state, so a rapidly changing current such as ac is continually forced to supply energy to the iron in order to overcome this "inertia." Losses caused

Fig. 38 — Typical construction of an iron-core inductor. The small air gap prevents magnetic saturation of the iron and thus maintains the inductance at high currents.

Fig. 39 — Inductances in series and parallel.

Fig. 40 — Mutual inductance. When S is closed, current flows through coil no. 1, setting up a magnetic field that induces an EMF in the turns of coil no. 2.

by this effect are referred to as hysteresis losses.

Eddy-current and hysteresis losses in iron increase rapidly as the frequency of the alternating current is increased. For this reason, ordinary iron cores can be used only at power-line and audio frequencies — up to approximately 15,000 hertz. Even then, a very good grade of iron or steel is necessary for the core to perform well at the higher audio frequencies. Iron cores of this type become completely useless at radio frequencies.

### Inductances in Series and Parallel

When two or more inductors are connected in series (Fig. 39A), the total inductance is equal to the sum of the individual inductances, provided the coils are sufficiently separated so that coils are not in the magnetic field of one another. That is,

$$L_{\text{total}} = L_1 + L_2 + L_3 + \dots$$

If inductors are connected in parallel (Fig. 39B), and if the coils are separated sufficiently, the total inductance is given by

$$L_{\text{total}} = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \dots}$$

and for two inductances in parallel,

$$L = \frac{L_1 \times L_2}{L_1 + L_2}$$

Thus, the rules for combining inductances in series and parallel are the same for resistances, assuming the coils are far enough apart so that each is unaffected by another's magnetic field. When this is not so, the formulas given above cannot be used.

### Mutual Inductance

When two coils are arranged with their axes on the same line, as shown in Fig. 40, current sent through coil 1 creates a magnetic field that cuts coil 2. Consequently, an EMF will be induced in coil 2 whenever the field strength is changing. This induced EMF is similar to the EMF of self-induction, but since it appears in the second coil because of current flowing in the first, it is a mutual effect and results from the mutual inductance between the two coils.

When all the flux set up by one coil cuts all the turns of the other coil, the mutual inductance has its maximum possible value. If only a small part of the flux set up by one coil cuts the turns of the other, the mutual inductance is relatively small. Two coils having mutual inductance are said to be coupled.

The ratio of actual mutual inductance to the maximum possible value that could theoretically be obtained with two given coils is called the coefficient of coupling between the coils. It is frequently expressed as a percentage. Coils that have nearly the maximum possible mutual inductance (coefficient = 1 or 100 percent) are said to be closely, or tightly, coupled. If the mutual inductance is relatively small the coils are said to be loosely coupled. The degree of coupling depends upon the physical spacing between the coils and how they are placed with respect to each other. Maximum coupling exists when they have a common axis and are as close together as possible (one wound over the other). The coupling is least when the coils are far apart or are placed so their axes are at right angles.

The maximum possible coefficient of coupling is closely approached when the two coils are wound on a closed iron core. The coefficient with air-core coils may run as high as 0.6 or 0.7 if one coil is wound over the other, but will be much less if the two coils are separated. Although unity coupling is suggested by Fig. 40, such coupling is possible only when the coils are wound on a closed magnetic core.

### RL TIME CONSTANT

A comparable situation to an RC circuit exists when resistance and inductance are connected in series. In Fig. 41, first consider L to have no resistance and also assume that R is zero. Closing S sends a current through the circuit. The instantaneous transition from no current to a finite value, however small, represents a very rapid change in current, and a back

Fig. 41 — Time constant of an RL circuit.

Fig. 42 — Instantaneously placing the switch in position B will discharge the inductor as shown in the graph. This is a theoretical model only; a mechanical switch cannot change state instantaneously.

EMF is developed by the self-inductance of L that is almost equal and opposite to the applied EMF. The resulting initial current is very small.

The back EMF depends on the change in current and would cease to offer opposition if the current did not continue to increase. With no resistance in the circuit (which would lead to an infinitely large current, by Ohm's Law) the current would increase forever, always growing just fast enough to keep the EMF of self-induction equal to the applied EMF.

When resistance in the circuit limits the current, Ohm's Law defines the value that the current can reach. The back EMF generated in L must only equal the difference between E and the drop across R, because the difference is the voltage actually applied to L. This difference becomes smaller as the current approaches the final Ohm's Law value. Theoretically, the back EMF never quite disappears and

so the current never quite reaches the Ohm's Law value, but practically the differences become unmeasurable after a time.

The current at any time after the switch in Fig. 41 has been closed can be found from

$$I(t) = \frac{E}{R} \left( 1 - e^{-\frac{tR}{L}} \right)$$

where

$I_t$  = current in amperes at time t

E = power supply potential in volts

t = time in seconds after initiation of current

e = natural logarithmic base = 2.718

R = circuit resistance in ohms

L = inductance in henrys

The time in seconds required for the current to build up to 63.2% of the maximum value is called the time constant, and is equal to  $L/R$ , where L is in henrys and R is in ohms. After each time interval equal to this constant the circuit conducts an additional 63.2% of the remaining current. This behavior is graphed in Fig. 41.

An inductor cannot be discharged in the simple circuit of Fig. 41 because the magnetic field disappears as soon as current flow ceases. Opening S does not leave the inductor charged. The energy stored in the magnetic field returns instantly to the circuit when S is opened. The rapid disappearance of the field causes a very large voltage to be induced in the coil. Usually the induced voltage is many times larger than the voltage applied, because induced voltage is proportional to the rate that the field changes. The common result of opening the switch in such a circuit is that a spark or arc forms at the switch contacts at the instant of opening. When the inductance is large and the current in the circuit is high, large amounts of energy are released in a very short time. It is not at all unusual for the switch contacts to burn or melt under such circumstances. The spark or arc at the opened switch can be reduced or suppressed by connecting a suitable capacitor and resistor in series across the contacts. Such an RC combination is called a snubber network.

If the excitation is removed without breaking the circuit, as diagrammed in Fig. 42, the current will decay according to the formula

$$I(t) = \frac{E}{R} \left[ 1 - \left( 1 - e^{-\frac{tR}{L}} \right) \right]$$

or

$$I(t) = \frac{E}{R} \left( e^{-\frac{tR}{L}} \right)$$

where t = time in seconds after removal of EMF.

After one time constant the current will lose 63.2% of its steady-state value (decay to 36.8% of the steady-state value). The graph in Fig. 42 shows the current decay

waveform to be identical to the voltage discharge waveform of a capacitor. However, one should be careful about applying the terms charge and discharge to an inductive circuit. These terms refer to energy storage in an electric field. An inductor stores energy in a magnetic field.

### Inductive Reactance

When an alternating voltage is applied to a pure inductance (one with no resistance — all practical inductors have some resistance) the current is  $90^\circ$  out of phase with the applied voltage. In this case the current lags  $90^\circ$  behind the voltage; the opposite of the capacitor current-voltage relationship (Fig. 43.)

The primary cause for current lag in an inductor is the back EMF generated in the inductance. The amplitude of the back EMF is proportional to the rate at which the current changes. This in turn is proportional to the frequency, so the amplitude of the current is inversely proportional to the applied frequency. Since the back EMF is proportional to inductance for a given rate of current change, the current is inversely proportional to inductance for a given applied voltage and frequency. (Another way of saying this is that just enough current flows to generate an induced EMF that equals and opposes the applied voltage.)

The combined effect of inductance and frequency is called inductive reactance, also expressed in ohms. The formula for it is

$$X_L = 2\pi fL$$

where

- $X_L$  = inductive reactance
- $f$  = frequency in hertz
- $L$  = inductance in henrys
- $\pi$  = 3.1416

Fig. 43 — Phase relationships between voltage and current when an alternating voltage is applied to an inductance.

Example: The reactance of a coil having an inductance of 8 henrys, at a frequency of 120 hertz, is

$$X_L = 2\pi fL = 6.2832 \times 120 \times 8$$

$$X_L = 6032 \text{ ohms}$$

In radio-frequency circuits the inductance values usually are small and the frequencies are large. When the inductance is expressed in millihenrys and the frequency in kilohertz, the conversion factors for the two units cancel, and the formula for reactance may be used without first converting to fundamental units. Similarly, no

conversion is necessary if the inductance is expressed in microhenrys and the frequency in megahertz.

Example: The reactance of a 15-microhenry coil at a frequency of 14 MHz is

$$X_L = 2\pi fL = 6.2832 \times 14 \times 15$$

$$X_L = 1319 \text{ ohms}$$

The resistance of the wire used to wind the coil has no effect on the reactance, but simply acts as a separate resistor connected in series with the coil.

## Reactance and Impedance

### Ohm's Law for Reactance

Ohm's Law equations for an ac circuit containing only reactance are

$$I = \frac{E}{X}, \quad E = IX, \quad X = \frac{E}{I}$$

where

- $E$  = EMF in volts
- $I$  = current in amperes
- $X$  = reactance in ohms

The reactance in the circuit may, of course, be either inductive or capacitive.

Example: If a current of 2 amperes is flowing through the capacitor of the earlier example (reactance = 47.4 ohms) at 7.15 MHz, the voltage drop across the capacitor is  $E = IX = 2 \times 47.4 = 94.8$  volts.

If 420 V at 120 hertz is applied to the

8-henry inductor of the earlier example, the current through the coil will be

$$I = \frac{E}{X} = \frac{420}{6032} = 0.0696 \text{ A}$$

$$= 69.6 \text{ mA}$$

### Reactance Chart

The accompanying chart, Fig. 44, shows the reactance of capacitances from 1 pF to 100  $\mu\text{F}$ , and the reactance of inductances from 0.1  $\mu\text{H}$  to 10 henrys, for frequencies between 100 hertz and 100 megahertz. The approximate value of reactance can be read from the chart. More exact values can be calculated from the formulas.

### Reactances in Series and Parallel

When reactances of the same kind are connected in series or parallel the resultant

reactance is that of the resultant inductance or capacitance. This leads to the same rules that are used when determining the resistance when resistors are combined. That is, for series reactances of the same kind the resultant reactance is

$$X = X_1 + X_2 + X_3 + X_4 + \dots$$

For reactances of the same kind in parallel the resultant is

$$X = \frac{1}{\frac{1}{X_1} + \frac{1}{X_2} + \frac{1}{X_3} + \frac{1}{X_4} + \dots}$$

or for two in parallel,

$$X = \frac{X_1 \times X_2}{X_1 + X_2}$$

Fig. 44 — Inductive and capacitive reactance vs. frequency. Heavy lines represent multiples of 10, intermediate light lines multiples of five. For example, the light line between 10  $\mu\text{H}$  and 100  $\mu\text{H}$  represents 50  $\mu\text{H}$ ; the light line between 0.1  $\mu\text{F}$  and 1  $\mu\text{F}$  represents 0.5  $\mu\text{F}$ , and so on. Intermediate values can be values within the chart range. For example, the reactance of 10 henrys at 60 Hz can be found by taking the reactance of 10 henrys at 600 Hz and dividing by 10 for the 10 $\times$  times decrease in frequency.

The situation is different when reactances of opposite kinds are combined. Since the current in a capacitance leads the applied voltage by 90° and the current in an inductance lags the applied voltage by 90°, the voltage at the terminals of opposite types of reactance are 180° out of phase in a series circuit. (In a series circuit the current has to be the same through all elements.)

In a parallel circuit (in which the same voltage is applied to all elements), the currents in reactances of opposite types are 180° out of phase. The 180° phase relationship means the currents or voltages are of opposite polarity, so in the series circuit of Fig. 45A the voltage  $E_L$  across the induc-

tive reactance  $X_L$  is of opposite polarity to the voltage  $E_C$  across the capacitive reactance  $X_C$ . Thus if we call  $X_L$  "positive" and  $X_C$  "negative" (a common convention) the applied voltage  $E_{AC}$  is  $E_L - E_C$ . In the parallel circuit at B the total current,  $I$ , is equal to  $I_L - I_C$ , since the currents are 180° out of phase. In the series case, therefore, the resultant reactance of  $X_L$  and  $X_C$  is  $X = X_L - X_C$  and in the parallel case (Fig. 45B),

$$X = \frac{-X_L X_C}{X_L - X_C}$$

Note that in the series circuit the total reactance is negative if  $X_C$  is larger than  $X_L$ ; this indicates that the total reactance

Fig. 45 — Series and parallel circuits containing opposite kinds of reactance.

is capacitive in such a case. The resultant reactance in a series circuit is always smaller

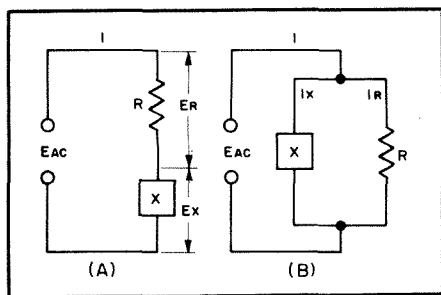

Fig. 46 — Series and parallel circuit containing resistance and reactance.

than the larger of the two individual reactances.

In the parallel circuit, the resultant reactance is positive (that is, inductive) if  $X_C$  is larger than  $X_L$ . This is just the opposite of the situation for reactances in series. In every case the resultant reactance is larger than the smaller of the two individual reactances.

There is one special case where  $X_L = X_C$ . The total reactance in this case is zero in the series circuit and infinitely large in the parallel circuit. In this case the circuit is said to be resonant.

### Reactive Power

In Fig. 45A the voltage drop across the inductor is larger than the voltage applied to the circuit. This might seem to be an impossible condition, but it is not; the explanation is that while energy is being stored in the inductor's magnetic field, energy is being returned to the circuit from the capacitor's electric field, and vice versa. This stored energy is responsible for the fact that the voltages across reactances in series can be larger than the voltage applied to them.

In a resistance the current causes heating and a power loss equal to  $I^2R$ . The power in a reactance is equal to  $I^2X$ , but is not a loss; it is simply power that is transferred back and forth between the field and the circuit but not used up in heating anything. To distinguish this nondissipated power from the power actually consumed, the unit of reactive power is called the volt-ampere-reactive, or VAR, instead of watt. Reactive power is sometimes called wattless power.

### Impedance

When a circuit contains both resistance and reactance the combined effect of the two is called impedance, symbolized by the letter  $Z$ . Impedance is thus a more general term than either resistance or reactance. The term is frequently used even for circuits that have only resistance or reactance, although usually with a qualification such as "resistive impedance" to indicate that the circuit has only resistance, for example.

The reactance and resistance comprising an impedance may be connected either in series or parallel, as shown in Fig. 46. In these circuits the reactance is shown as a

box to indicate that it may be either inductive or capacitive. In the series circuit at A the current is the same in both elements, with (generally) different voltages appearing across the resistance and reactance. In the parallel circuit at B the same voltage is applied to both elements, but different currents may flow in the two branches.

In a resistance the current is in phase with the applied voltage, while in a reactance it is  $90^\circ$  out of phase with the voltage. Thus, the phase relationship between current and voltage in the circuit as a whole may be anything between zero and  $90^\circ$ , depending on the relative amount of resistance and reactance.

### The Complex Impedance Plane

The use of complex numbers in the analysis of ac circuits allows quicker solution without guess work. A complex number treats not only real numbers, but also "imaginary" numbers. An imaginary number is a number that cannot be plotted on the real axis of a graph such as shown in Fig. 47. On this graph the real axis is the horizontal axis, with positive values increasing to the right and negative values increasing to the left. Imaginary numbers are plotted on the Y axis with positive values rising from the origin and negative values descending from the origin.

In mathematical terms an imaginary number is an even root of a negative number. Since there is no real number when squared that will give a negative quantity, the imaginary system is used. Mathematicians define the value  $i$  as the square root of negative 1. In electronics, the symbol  $i$  is already used as a designation for current, so the symbol  $j$  is substituted;  $j \times j$  is equal to negative 1.

The graph of Fig. 47, when used in electrical circuit analysis, is known as the complex impedance plane. The resistive components of the circuit have real values and are plotted along the real or X axis. Reactive values are plotted along the imaginary or Y axis. Inductive reactances,  $X_L$ , take on positive imaginary values because the voltage across an inductor leads the current through the inductor by  $90^\circ$  degrees. Capacitive reactances,  $X_C$ , take on negative imaginary values because the capacitive voltage lags the current by  $90^\circ$  degrees.

The familiar form,  $R \pm jX$  is the rectangular coordinate form for a complex impedance as might be plotted on the complex impedance plane. For example, the value  $27 - j8$  is plotted in Fig. 48A. The resistive value is 27 ohms and the capacitive reactance value is 8 ohms. So, 27 ohms positive and 8 imaginary ohms negative gives point A.

Fig. 48B shows another impedance value, where the resistance is 0.61 ohm and the inductive reactance is 1.15 ohms. The same impedance can be described in a secondary form called polar coordinate form. Here, instead of the point being

Fig. 47 — Real numbers are plotted on the X axis of the complex impedance plane; imaginary numbers are plotted on the Y axis.

Fig. 48 — At A, the complex impedance  $27 - j8$  is plotted graphically in rectangular coordinate form. At B, the complex impedance  $0.61 + j1.15$  is plotted in rectangular coordinate form and is also shown in polar coordinate form.

described by its X-Y values, its position is described by the magnitude of the distance from the origin and the angle in degrees rotated counterclockwise from the positive X-axis. This is shown in Fig. 48B. The impedance now is described in the form of some magnitude times a phase angle. For example,  $1.3 / 62^\circ$ .

The values  $0.61 + j1.15$  and  $1.3 / 62^\circ$  both describe the same impedance, only in different forms. The values are identical and each form can be easily converted to the other. There are advantages to each form. In rectangular form, complex numbers are easily added or subtracted. In polar form, complex numbers are easily multiplied and divided. The form used is largely dependent on the mathematical process to be performed on the complex number.

### Addition and Subtraction of Complex Numbers

The rule for adding and subtracting com-

Fig. 49 — Converting from rectangular to polar form.

Fig. 50 — Converting from polar to rectangular form.

plex numbers in rectangular form is very simple: add or subtract the real and imaginary terms separately.

For example:  $(15 + j32) + (10 - j8) = 25 + j24$

### Multiplication and Division of Complex Numbers

The rule for multiplying complex numbers in the polar form is: multiply the magnitudes and add the angles.

For example:  $(8 \angle 27^\circ) \times (2 \angle 3^\circ) = 16 \angle 30^\circ$

The rule for dividing complex numbers in polar form is: divide the magnitudes, but subtract the angle of denominator from the angle of the numerator.

For example:  $(8 \angle 27^\circ) / (2 \angle 3^\circ) = 4 \angle 24^\circ$

### Converting from Rectangular to Polar Form

The easiest way to perform multiplication or division on a complex number is the use of polar form. Although it is possible to multiply complex numbers in their rectangular form, it is actually easier to first convert rectangular form to polar form and then perform the operations necessary. The magnitude of an impedance in polar form is equal to the distance the plotted impedance is from the origin. The

Pythagorean Theorem provides a simple means of calculating this distance. The magnitude is equal to

$$Z = \sqrt{R^2 + X^2}$$

This also is the formula for finding ac impedance.

The phase angle referenced to the positive real axis can also be found through simple trigonometry.

$$\theta = \arctan \frac{X}{R}$$

or

$$\theta = \arcsin \frac{X}{Z}$$

or

$$\theta = \arccos \frac{R}{Z}$$

For example:  $10 - j10 = 14.14 \angle -45^\circ$  as shown in Fig. 49.

### Converting from Polar to Rectangular Form

As shown in Fig. 50, the real term of an impedance plotted in polar form is equal to  $Z \cos \theta$ , and the imaginary term is equal to  $Z \sin \theta$ . Multiplying the magnitude of the impedance in polar form by the cosine of the phase angle gives the real term. Multiplying the magnitude of the impedance in polar form by the sine of the angle gives the reactive term.

For example:  $12 \angle 42^\circ$

$$R = 12 \times \cos(42^\circ) = 8.92$$

$$X = j \times 12 (\sin 42^\circ) = j8.03$$

$$12 \angle 42^\circ = 8.92 + j8.03$$

### Series Circuits

When resistance and reactance are in series, the impedance of the circuit is

$$Z = \sqrt{R^2 + X^2}$$

where

$Z$  = impedance in ohms

$R$  = resistance in ohms

$X$  = reactance in ohms

The reactance may be either capacitive or inductive. If there are two or more reactances in the circuit they may be combined into a resultant by the rules previously given before substitution into the formula above; similarly for resistances.

### Parallel Circuits

With resistance and reactance in parallel, as in Fig. 46B, the impedance is

$$Z = \frac{RX}{\sqrt{R^2 + X^2}}$$

where the symbols have the same meaning as for series circuits.

Just as in the case of series circuits, a number of reactances in parallel should be combined to find the resultant reactance before substitution in the formula above;

similarly for a number of resistances in parallel.

### Equivalent Series and Parallel Circuits

The two circuits shown in Fig. 46 are equivalent if the same current flows when a given voltage of the same frequency is applied, and if the phase angle between voltage and current is the same in both cases. It is in fact possible to transform any given series circuit into an equivalent parallel circuit, and vice versa.

Transformations of this type often lead to simplification in the solution of complicated circuits. However, from the standpoint of practical work the usefulness of such transformations lies in the fact that the impedance of a circuit may be modified by the addition of either series or parallel elements, depending on which happens to be more convenient in the particular case. Typical applications are considered later in connection with tuned circuits and transmission lines.

A series RX circuit can be converted into its parallel equivalent by means of the formula

$$R_p = \frac{R_s^2 + X_s^2}{R_s}$$

$$X_p = \frac{R_s^2 + X_s^2}{X_s}$$

where the subscripts p and s represent the parallel- and series-equivalent values, respectively. If the parallel values are known, the equivalent series circuit can be found from

$$R_s = \frac{R_p}{1 + \left(\frac{R_p}{X_p}\right)^2}$$

and

$$X_s = \frac{R_s R_p}{X_p}$$

### Ohm's Law for Impedance

Ohm's Law can be applied to circuits containing impedance just as readily as to circuits having resistance or reactance only. The formulas are

$$I = \frac{E}{Z}$$

$$E = IZ$$

$$Z = \frac{E}{I}$$

where

$E$  = EMF in volts

$I$  = current in amperes

$Z$  = impedance in ohms

Fig. 51 shows a simple circuit consisting of a resistance of 75 ohms and a reactance of 100 ohms in series. From the formula previously given, the impedance is

$$Z = \sqrt{R^2 + X^2} = \sqrt{75^2 + 100^2} = 125$$

If the applied voltage is 250, then

$$I = \frac{E}{Z} = \frac{250}{125} = 2 \text{ amperes}$$

This current flows through both the resistance and reactance, so the voltage drops are

$$E_R = IR = 2 \times 75 = 150 \text{ volts}$$

$$EX_L = IX_L = 2 \times 100 = 200 \text{ volts}$$

The simple arithmetical sum of these two drops, 350 V, is greater than the applied voltage because the two voltages are 90° out of phase. Their actual resultant, when phase is taken into account, is

$$\sqrt{150^2 + 200^2} = 250 \text{ volts}$$

### Power Factor

In the circuit of Fig. 51 an applied EMF of 250 V results in a current of 2 amperes, giving an apparent power of  $250 \times 2 = 500$  watts. However, only the resistance actually consumes power. The power in the resistance is

$$P = I^2R = 2^2 \times 75 = 300 \text{ watts}$$

The ratio of the power consumed to the apparent power is called the power factor of the circuit. In this example the power factor would be  $300/500 = 0.6$ . Power factor is frequently expressed as a percentage; in this case, it is 60 percent.

Real or dissipated power is measured in watts; apparent power, to distinguish it

Fig. 51 — Circuit used as an example for impedance calculations.

Fig. 52 — A series circuit containing L, C and R is resonant at the applied frequency when the reactance of C is equal to the reactance of L. The I in the circle is the schematic symbol for an ammeter.

from real power, is measured in volt-amperes (VA). It is simply the product of volts and amperes and has no direct relationship to the power actually used up unless the power factor of the circuit is known. The power factor of a purely resistive circuit is 100% or 1, while the power factor of a pure reactance is zero. In this illustration, the reactive power is

$$\text{VAR} = I^2X = 2^2 \times 100$$

$$\text{VAR} = 400 \text{ volt-amperes}$$

An equivalent definition of power factor is

$$\text{PF} = \frac{R}{Z} = \cos \theta$$

Since power factor is always rendered as a positive number, the value must be followed by the words leading or lagging to identify the phase of the voltage with respect to the current. Specifying the numerical power factor is not always sufficient. For example, many dc-to-ac power inverters can safely operate loads having a large net reactance of one sign but only a small reactance of the opposite sign.

### Reactance and Complex Waves

It was pointed out earlier in this chapter that a complex wave (a nonsinusoidal wave) can be resolved into a fundamental frequency and a series of harmonic frequencies. When such a complex voltage wave is applied to a circuit containing reactance, the current through the circuit will not have the same wave shape as the applied voltage. This is because the reactance of an inductor and capacitor depend on the applied frequency. For the second-harmonic component of a complex wave, the reactance of the inductor is twice and the reactance of the capacitor is half their respective values at the fundamental frequency; for the third harmonic the inductive reactance is three times and the capacitive reactance is a third, and so on. Thus, the circuit impedance is different for each harmonic component.

Just what happens to the current wave shape depends on the values of resistance and reactance involved and how the circuit is arranged. In a simple circuit with resistance and inductive reactance in series, the amplitudes of the harmonic currents will be reduced because the inductive reactance increases in proportion to frequency. When capacitance and resistance are in series, the harmonic current is likely to be accentuated because the capacitive reactance becomes lower as the frequency is raised. When both inductive and capacitive reactance are present, the shape of the current wave can be altered in a variety of ways. The shape will depend on the circuit and the constants, or the relative values of L, C and R that are selected.

This property of nonuniform behavior with respect to fundamental and harmonics is an extremely useful one. It is the basis

of filtering, or the suppression of undesired frequencies in favor of a single desired frequency or group of such frequencies.

### Resonance in Series Circuits

Fig. 52 shows a resistor, capacitor and inductor connected in series with a source of alternating current, the frequency of which can be varied over a wide range. At some low frequency the capacitive reactance will be much larger than the resistance of R, and the inductive reactance will be small compared with either the reactance of C or the resistance of R. (R is assumed to be the same at all frequencies.) On the other hand, at some very high frequency the reactance of C will be very small and the reactance of L will be very large. In either case the current will be small, because the net reactance is large.

At some intermediate frequency, the reactances of C and L will be equal. At this frequency the voltage drops across the coil and capacitor will be equal and 180° out of phase. Therefore, they cancel each other completely and the current flow is determined wholly by the resistance, R. At that frequency the current has its largest possible value, assuming the source voltage to be constant regardless of frequency. A series circuit in which the inductive and capacitive reactances are equal is said to be resonant.

The principle of resonance finds its most extensive application in radio-frequency circuits. The reactive effects associated with even small inductances and capacitances would place drastic limitations on RF circuit operation if it were not possible to cancel them out by supplying the right amount of reactance of the opposite kind — in other words, tuning the circuit to resonance.

### Resonant Frequency

The frequency at which a series circuit is resonant is that at which  $X_L = X_C$ . Substituting the formulas for inductive and capacitance reactance gives

$$X_L = 2\pi fL = X_C = \frac{1}{2\pi fC}$$

$$2\pi fL = \frac{1}{2\pi fC}$$

$$f^2 = \frac{1}{4\pi^2 LC}$$

$$f = \frac{1}{2\pi \sqrt{LC}}$$

where

f = frequency in hertz

L = inductance in henrys

C = capacitance in farads

$\pi = 3.14$

These units are inconveniently large for radio-frequency circuits. A formula using

more appropriate units is

$$f = \frac{10^6}{2\pi \sqrt{LC}}$$

where

- f = frequency in kilohertz (kHz)
- L = inductance in microhenrys ( $\mu\text{H}$ )
- C = capacitance in picofarads (pF)
- $\pi = 3.14$

**Example:** The resonant frequency of a series circuit containing a 5- $\mu\text{H}$  inductor and a 35-pF capacitor is

$$f = \frac{10^6}{2\pi \sqrt{LC}} = \frac{10^6}{6.28 \times \sqrt{5 \times 35}}$$

$$f = \frac{10^6}{6.28 \times 13.23} = 12,037 \text{ kHz}$$

The resonant frequency is not affected by resistance in the circuit.

### Resonance Curves

When a plot is drawn of the current in the circuit of Fig. 52 as the frequency is varied (the applied voltage being constant), it looks like one of the curves in Fig. 53. The shape of the resonance curve is determined by the ratio of reactance to resistance.

When the reactance of either the coil or capacitor is of the same order of magnitude as the resistance, the current decreases rather slowly as the frequency is moved in either direction away from resonance. Such a curve is said to be broad. Conversely, when the reactance is considerably larger than the resistance the current decreases rapidly as the frequency moves away from resonance and the circuit is said to be sharp. A sharp circuit will respond a great deal more readily to the resonant frequency than to frequencies quite close to resonance; a broad circuit will respond almost equally well to a group or band of frequencies centered around the resonant frequency.

Both types of resonance curves are useful. A sharp circuit gives good selectivity — the ability to respond strongly (in terms of current amplitude) at one desired frequency, and to discriminate against others. A broad circuit is used when the apparatus must give about the same response over a band of frequencies, rather than at a single frequency alone.

### Q

Most diagrams of resonant circuits show only inductance and capacitance; no resistance is indicated. Nevertheless, resistance is always present. At frequencies up to perhaps 30 MHz this resistance is mostly in the wire of the coil. At higher frequencies energy loss in the capacitor (principally in the solid dielectric that must be used to form an insulating support for the capacitor plates) also becomes a factor. This energy loss is equivalent to resistance. When maximum sharpness or selectivity is

needed, the objective of design is to reduce the inherent resistance to the lowest possible value.

The value of the reactance of either the inductor or capacitor at the resonant frequency of a series-resonant circuit, divided by the series resistance in the circuit, is called the Q (quality factor) of the circuit, or

$$Q = \frac{X}{R}$$

where

- Q = quality factor
- X = reactance of either coil or capacitor in ohms
- R = series resistance in ohms

**Example:** The inductor and capacitor in a series circuit each has a reactance of 350 ohms at the resonant frequency. The resistance is 5 ohms. The Q is

$$Q = \frac{X}{R} = \frac{350}{5} = 70$$

The effect of Q on the sharpness of resonance of a circuit is shown by the curves of Fig. 54. In these curves the frequency change is shown in percentage above and below the resonant frequency. Q values of 10, 20, 50 and 100 are shown; these values cover much of the range commonly used in radio work. The unloaded Q of a circuit is determined by the inherent resistances associated with the components.

### Voltage Rise at Resonance

When a voltage of the resonant frequency is inserted in series in a resonant circuit, the voltage that appears across either the inductor or capacitor is considerably higher than the applied voltage. The current in the circuit is limited only by the resistance and may have a relatively high value. However, the same current flows through the high reactances of the inductor and capacitor and causes large voltage drops.

The ratio of the reactive voltage to the applied voltage is equal to the ratio of reactance to resistance. This ratio is also the Q of the circuit. Therefore, the voltage across either the inductor or capacitor is equal to QE, where E is the voltage being applied to the series circuit. This fact accounts for the high voltages developed across the components of series-tuned antenna couplers.

### Resonance in Parallel Circuits

When a variable-frequency source of constant voltage is applied to a parallel circuit of the type shown in Fig. 55, there is a resonance effect similar to that in a series circuit. In this case the line current (measured at the point indicated by the ammeter) is smallest at the frequency for which the inductive and capacitive reactances are equal. At that frequency the current through L is exactly canceled by the out-of-phase current through C, and only the current taken by R flows in the line. At frequencies below resonance the current

Fig. 53 — Current in a series-resonant circuit with various values of series resistance. The values are arbitrary and would not apply for all circuits, but represent a typical case. It is assumed that the reactances (at the resonant frequency) are 1000 ohms. Note that the current is substantially unaffected by the resistance in the circuit at frequencies more than plus or minus 10% away from the resonant frequency.

Fig. 54 — Current in series-resonant circuits having different Q values. In this graph the current at resonance is assumed to be the same in all cases. The lower the Q, the more slowly the current decreases as the applied frequency is moved away from resonance.

Fig. 55 — Circuit illustrating parallel resonance.

Fig. 56 — Series and parallel equivalents when the two circuits are resonant. The series resistance,  $R_1$  in A, is replaced in B by the equivalent parallel resistance  $R_2$ , and vice versa.

$$R_2 = \frac{X_L^2}{R_1} = \frac{X_C^2}{R_1}$$

Fig. 57 — Relative impedance of parallel-resonant circuits with different  $Q$  values. These curves are similar to those in Fig. 54 for current in a series-resonant circuit. The effect of  $Q$  on impedance is most marked near the resonant frequency.

through  $L$  is larger than that through  $C$ , because the reactance of  $L$  is smaller and that of  $C$  is larger than at resonance.

There is only partial cancellation of the two reactive currents, and the line current therefore is larger than the current taken by  $R$  alone. At frequencies above resonance the situation is reversed and more current flows through  $C$  than through  $L$ , so the line current again increases. The current at resonance, being determined wholly by  $R$ , will be small if  $R$  is large, and large if  $R$  is small.

The  $R$  shown in Fig. 55 is not necessarily an actual resistor. In many cases it will be the series resistance of the coil transformed to an equivalent parallel resistance (see below). It may be antenna or other load resistance coupled into the tuned circuit. In all cases it represents the total effective resistance in the circuit.

Parallel and series resonant circuits are quite alike in some respects. For instance, when an external voltage is applied the circuits given at A and B in Fig. 56 will behave

identically, if (1)  $L$  and  $C$  are the same in both cases, and (2)  $R_1$  multiplied by  $R_2$ , equals the square of the reactance (at resonance) of either  $L$  or  $C$ . When these conditions are met the two circuits will have the same  $Q$ . (These statements are approximate, but are quite accurate if the  $Q$  is 10 or more.) The circuit at A is a series circuit if it is viewed from within — that is, going around the loop formed by  $L$ ,  $C$  and  $R_1$  — so its  $Q$  can be found from the ratio of  $X$  to  $R_1$ .

Thus, a circuit like that of Fig. 56A has an equivalent parallel resistance (at resonance) of

$$R_2 = \frac{X^2}{R_1}$$

where  $X$  is the reactance of either the inductor or the capacitor. Although  $R_2$  is not an actual resistor, to the source of voltage the parallel-resonant circuit looks like a pure resistance of that value. It is pure resistance because the inductive and capacitive currents are  $180^\circ$  out of phase and are equal; thus there is no reactive current in the line. In a practical circuit with a high- $Q$  capacitor, the parallel impedance at the resonant frequency is

$$Z_R = QX$$

where

$Z_R$  = resistive impedance at resonance

$Q$  = quality factor of inductor

$X$  = reactance (in ohms) of either the inductor or capacitor

Example: The parallel impedance of a circuit with a coil  $Q$  of 50 and having inductive and capacitive reactance of 300 ohms will be

$$Z_R = QX = 50 \times 300 = 15,000 \text{ ohms}$$

At frequencies off resonance the impedance is no longer purely resistive because the inductive and capacitive currents are not equal. The off-resonant impedance therefore is complex, and is lower than the resonant impedance for the reasons previously outlined.

The higher the circuit  $Q$ , the higher the parallel impedance. Curves showing the variation of impedance (with frequency) of a parallel circuit have the same shape as the curves showing the variation of current with frequency in a series circuit. Fig. 57 is a set of such curves. A set of curves showing the relative response as a function of the departure from the resonant frequency would be similar to Fig. 54. The  $-3$  dB bandwidth (bandwidth at 0.707 relative response) is given by

$$\text{Bandwidth } -3 \text{ dB} = \frac{f_0}{Q}$$

where

$f_0$  = the resonant frequency

$Q$  = the circuit  $Q$

It is also called the half-power bandwidth.

### Parallel Resonance in Low- $Q$ Circuits

The preceding discussion is accurate for  $Q$  values of 10 or more. When the  $Q$  is below 10, resonance in a parallel circuit having resistance in series with the coil, as in Fig. 56A, is not so easily defined. There is a set of values for  $L$  and  $C$  that will make the parallel impedance a pure resistance, but with these values the impedance does not have its maximum possible value. Another set of values for  $L$  and  $C$  will make the parallel impedance a maximum, but this maximum value is not a pure resistance.

Either condition could be called resonance, so with low- $Q$  circuits it is necessary to distinguish between maximum impedance and resistive impedance when discussing parallel resonance. The difference between these  $L$  and  $C$  values and the equal reactances of a series-resonant circuit is appreciable when the  $Q$  is in the vicinity of 5, and becomes more marked with still lower  $Q$  values.

### $Q$ of Loaded Circuits

In many applications of resonant circuits the only power lost is that dissipated in the resistance of the circuit itself. At frequencies below 30 MHz most of this resistance is in the coil. Within limits, increasing the number of turns in the coil increases the reactance faster than it raises the resistance, so coils for circuits in which the  $Q$  must be high are made with relatively large inductance for the frequency.

However, when the circuit delivers energy to a load (as in the case of the resonant circuits used in transmitters) the energy consumed in the circuit itself is usually negligible compared with that consumed by the load. The equivalent of such a circuit is shown in Fig. 58A, where the parallel resistor represents the load to which power is delivered. If the power dissipated in the load is at least 10 times as great as the power lost in the inductor and capacitor, the parallel impedance of the resonant circuit itself will be so high compared with the resistance of the load that for all practical purposes the impedance of

Fig. 58 — Equivalent diagram of a resonant circuit delivering power to a load. This resistor  $R$  represents the load resistance. At B the load is tapped across part of  $L$ , by which transformer action is equivalent to using a higher load resistance across the whole circuit.

the combined circuit is equal to the load resistance. Under these conditions the  $Q$  of a parallel resonant circuit loaded by a resistive impedance is

$$Q = \frac{R}{X}$$

where

$R$  = parallel load resistance (ohms)

$X$  = reactance (ohms)

Example: A resistive load of 3000 ohms is connected across a resonant circuit in which the inductive and capacitive reactances are each 250 ohms. The circuit  $Q$  is then

$$Q = \frac{R}{X} = \frac{3000}{250} = 12$$

The effective  $Q$  of a circuit loaded by a parallel resistance increases when the reactances are decreased. A circuit loaded with a relatively low resistance (a few thousand ohms) must have low-reactance elements (large capacitance and small inductance) to have reasonably high  $Q$ .

### Impedance Transformation

An important application of the parallel-resonant circuit is as an impedance-matching device in the output circuit of an RF power amplifier. There is an optimum value of load resistance for each type of tube or transistor and set of operating conditions. However, the resistance of the load to which the active device is to deliver power usually is considerably lower than the value required for proper device operation.

To transform the actual load resistance to the desired value, the load may be tapped across part of the coil, as shown in Fig. 58B. This is equivalent to connecting a higher value of load resistance across the whole circuit, and is similar in principle to impedance transformation with an iron-core transformer. In high-frequency resonant circuits the impedance ratio does not vary exactly as the square of the turns ratio, because all the magnetic flux lines do not cut every turn of the coil. A desired reflected impedance usually must be obtained by experimental adjustment.

When the load resistance has a very low value (say below 100 ohms) it may be connected in series in the resonant circuit (as in Fig. 56A, for example), in which case it is transformed to an equivalent parallel impedance as previously described. If the  $Q$  is at least 10, the equivalent parallel impedance is

$$Z_R = \frac{X^2}{R}$$

where

$Z_R$  = resistive parallel impedance at resonance

$X$  = reactance (in ohms) of either the coil or the capacitor

$R$  = load resistance inserted in series

If the  $Q$  is lower than 10 the reactance will have to be adjusted somewhat, for the reasons given in the discussion of low- $Q$  circuits, to obtain a resistive impedance of the desired value.

While the circuit shown in Fig. 58B will usually provide an impedance step-up as with an iron-core transformer, the network has some serious disadvantages for some applications. For instance, the common connection provides no dc isolation, and the common ground is sometimes troublesome with regard to ground-loop currents. Consequently, a network with only mutual magnetic coupling is usually preferable. No impedance step-up will result unless the two coils are coupled tightly enough. The equivalent resistance seen at the input of the network will always be lower regardless of the turns ratio employed. However, such networks are still useful in impedance-transformation applications if the appropriate capacitive elements are used. A more detailed treatment of matching networks will be presented in a later section.

Unfortunately, networks involving reactive elements are usually narrowband in nature; it would be desirable if such elements could be eliminated in order to increase the bandwidth. With the advent of ferrites, this has become possible, and it is now relatively easy to construct actual impedance transformers that are both broadband and permit operation well up into the VHF portion of the spectrum. This is also accomplished in part by tightly coupling the two (or more) coils that make up the transformer, either by twisting the conductors together or winding them in a parallel fashion. The latter configuration is sometimes called a bifilar winding, as discussed in the section on ferromagnetic transformers.

## Transformers

Two coils having mutual inductance constitute a transformer. The coil connected to the source of energy is called the primary coil, and the other is called the secondary coil.

The usefulness of the transformer lies in the fact that electrical energy can be transferred from one circuit to another without direct connection, and in the process can be readily changed from one voltage level to another. Thus, if a device to be operated requires, for example, 7-V ac and only a 440-V source is available, a transformer can be used to change the source voltage to that required. A transformer can be used only with ac, since no voltage will be induced in the secondary if the magnetic field is not changing. If dc is applied to the primary of a transformer, a voltage will be induced in the secondary only at the instant of closing or opening the primary circuit, since it is only at these

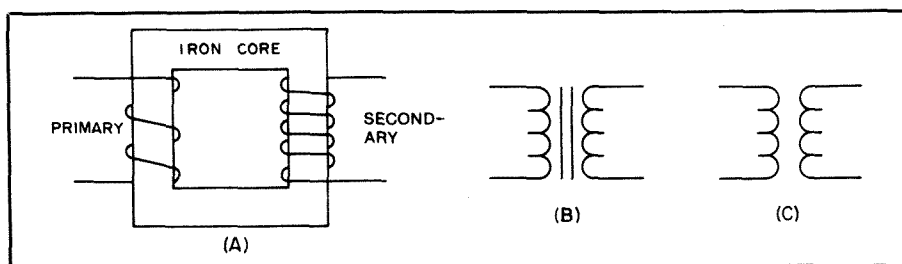

Fig. 59 — The transformer. A is a pictorial diagram. Power is transferred from the primary coil to the secondary by means of the magnetic field. B is a schematic diagram for an iron-core transformer, and C is for an air-core transformer.

times that the field is changing.

### The Iron-Core Transformer

As shown in Fig. 59, the primary and secondary coils of a transformer may be wound on a core of magnetic material. This increases the inductance of the coils so that

a relatively small number of turns may be used to induce a given value of voltage with a small current. A closed core (one having a continuous magnetic path) such as that shown in Fig. 59 also tends to ensure that practically all of the field set up by the current in the primary coil will cut the turns

of the secondary coil. However, the core introduces a power loss because of hysteresis and eddy currents, so this type of construction is normally practicable only at power and audio frequencies. The discussion in this section is confined to transformers operating at such frequencies.

### Voltage and Turns Ratio

For a given varying magnetic field, the voltage induced in a coil in the field is proportional to the number of turns in the coil. When the two coils of a transformer are in the same field (which is the case when both are wound on the same closed core) it follows that the induced voltages will be proportional to the number of turns in each coil. In the primary the induced voltage practically equals and opposes, the applied voltage, as described earlier. Hence,

$$E_s = E_p \left( \frac{n_s}{n_p} \right)$$

where

$E_s$  = secondary voltage

$E_p$  = primary applied voltage

$n_s$  = number of turns on secondary

$n_p$  = number of turns on primary

Example: A transformer has a primary of 400 turns and a secondary of 2800 turns, and an EMF of 117 V is applied to the primary.

$$E_s = 117 \left( \frac{2800}{400} \right) = 117 \times 7$$

$$E_s = 819 \text{ volts}$$

Also, if an EMF of 819 V is applied to the 2800-turn winding (which then becomes the primary) the output voltage from the 400-turn winding will be 117 V.

Either winding of a transformer can be used as the primary, provided the winding has enough turns (enough inductance) to induce a voltage equal to the applied voltage without requiring an excessive current flow.

### Secondary Current

The current that flows in the primary when no current is taken from the secondary is called the magnetizing current of the transformer. In any properly designed transformer the primary inductance is quite small. The power consumed by the transformer when the secondary is open (not delivering power) is only the amount necessary to overcome the losses in the iron core and in the resistance of the wire with which the primary is wound.

When power is taken from the secondary winding, the secondary current sets up a magnetic field that opposes the field set up by the primary current. For the induced voltage in the primary to equal the applied voltage, the original field must be maintained. The primary must draw enough additional current to set up a field exactly

Fig. 60 — The equivalent circuit of a transformer includes the effects of leakage inductance and resistance of both primary and secondary windings. The resistance  $R_c$  is an equivalent resistance representing the core losses. Since these are comparatively small, their effect may be neglected in many approximate calculations.

equal and opposite to the field set up by the secondary current.

In practical calculations on transformers it may be assumed that the entire primary current is caused by the secondary load. This is justifiable because the magnetizing current should be very small in comparison with the primary load current at rated power output.

If the magnetic fields set up by the primary and secondary currents are to be equal, the primary current multiplied by the primary turns must equal the secondary current multiplied by the secondary turns. From this it follows that

$$I_p = I_s \left( \frac{n_s}{n_p} \right)$$

where

$I_p$  = primary current

$I_s$  = secondary current

$n_p$  = number of turns on primary

$n_s$  = number of turns on secondary

Example: Suppose the secondary of the transformer in the previous example is delivering a current of 0.2 ampere to a load. Then the primary current will be

$$I_p = I_s \left( \frac{n_s}{n_p} \right) = 0.2 \left( \frac{2800}{400} \right) = 0.2 \times 7$$

$$I_p = 1.4 \text{ amperes}$$

Although the secondary voltage is higher than the primary voltage, the secondary current is lower than the primary current, and by the same ratio.

### Power Relationships and Efficiency

A transformer cannot create power; it can only transfer it and change the EMF. Hence, the power taken from the secondary cannot exceed that taken by the primary from the source of applied EMF. There is always some power loss in the resistance of the coils and in the iron core, so in all practical cases the power taken from the source will exceed that taken from the secondary. Thus,

$$P_o = nP_i$$

where

$P_o$  = power output from secondary

$P_i$  = power input to primary

$n$  = efficiency factor

The efficiency,  $n$ , is always less than 1. It is usually expressed as a percentage; if  $n$  is 0.65, for instance, the efficiency is 65%.

Example: A transformer has an efficiency of 85% at its full-load output of 150 watts. The power input to the primary at full secondary load will be

$$P_i = \frac{P_o}{n} = \frac{150}{0.85} = 176.5 \text{ watts}$$

A transformer is usually designed to have the highest efficiency at the power output for which it is rated. The efficiency decreases with either lower or higher outputs. On the other hand, the losses in the transformer are relatively small at low output but increase as more power is taken. The amount of power that the transformer can handle is determined by its own losses, because these losses heat the wire and core. There is a limit to the temperature rise that can be tolerated, because too high a temperature can either melt the wire or cause the insulation to break down. A transformer can be operated at reduced output, even though the efficiency is low, because the actual loss will be low under such conditions. The full-load efficiency of small power transformers such as are used in radio receivers and transmitters usually lies between about 60 and 90 percent, depending on the size and design.

### Leakage Reactance

In a practical transformer not all of the magnetic flux is common to both windings, although in well designed transformers the amount of flux that cuts one coil and not the other is only a small percentage of the total flux. This leakage flux causes an EMF of self-induction; consequently, there are small amounts of leakage inductance associated with both windings of the transformer. Leakage inductance acts in exactly the same way as an equivalent amount of ordinary inductance inserted in series with the circuit. It has, therefore, a certain reactance, depending on the amount of leakage inductance and the frequency. This reactance is called leakage reactance.

Current flowing through the leakage reactance causes a voltage drop. This voltage drop increases with increasing current, hence it increases as more power is taken from the secondary. Thus, the

greater the secondary current, the smaller the secondary terminal voltage becomes. The resistances of the transformer windings also cause voltage drops when current is flowing; although these voltage drops are not in phase with those caused by leakage reactance, together they result in a lower secondary voltage under load than is indicated by the turns ratio of the transformer.

At power frequencies (60 Hz) the voltage at the secondary, with a reasonably well designed transformer, should not drop more than about 10% from open-circuit conditions to full load. The drop in voltage may be considerably more than this in a transformer operating at audio frequencies because the leakage reactance increases directly with the frequency. The various transformer losses are modeled in Fig. 60.

### Impedance Ratio

In an ideal transformer — one without losses or leakage reactance — the following relationship is true:

$$Z_p = Z_s \left( \frac{n_p}{n_s} \right)^2$$

where

$Z_p$  = impedance looking into primary terminals from source of power

$Z_s$  = impedance of load connected to secondary

$n_p/n_s$  = turns ratio, primary to secondary

That is, a load of any given impedance connected to the secondary of the transformer will be transformed to a different value looking into the primary from the source of power. The impedance transformation is proportional to the square of the primary-to-secondary turns ratio.

Example: A transformer has a primary-to-secondary turns ratio of 0.6 (primary has 6/10 as many turns as the secondary) and a load of 3000 ohms is connected to the secondary. The impedance at the primary then will be

$$Z_p = Z_s \left( \frac{n_p}{n_s} \right)^2 = 3000 \times (0.6)^2$$

$$Z_p = 3000 \times 0.36 = 1080 \text{ ohms}$$

By choosing the proper turns ratio, the impedance of a fixed load can be transformed to any desired value, within practical limits. If transformer losses can be neglected, the transformed (reflected) impedance has the same phase angle as the actual load impedance. Thus, if the load is a pure resistance, the load presented by the primary to the source of power will also be a pure resistance. The above relationship may be used in practical work even though it is based on an ideal transformer. Aside from the normal design requirements of reasonably low internal losses and low leakage reactance, the only requirement is

that the primary have enough inductance to operate with low magnetizing current at the voltage applied to the primary.

The primary terminal impedance of a transformer is determined wholly by the load connected to the secondary and by the turns ratio. If the characteristics of the transformer have an appreciable effect on the impedance presented to the power source, the transformer is either poorly designed or is not suited to the voltage and frequency at which it is being used. Most transformers will operate quite well at voltages from slightly above to well below the design figure.

### Impedance Matching

Many devices require a specific value of load resistance (or impedance) for optimum operation. The impedance of the actual load that is to dissipate the power may differ widely from this value, so a transformer is used to change the actual load into an impedance of the desired value. This is called impedance matching. From the preceding,

$$\frac{n_p}{n_s} = \sqrt{\frac{Z_p}{Z_s}}$$

where

$n_p/n_s$  = required turns ratio, primary to secondary

$Z_p$  = primary impedance required

$Z_s$  = impedance of load connected to secondary

Example: A transistor AF amplifier requires a load of 150 ohms for optimum performance, and is to be connected to a loudspeaker having an impedance of 4 ohms. The turns ratio, primary to secondary, required in the coupling transformer is

$$\frac{n_p}{n_s} = \sqrt{\frac{Z_p}{Z_s}} = \sqrt{\frac{150}{4}} = \sqrt{37.5} = 6.1$$

The primary therefore must have 6.1 times as many turns as the secondary.

Impedance matching implies adjusting the load impedance, by means of a transformer or otherwise, to a desired value. However, there is also another meaning. It is possible to show that any source of power will deliver its maximum possible output when the impedance of the load is equal to the internal impedance of the source. The impedance of the source is said to be matched under this condition. The efficiency is only 50% in such a case; just as much power is used up in the source as is delivered to the load. Because of the poor efficiency, this type of impedance matching is limited to cases where only a small amount of power is available and heating from power loss in the source is not important.

### TRANSFORMER CONSTRUCTION

Transformers usually are designed so that the magnetic path around the core is

Fig. 61 — Two common types of transformer construction. Core pieces are interleaved to provide a continuous magnetic path.

as short as possible. A short magnetic path means that the transformer will operate with fewer turns, for a given applied voltage, than if the path were long. A short path also helps to reduce flux leakage and therefore minimizes leakage reactance.

Two core shapes are in common use, as shown in Fig. 61. In the shell type, both windings are placed on the inner leg, while in the core type the primary and secondary windings may be placed on separate legs, if desired. This is sometimes done when it is necessary to minimize capacitive effects between the primary and secondary, or when one of the windings must operate at very high voltage.

Core material for small transformers is usually silicon steel, called transformer iron. The core is built up of laminations, insulated from each other (by a thin coating of shellac, for example) to prevent eddy currents. The laminations are interleaved at the ends to make the magnetic path as continuous as possible and thus reduce leakage.

The number of turns required in the primary for a given applied EMF is determined by the size, shape and type of core material used, and the frequency. The number of turns required is inversely proportional to the cross-sectional area of the core. As a rough indication, windings of small power transformers frequently have about six to eight turns per volt on a core of 1-square-inch cross section and have a magnetic path 10 or 12 inches in length. A longer path or smaller cross section requires more turns per volt, and vice versa.

In most transformers the coils are wound

Fig. 62 — The autotransformer is based on the transformer principle, but uses only one winding. The line and load currents in the common winding (A) flow in opposite directions, so the resultant current is the difference between them. The voltage across A is proportional to the ratio of total turns to turns in A.

Fig. 63 — An assortment of toroid cores. A ferrite rod is placed at the top of the picture for comparison. The two light-colored, plastic-encased toroids at the upper left are tape-wound types (Hypersil steel), and are suitable for audio and dc-to-dc converter transformers. The wound toroid at the right center contains two toroid cores that have been stacked atop one another to increase the power capability.

in layers, with a thin sheet of treated-paper insulation between each layer. Thicker insulation is used between adjacent coils and between the first coil and the core.

### Autotransformers

The transformer principle can be used with only one winding instead of two, as shown in Fig. 62; the principles just discussed apply equally well. A one-winding transformer is called an autotransformer. The current in the common section (A) of the winding is the difference between the line (primary) and the load (secondary) currents, since these currents are out of phase. Hence, if the line and load currents are

nearly equal, the common section of the winding may be wound with comparatively small wire. The line and load currents will be equal only when the primary (line) and secondary (load) voltages are not very different.

The autotransformer is used chiefly for boosting or reducing the power-line voltage by relatively small amounts. Continuously variable autotransformers are commercially available under a variety of trade names; Variac and Powerstat are typical examples.

### Ferromagnetic Transformers and Inductors

The design concepts and general theory of transformers presented earlier in this chapter apply also to transformers wound on ferromagnetic-core materials (ferrite and powdered iron). As is the case with stacked cores made of laminations in the classic I and E shapes, the core material has a specific permeability factor that determines the inductance of the windings versus the number of wire turns used.

Both ferrite and powdered-iron materials are manufactured with a wide range of  $\mu_i$  (initial permeability) characteristics. The value chosen by the designer depends on the intended operating frequency and the desired bandwidth of a given broadband transformer.

### Core Types in Use at RF

For use in radio-frequency circuits especially, a suitable core type must be chosen to provide the Q required by the designer. The wrong core material destroys the Q of an inductor at RF.

Toroid cores are useful from a few hundred hertz well into the UHF spectrum. Tape-wound steel cores are employed in some types of power supplies — notably dc-to-dc converters. The toroid core is doughnut shaped, as shown in Fig. 63.

The principal advantage of this type of core is the self-shielding characteristic. Another feature is the compactness of a transformer or inductor. Therefore, toroids are excellent not only in dc-to-dc converters, but at audio and radio frequencies up to at least 1000 MHz, assuming the proper core material is selected for the range of operating frequencies. Toroid cores are available from microminiature sizes up to several inches in diameter. The latter can be used, as one example, to build a 20-kW balun for use in antenna systems.

Another form taken in ferromagnetic transformers and inductors is the pot-core or cup-core device. Unlike the toroid, which has the winding over the outer surface of the core material, the pot-core winding is inside the ferromagnetic material (Fig. 64). There are two cup-shaped halves to the assembly, both made of ferrite or powdered iron, which are connected tightly together by means of a screw that is passed through a center hole. The wire for the assembly is wound on an insulating bobbin that fits inside the

Fig. 64 — View of a disassembled pot core (left) and an assembled pot core (right).

Fig. 65 — A BC-band ferrite-rod loop antenna is shown at the top of the picture (J. W. Miller Co.). A blank ferrite rod is visible at the center, and a flat BC-band ferrite loop antenna in the lower foreground.

two halves of the pot-core unit.

The advantage to this type of construction is that the core permeability can be chosen to ensure a minimum number of wire turns for a given value of inductance. This reduces the wire resistance and increases the Q as opposed to an equivalent inductance wound on a core that has relatively low permeability. By virtue of the winding being contained inside the ferrite or powdered-iron pot core, shielding is excellent.

Still another kind of ferromagnetic-core inductor is the solenoidal type (Fig. 65). Transformers and inductors fabricated in this manner consist of a cylindrical, oval or rectangular rod of material over which the wire winding is placed. This variety of device does not have a self-shielding trait. Therefore, it must be treated in the same manner as any solenoidal-wound inductor (using external shield devices). An example of a ferrite-rod inductor is the built-in loop antennas found in portable radios and direction finders.

### Core Size

The cross-sectional area of a ferromagnetic core should be chosen to prevent saturation from the load seen by the transformer. This means that the proper thickness and diameter are essential parameters to consider. For a specific core the maximum operational ac excitation can be determined by

$$B = \frac{E_{RMS} \times 10^8}{4.44 f n_p A_e}$$

Fig. 66 — Schematic and pictorial representations of one type of conventional transformer. This style is used frequently at the input and output ports of RF power amplifiers that use transistors. The magnetic material consists of two rows of 950- $\mu$  toroid cores for use from 1.8 to 30 MHz. The primary and secondary windings are passed through the center holes of the toroid-stack rows as shown.

where

$A_e$  = equivalent area of the magnetic path in sq. cm.

$E_{RMS}$  = applied voltage

$n_p$  = number of core turns

$f$  = operating frequency in hertz

$B$  = flux density in gauss

This equation is applicable to inductors that do not have dc flowing in the winding along with ac. When both ac and dc flow

$$B = \frac{E_{RMS} \times 10^8}{4.44 f n_p A_e} + \frac{N_p I_{dc} A_L}{10 A_e}$$

where

$I_{dc}$  = the dc current through the winding

$A_L$  = the manufacturer's index for the core being used, which can be obtained by consulting the manufacturer's data sheet.

### Types of Transformers

The most common ferromagnetic transformers used in Amateur Radio work are the narrow-band, conventional, broadband and transmission-line varieties. Narrow-band transformers are used when selectivity is desired in a tuned circuit, such as an audio peaking or notching circuit, a resonator in an RF filter, or a tuned circuit associated with an RF amplifier. Broadband transformers are employed in circuits which must have a uniform response over a substantial spread of frequency, as in a 2- to 30-MHz broadband amplifier. In such an example the reactance of the windings should be at least four

times the impedance the winding is designed to look into. Therefore, a transformer that has a 300-ohm primary and a 50-ohm secondary load should have winding reactances ( $X_L$ ) of at least 1200 ohms and 200 ohms, respectively. The windings, for all practical purposes, can be graded as RF chokes, and the same rules apply.

The permeability of the core material plays a vital role in designing a good broadband transformer. The performance of the transformer at the low-frequency end of the operating range depends on the permeability. That is, the  $\mu_e$  (effective permeability) must be high enough in value to provide ample winding reactance at the low end of the operating range. As the operating frequency is increased, the effects of the core tend to disappear until there are scarcely any core effects at the upper limit of the operating range. For this reason it is common to find very low frequency core materials in transformers that are used in broadband circuits operating into the upper HF region, or even into the VHF spectrum. By way of simple explanation, at high frequencies the low-frequency core material becomes inefficient and tends to vanish electrically. This desirable trait makes possible the use of ferromagnetics in broadband applications.

Conventional transformers are those that are wound in the same manner as a power transformer. That is, each winding is made from a separate length of wire, with one winding being placed over the previous one with suitable insulation between (Figs. 66 and 67). A transmission-line transformer is, conversely, one that uses windings that are arranged to simulate a piece of transmission line of a specific impedance. This can be done by twisting the wires together a given number of times per inch, or by laying the wires on the core (adjacent to one another) at a distance apart which provides a two-wire line impedance of a particular value. In some applications these windings are called bifilar. A three-wire winding is known as a trifilar one, and so forth (Fig. 68).

It can be argued that a transmission-line transformer is more efficient than a conventional one, but in practice it is difficult to observe a significant difference in the performance characteristics. An interesting technical paper on the subject of toroidal broadband transformers was published by Sevick, W2FMI.<sup>1</sup> The classic reference work on the subject is by Ruthroff.<sup>2</sup>

### Ferrite Beads

Another form of toroidal inductor is the ferrite bead. This component is available in various  $\mu_i$  values and sizes, but most beads are less than 0.25 inch in diameter.

<sup>1</sup>J. Sevick, "Simple Broadband Matching Networks," QST, January 1976.

<sup>2</sup>Ruthroff, "Some Broadband Transformers," Proc. IRE, Vol. 47, August 1959, p. 137.

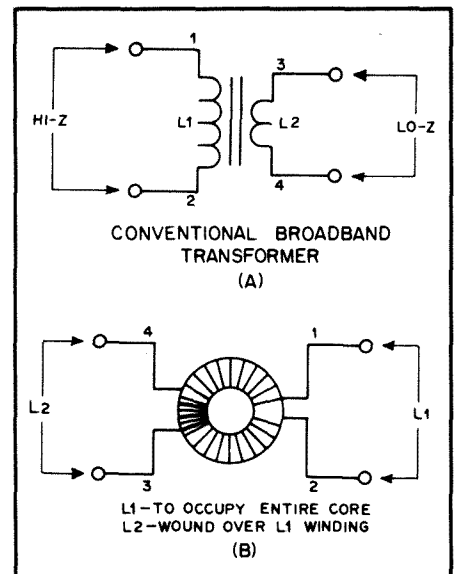

Fig. 67 — Another conventional transformer. Primary and secondary windings are wound over the outer surface of a toroid core.

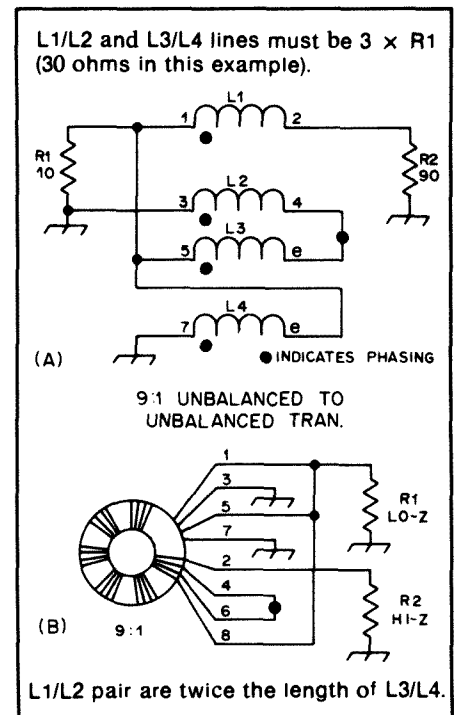

Fig. 68 — Schematic and pictorial presentations of a transmission-line transformer in which the windings need to be arranged for a specific impedance.

Ferrite beads are used principally as VHF and UHF parasitic suppressors at the input and output terminals of amplifiers. Another practical application is in decoupling networks that are used to prevent unwanted migration of RF energy from one section of a circuit to another. They are used also in suppressing RFI and TVI in hi-fi and television sets.

In some circuits it is necessary only to

place one or more beads over a short length of wire to obtain ample inductive reactance for creating an RF choke. A few turns of small-diameter enameled wire can be looped through the larger beads to increase the effective inductance. Ferrite beads are suitable as low-Q base impedances in solid-state VHF and UHF amplifiers. The low-Q characteristic prevents self-oscillation that might occur if a high-Q solenoidal RF choke were used in place of one made from beads. Miniature broadband transformers are sometimes fashioned from ferrite beads. For the most part, ferrite

beads can be regarded as small toroid cores.

## Number of Turns

The number of wire turns used on a toroid core can be calculated by knowing the  $A_L$  of the core and the desired inductance. The  $A_L$  is simply the inductance index for the core size and permeability being used. Table 6 provides information of interest concerning a popular assortment of powdered-iron toroid cores. The complete number for a given core is composed of the core-size designator in the upper left column, plus the corresponding mix num-

ber. For example, a half-inch diameter core with a no. 2 mix would be designated as a T-50-2 unit. The  $A_L$  would be 49 and the suggested operating frequency would be from 1 to 30 MHz. The  $\mu_i$  for that core is 10.

The required number of wire turns for a specified inductance on a given type of core can be determined by

$$\text{Turns} = 100 \sqrt{\text{desired } L (\mu\text{H}) \div A_L}$$

where  $A_L$  is obtained from Table 6. The table also indicates how many turns of a

Courtesy of Amidon Assoc., N. Hollywood, CA 91607

particular wire gauge can be close wound to fill a specified core. For example, a T-68 core will contain 49 turns of no. 24 enamelled wire, 101 turns of no. 30 enamelled wire, and so on. Generally speaking, the larger the wire gauge the higher the unloaded Q of the toroidal inductor. The inductance values are based on the winding covering the entire circumference of the core. When there is space between the turns of wire, some control over the net inductance can be effected by compressing the turns or spreading them. The inductance will increase if compression is used and will decrease when the turns are spread farther apart.

Table 7 contains data for ferrite cores. The number of turns for a specified inductance in mH versus the  $A_L$  can be determined by

$$\text{Turns} = 1000 \sqrt{\text{desired } L \text{ (mH)} \div A_L}$$

where the  $A_L$  for a specific core can be taken from Table 7. Thus, if you required a 1-mH inductor and chose a no. FT-82-43 toroid core, the number of turns would be

$$\begin{aligned} \text{Turns} &= 1000 \sqrt{1 \div 557} \\ &= 1000 \sqrt{0.001795} \\ &= 1000 \times 0.0424 = 42.4 \text{ turns} \end{aligned}$$

For an FT-82 size core, no. 22 enamelled wire would be suitable as indicated in Table 6 (using the T-80 core size as the nearest one to an FT-82). If the toroid core has rough edges (untumbled), it is suggested that insulating tape (3M glass epoxy tape or Mylar tape) be wrapped through the core before the wire is added. This will prevent the rough edges of the core from abrading the enamelled wire.

## Checking RF Toroidal Devices

The equations given previously will provide the number of wire turns needed for a particular inductance, plus or minus 10%. However, slight variations in core permeability may exist from one production run to another. Therefore, for circuits that require exact values of inductance, it is necessary to check the toroid winding by means of an RCL bridge or an RX meter. If these instruments are not available, close approximations can be had by using a dip

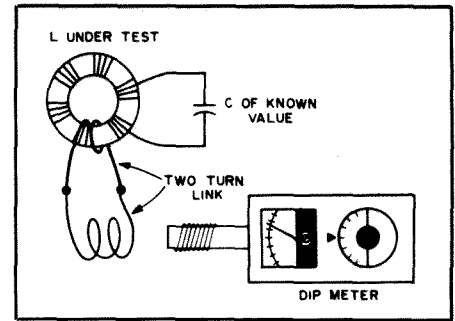

Fig. 69 — Method for checking the inductance of a toroid winding by means of a dip meter, known capacitance value and a calibrated receiver. The self-shielding properties of a toroidal inductor prevent dip meter readings when the instrument is coupled directly to the toroid. Sampling is done by means of a coupling link as illustrated.

meter, standard capacitor (known value, stable type, such as a silver mica) and a calibrated receiver against which to check the dipper frequency.

Fig. 69 shows how to couple a dip meter to a completed toroid for testing. The coupling link in the illustration is necessary because the toroid has a self-shielding characteristic. That characteristic makes it difficult, and often impossible, to obtain a dip in the meter reading when coupling the instrument directly to the toroidal inductor or transformer. The inductance can be determined by  $X_L$  since  $X_L = X_C$  at resonance. Therefore,

$$X_C = \frac{1}{2\pi fC} \text{ and } L_{(\mu H)} = \frac{X_L}{2\pi f}$$

where

 $X_C$  = the reactance of the known capacitor value

f = frequency in MHz

C = capacitance in  $\mu F$ 

Using an example, where f is 3.5 MHz (as noted on a dip meter) and C is 100 pF, L is determined by

$$\begin{aligned} X_C &= \frac{1}{6.28 \times 3.5 \times 0.0001} = 454.7 \text{ ohms} \\ L &= X_C \text{ at resonance, where} \end{aligned}$$

$$L_{(\mu H)} = \frac{454.7}{6.28 \times 3.5} = 20.7 \mu H$$

It is assumed, for the purpose of accuracy, that the dip-meter signal is checked for precise frequency by means of a calibrated receiver.

## Practical Considerations

Amateurs who work with toroidal inductors and transformers are sometimes confused by the winding instructions given in construction articles. For the most part, winding a toroid core with wire is less complicated than winding a cylindrical single-layer coil.

When many turns of wire are required,

Fig. 70 — (A) Illustration of a homemade winding shuttle for toroids. The wire is stored on the shuttle and the shuttle is passed through the center hole of the toroid, again and again, until the required number of turns is in place. (B) It is best to leave a 30° gap between the ends of the toroid winding. This will reduce the distributed capacitance considerably. (C) Edgewise view of a toroid core, illustrating the method for counting the turns accurately. (D) The low-impedance winding of a toroidal transformer is usually wound over the large winding, as shown. For narrow-band applications the link should be wound over the cold end of the main winding (see text).

or a transformer winding depends in part on the distributed capacitance between the coil turns and between the ends of the winding. When a large number of turns are used (for example, 500 or 1000), the distributed capacitance can be as great as 100 pF. Ideally, there would be no distributed or parasitic capacitance, but this is not possible. Therefore, the unwanted capacitance must be kept as low as possible in order to take proper advantage of the  $A_L$  factors discussed earlier in this section. The greater the distributed capacitance, the more restrictive the transformer or inductor becomes when applied in a broadband circuit. In the case of a narrow-band application, the  $Q$  can be affected by the distributed capacitance.

The pictorial illustration at Fig. 70B shows the inductor turns distributed uniformly around the toroid core, but a gap of approximately 30° is maintained between the ends of the winding. This method is recommended to reduce the distributed capacitance of the winding. The closer the ends of the winding are to one another, the greater the unwanted capacitance. Also, in order to closely approximate the desired toroid inductance when using the  $A_L$  formula, the winding should be spread over

a homemade winding shuttle can be used to simplify the task. Fig. 70A illustrates this method. The shuttle can be fashioned from a piece of circuit-board material. A stiff piece of plastic works as well. The wire is wound on the shuttle after determining how many inches are required to provide the desired number of toroid turns. (A sample turn around the toroid core will reveal the

wire length per turn.) Once the shuttle is loaded, it is passed through the toroid center again and again until the winding is completed. The edges of the shuttle should be kept smooth to prevent abrasion of the wire insulation.

#### How to Wind Toroids

The effective inductance of a toroid coil

the core as shown. When the turns of the winding are not close wound, they can be spread apart to decrease the effective inductance (this lowers the distributed C). Conversely, as the turns are pushed closer together, the effective inductance is increased by virtue of the greater distributed capacitance. This phenomenon can be used to advantage during final adjustment of narrow-band circuits in which toroids are used.

The proper method for counting the turns on a toroidal inductor is shown in Fig. 70C. The core is shown as it would appear when stood on its edge with the narrow dimension toward the viewer. In this example a four-turn winding has been placed on the core.

Some manufacturers of toroids recommend that the windings on toroidal transformers be spread around all of the core in the manner shown in Fig. 70B. That is, the primary and secondary windings should each be spread around most of the core. This is a proper method when wind-

ing conventional broadband transformers. However, it is not recommended when narrow-band transformers are being built. It is better to place the low-impedance winding (L1 of Fig. 70D) at the cold or grounded end of L2 on the core.

This is shown in pictorial and schematic form at Fig. 70D. The windings are placed on the core in the same rotational sense, and L1 is wound over L2 at the grounded end of L2. The purpose of this winding method is to discourage unwanted capacitive coupling between the windings, which aids in the reduction of spurious energy (harmonics, and so on) that might be present in the circuit where the transformer is used.

In circuits that have a substantial amount of voltage present in the transformer windings, it is good practice to use a layer of insulating material between the toroid core and the first winding. Alternatively, the wire itself can have high dielectric insulation, such as Teflon. This procedure

prevents arcing between the winding and the core. Similarly, a layer of insulating tape (3-M glass tape, Mylar or Teflon) can be placed between the primary and secondary windings of the toroidal transformer (Fig. 70D). Normally, these precautions are not necessary at impedance levels under a few hundred ohms for RF power levels below 100 watts.

Once the inductor or transformer is wound and tested for proper performance, a coating or two of high-dielectric cement should be applied to the winding(s) of the toroid. This protects the wire insulation from abrasion, holds the turns in place and seals the assembly against moisture and dirt. Polystyrene Q Dope is excellent for the purpose.

The general guidelines given for toroidal components can be applied to pot cores and rods when they are used as foundations for inductors or transformers. The important thing to remember is that all of the powdered-iron and ferrite core materials are brittle. They break easily under stress.

## Radio-Frequency Circuits

The designer of amateur equipment needs to be familiar with radio-frequency circuits and the various related equations. This section provides the basic data for most amateur circuit development.

### COUPLED CIRCUITS AND FILTERS

Two circuits are said to be coupled when a voltage or current in one network produces a voltage or current in the other. The network where the energy originates is often called the primary circuit, and the network that receives the energy is called the secondary circuit. Such coupling is often desirable since, in the process, unwanted frequency components or noise may be rejected or isolated, and power may be transferred from a source to a load with greatest efficiency. On the other hand, two or more circuits may be coupled inadvertently and undesirable effects produced. While a great number of coupling-circuit configurations are possible, one very important class covers so many practical applications that it will be analyzed in detail. This class includes ladder networks and filters.

#### Ladder Networks

Any two circuits that are coupled can be drawn schematically as shown in Fig. 71A. A voltage source represented by  $E_{ac}$  with a source resistance  $R_p$  and a source reactance  $X_p$  is connected to the input of the coupling network, thus forming the primary circuit. At the output, a load reactance  $X_s$  and a load resistance  $R_s$  are con-

Fig. 71 — A representative coupling circuit (A) and ladder network (B).

nected as shown to form the secondary circuit. The circuit in the box could consist of an infinite variety of resistors, capacitors, inductors and even transmission lines. However, it will be assumed that the network can be reduced to a combination of series and shunt elements consisting only of inductors and capacitors, as indicated by the circuit shown in Fig. 71B. For obvious reasons, the circuit is often called a ladder network. In addition, if no resistive

elements are present or if such elements can be neglected, the network is said to be dissipationless. It will consume no power.

If a network is dissipationless, all the power delivered to the input of the network will be dissipated in the load resistance,  $R_s$ . This effect leads to important simplifications in computations involved in coupled networks. The assumption of a dissipationless network is usually not valid with transmitting circuits since even a small network loss (0.5 dB) will result in considerable heating at the higher power levels used in amateur applications. On the other hand, coupled circuits used in some receiving stages may have considerable loss. This is because the network may have some advantage and its high loss can be compensated by additional amplification in another stage. However, such devices form a relatively small minority of coupled networks commonly encountered, and only the dissipationless case will be considered in this section.

#### Effective Attenuation and Insertion Loss

The most important consideration in any coupled network is the amount of power delivered to the load resistance,  $R_s$  from the source,  $E_{ac}$  with the network present. Rather than specify the source voltage each time, a comparison is made with the maximum available power from any source with a given primary resistance,  $R_p$ . The value of  $R_p$  might be considered as the impedance level associated with a complex combination of sources, transmission lines,

coupled networks and even antennas. Typical values of  $R_p$  are 52, 75, 300 and 600 ohms. The maximum available power is given by

$$P_{\max} = \frac{E_{ac}^2}{4 R_p}$$

If the network is also dissipationless, the power delivered to the load resistance,  $R_s$  is just the power dissipated in  $R_{in}$ . This power is related to the input current by

$$P_o = I_{in}^2 R_{in}$$

and the current in terms of the other variables is

$$I_{in} = \frac{E_{ac}}{\sqrt{(P_{\pi} + R_{in})^2 + (X_p + X_{in})^2}}$$

Combining these expressions gives a very useful formula for the ratio of power delivered to a load in terms of the maximum available power. This ratio, expressed in decibels, is given by

$$\begin{aligned} \text{Attn} &= -10 \log \left( \frac{P_o}{P_{in}} \right) \\ &= -10 \log \left[ \frac{4 R_{in} R_p}{(R_p + R_{in})^2 + (X_p + X_{in})^2} \right] \end{aligned}$$

and is sometimes called the effective attenuation.

In the special case where  $X_p$  and  $X_s$  are either zero or can be combined into a coupling network, and where  $R_p$  is equal to  $R_s$  the effective attenuation is also equal to the insertion loss of the network. The insertion loss is the ratio of the power delivered to the load (with the coupling network in the circuit) to the power delivered to the load with the network absent. Unlike the effective attenuation, which is always positive when defined by the previous formula, the insertion loss can take on negative values if  $R_p$  is not equal to  $R_s$  or if  $X_p$  and  $X_s$  are not zero. In effect, the insertion loss would represent a power gain under these conditions. The interpretation of this effect is that maximum available power does not occur with the coupling network out of the circuit because of the unequal source and load resistances and the nonzero reactances.

With the network in the circuit, the resistances are now matched, and the reactances are said to be "tuned out." The action of the coupling network in this instance is very similar to that of a transformer (which was discussed in a previous section), and networks consisting of pure inductors and capacitors are often used for this purpose. Such circuits are often called matching networks. On the other hand, it is often desired to deliver the greatest amount of power to a load at some frequencies while rejecting energy at other frequencies. A device that accomplishes this action is called a filter. In the case of unequal source and load resistance, it is often possible to combine the processes of filter-

ing and matching into one network.

### Solving Ladder-Network Problems

From the previous section it is evident that if the values of  $R_{in}$  and  $X_{in}$  of Fig. 71A can be determined, the effective attenuation and possibly the insertion loss are also easily found. Being able to solve this problem has wide applications in RF circuits. For instance, design formulas for filters often include a simplifying assumption that the load resistance is constant with frequency. In the case of many circuits, this assumption is not true. However, if the values of  $R_s$  and  $X_s$  at any particular frequency are known, the attenuation of the filter can be determined even though it is terminated improperly.

Unfortunately, while the solution to any ladder problem is possible from a theoretical standpoint, practical difficulties are encountered as the network complexity increases. Many computations with a high degree of accuracy may be required, making the process a tedious one. Consequently, the use of a calculator or similar computing device is recommended. The approach used here is adapted readily to any calculating method including the use of inexpensive pocket calculators.

### SUSCEPTANCE AND ADMITTANCE

The respective reactances of an inductor and a capacitor are given by

$$X_L = 2\pi fL \text{ and } X_C = \frac{-1}{2\pi fC}$$

In a simple series circuit, the total resistance is just the sum of the individual resistances in the network, and the total reactance is the sum of the reactances. However, it is important to note the sign of the reactance. Since capacitive reactance is negative and inductive reactance is positive, it is possible that the sum of the reactances might be zero even though the individual reactances are not zero. Recall that a series-circuit network is said to be resonant at the frequency where the reactances cancel.

A complementary condition exists in a parallel combination of circuit elements, and it is convenient to introduce the concepts of admittance, conductance and susceptance. In the case of a simple resistance, the conductance is merely the reciprocal. That is, the conductance of a 50-ohm resistance is  $1/50$  or  $2 \times 10^{-2}$ . The unit of conductance is the siemens, the reciprocal of the ohm. For simple inductances and capacitances, the formulas for the respective reciprocal entities are

$$B_L = \frac{-1}{2\pi fL} \text{ and } B_C = 2\pi fC$$

These entities are defined as susceptances. In a parallel combination of conductances and susceptances, the total conductance is the sum of the individual conductances, and the total susceptance is the

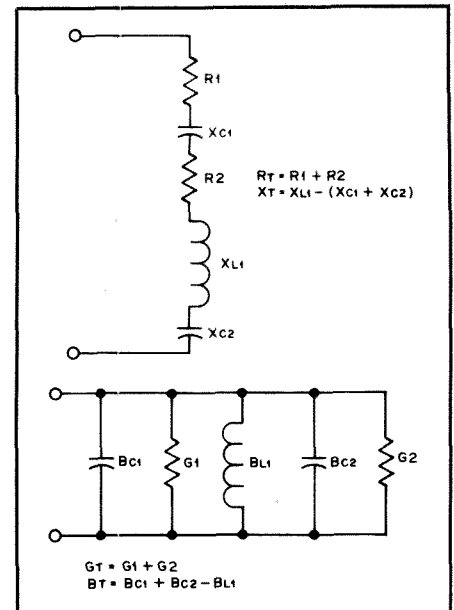

Fig. 72 — Resistances and reactances add in series circuits while conductances and susceptances add in parallel circuits.

Fig. 73 — Conversion formulas can be used to transform a shunt conductance and susceptance to a series-equivalent circuit, A. The converse is illustrated at B.

sum of the individual susceptances, taking the respective susceptance signs into account. A comparison between the way resistance and reactance add and the manner in which conductance and susceptance add is shown in Fig. 72. An entity called admittance may be considered as the reciprocal of impedance. Admittance can be defined in terms of the total conductance and total susceptance by the formula

$$Y = \sqrt{G_T^2 + B_T^2}$$

where

- $Y$  = the admittance
- $G_T$  = total conductance
- $B_T$  = total susceptance

If the impedance of a circuit is known, the admittance is merely the reciprocal. Likewise, if the admittance of a circuit is known, the impedance is the reciprocal of the admittance. However, conductance, reactance, resistance and susceptance are not so simply related. If the total resistance and total reactance of a series circuit are known, the conductance and susceptance

of the circuit are related to them by the formulas

$$G = \frac{R_T}{R_T^2 + X_T^2} \text{ and}$$

$$B = \frac{-X_T}{R_T^2 + X_T^2}$$

On the other hand, if the total conductance and total susceptance of a parallel combination are known, the equivalent resistance and reactance can be found from the formulas

$$R = \frac{G_T}{G_T^2 + B_T^2} \text{ and}$$

$$X = \frac{-B_T}{G_T^2 + B_T^2}$$

The relationships are illustrated in Fig. 73. While the derivation of the mathematical expressions will not be given, the importance of the sign change cannot be stressed too highly. Solving network problems with a calculator is merely a matter of bookkeeping, and failure to take the sign change associated with the transformed reactance and susceptance into account is the most common source of error.

#### A Sample Problem

The following example illustrates the manner in which the theory just discussed can be applied to a practical problem. A filter with the schematic diagram shown in Fig. 74A has an insertion loss of 3 dB at 6 MHz when connected between a 52-ohm load and a source with a 52-ohm primary resistance (both  $X_p$  and  $X_s$  are zero). Find  $R_{in}$  and  $X_{in}$ . Since this is a case where the effective attenuation is equal to the insertion loss, the previous formula for effective attenuation applies.

Starting at the output, the values for the conductance and susceptance of the parallel RC circuit must be determined first. The conductance is just the reciprocal of 52 ohms and the previous formula for capacitive susceptance gives the values shown in parentheses in Fig. 74A. The next step is to apply the formulas for resistance and reactance in terms of the conductance and susceptance, and the results give a 26-ohm resistance in series with a -26-ohm capacitive reactance, indicated in Fig. 74B. The reactance of the inductor can now be added to give a total reactance of 78.01 ohms.

The conductance and susceptance formulas can now be applied; the results of both of these operations is shown in Fig. 74C. Finally, adding the susceptance of the 510.1-pF capacitor (Fig. 74A) and applying the formulas once more gives the value of  $R_{in}$  and  $X_{in}$  (Fig. 74F). If the latter values are substituted into the effective attenuation formula, the insertion loss and effective attenuation are 3.01 dB, which is very close to the value specified. The reader might verify that the insertion loss is 0.167, 0.37 and 5.5 dB at 3.5, 4.0 and 7.0 MHz,

respectively. If a plot of insertion loss versus frequency was constructed it would give the frequency response of the filter.

#### Frequency Scaling and Normalized Impedance

Often, it is desirable to change a coupling network at one frequency and impedance level to another one. For example, suppose it was desired to move the 3-dB point of the filter in the preceding illustration from 6 to 7 MHz. An examination of the reactance and susceptance formulas reveals that multiplying the frequency by some constant  $k$  and dividing both the inductance and capacitance by the same value of  $k$  leaves the equations unchanged. Thus, if the capacitances and inductance in Fig. 74A are multiplied by 6/7, all the reactances and susceptances in the new circuit will now have the same value at 7 MHz that the old one had at 6 MHz.

It is common practice, especially with many filter tables, to present all the circuit components for a number of designs at some convenient frequency. Translating the design to a desired frequency is accomplished simply by multiplying all the components by some constant factor. The most common frequency used is the value of  $f$  such that  $2\pi f$  is equal to 1.0. This is sometimes called a radian frequency of 1.0 and corresponds to 0.1592 Hz. To change a 1-radian filter to a new frequency  $f_0$  (in Hz), all that is necessary is to multiply the inductances and capacitances by  $0.1592/f_0$ .

In a similar manner, if one resistance (or conductance) is multiplied by some factor  $n$ , all the other resistances (or conductances) and reactances (or susceptances) must be multiplied by the same factor to preserve the network characteristics. For instance, if the secondary resistance,  $R_s$ , is multiplied by  $n$ , all circuit inductances must be multiplied by  $n$  and the circuit capacitances divided by  $n$  (since capacitive reactance varies as the inverse of  $C$ ). If, in addition to converting the filter of Fig. 74A to 7 MHz from 6 MHz, it was also desired to change the impedance level from 52 to 600 ohms, the inductance would have to be multiplied by  $(6/7) \times (600/52)$  and the capacitances by  $(6/7) \times (52/600)$ .

#### USING FILTER TABLES

In a previous example, it was indicated that the frequency response of a filter could be derived by solving for the insertion loss of the ladder network for a number of frequencies. The question might be asked if the converse is possible. That is, given a desired frequency response, could a network be found that would have this response? The answer is a qualified yes, and the technical nomenclature for this sort of process is network synthesis. Frequency responses can be cataloged and, if a suitable response can be found, the corresponding network elements can be determined from an associated table. Filters

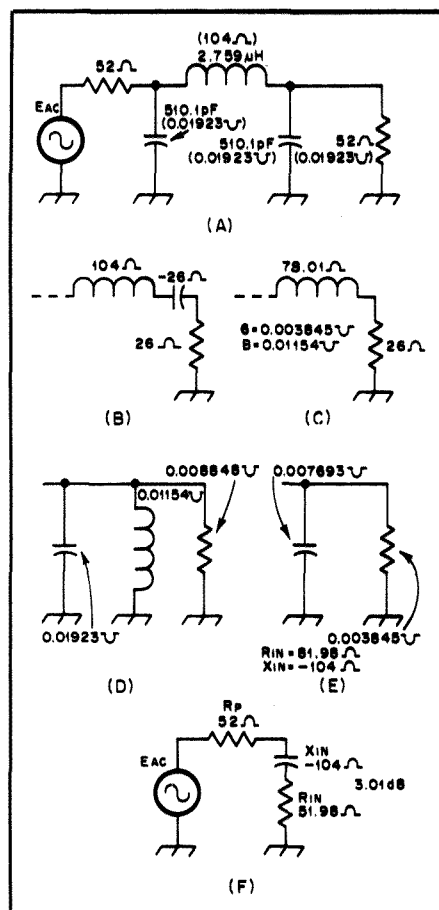

Fig. 74 — Problem illustrating network reduction to find insertion loss.

derived by network synthesis and similar methods (such as optimized computer designs) are often referred to as modern filters even though the theory has been in existence for years. The term is useful in distinguishing such designs from those of an older approximate method called image-parameter theory.

#### Butterworth Filters

Filters can be grouped into four general categories, as illustrated in Fig. 75A. Low-pass filters have zero insertion loss up to some critical frequency ( $f_c$ ) or cutoff frequency, and then provide high rejection above this frequency. (The cutoff condition is indicated by the shaded lines in Fig. 75.) Band-pass filters have zero insertion loss between two cutoff frequencies, with high rejection outside of the prescribed bandwidth. Band-stop filters reject a band of frequencies while passing all others. And high-pass filters reject all frequencies below some cutoff frequency.

The attenuation shapes shown in Fig. 75A are ideal and can only be approached or approximated in practice. For instance, if the filter in the preceding problem was used for low-pass purposes in an 80-meter transmitter to reject harmonics on 40 meters, its performance would leave a lot to be desired. While insertion loss at

Fig. 75 — Ideal filter response curves are shown at A, and characteristics of practical filters are shown at B.

3.5 MHz was acceptable, it would likely be too high at 4.0 MHz, and rejection would probably be inadequate at 7.0 MHz.

Fortunately, design formulas exist for this type of network, classed as Butterworth filters. The name is derived from the shape of the curve for insertion-loss vs. frequency and is sometimes called a maximally flat response. A formula for the frequency response curve is given by

$$A = 10 \log_{10} \left[ 1 + \left( \frac{f}{f_c} \right)^{2k} \right]$$

where

$f$  = the frequency for an insertion loss of "A" dB

$f_c$  = the frequency for an insertion loss of 3.01 dB

$k$  = the number of circuit elements

The shape of a Butterworth low-pass filter is shown in the left-hand portion of Fig. 75B. (Another type that is similar but allows some ripple in the passband, is also shown in Fig. 75B. Here, a high-pass characteristic illustrates a Chebyshev response.)

As can be seen from the formula, increasing the number of elements will result in a filter that approaches the ideal low-pass shape. For instance, a 20-element filter designed for a 3.01-dB cutoff frequency of 4.3 MHz would have an insertion loss of 0.23 dB at 4 MHz, and a loss of 84.7 dB at 7 MHz. However, practical difficulties would make such a filter very hard to construct. Some compromises are always required between a theoretically perfect frequency response and ease of construction.

#### Element Values

Once the number of elements,  $k$ , is determined, the next step is to find the network configuration corresponding to  $k$ . Filter tables sometimes have sets of curves that enable the user to select the desired frequency response curve rather than use a formula. Once the curve with the fewest

Fig. 76 — Schematic diagram of a Butterworth low-pass filter. (See Table 10 for element values).

number of elements for the specified pass-band and stop-band insertion loss is found, the filter is then fabricated around the corresponding value of  $k$ . Table 10 gives normalized element values for values of  $k$  from 1 to 10. This table is for 1-ohm source and load resistances (reactance equal zero) and a 3.01-dB cutoff frequency of 1 radian/second (0.1592 Hz). There are two possible circuit configurations, and these are shown in Fig. 76. Here, a five-element filter is given as an example with either a shunt element next to the load (Fig. 76A) or a series element next to the load (Fig. 76B). Either filter will have the same response.

After the values for the 1-ohm, 1-radian/second prototype filter are found, the corresponding values for the actual frequency/impedance level can be determined (see the section on frequency and impedance scaling). The prototype inductance and capacitance values are multiplied by the ratio  $(0.1592/f_c)$  where  $f_c$  is the actual 3.01-dB cutoff frequency. Next, this number is multiplied by the load resistance in the case of an inductor and divided by the load resistance if the element is a capacitance. For instance, the filter in the preceding example is for a three-element

design ( $k$  equal to 3), and the reader might verify the values for the components for an  $f_c$  of 6 MHz and load resistance of 52 ohms.

The formulas for change of impedance and frequency from the 1-ohm, 1-radian/second prototype to some desired level can also be conveniently written as

$$L = \frac{R}{2\pi f_c} L_{\text{prototype}}$$

$$C = \frac{1}{2\pi f_c R} C_{\text{prototype}}$$

where

$R$  = the load resistance in ohms

$f_c$  = the desired 3.01-dB frequency in Hz

Then  $L$  and  $C$  give the actual circuit-element values in henrys and farads in terms of the prototype element values from Table 10.

#### High-Pass Butterworth Filters

The usefulness of the low-pass prototype does not end here. If the following set of equations is applied to the prototype values, circuit elements for a high-pass filter can be obtained. The filters are shown

Fig. 77 — Network configuration of a Butterworth high-pass filter. The low-pass prototype can be transformed as described in the text.

in Fig. 77A and B, which correspond to Fig. 76A and B in Table 10. The equations for the actual high-pass circuit values in terms of the low-pass prototype are given by

$$C = \frac{1}{R2\pi f_c C_{\text{prot.}}}$$

$$L = \frac{R}{2\pi f_c L_{\text{prot.}}}$$

and the frequency response curve can be obtained from

$$A = 10 \log \left[ 1 + \left( \frac{f_c}{f} \right)^{2k} \right]$$

For instance, a high-pass filter with three elements, a 3.01-dB  $f_c$  of 6 MHz and a load resistance of 52 ohms, has a C1 and C3 of 510 pF and an L2 of 0.6897  $\mu$ H. The insertion loss at 3.5 and 7 MHz would be 14.21 and 1.45 dB, respectively.

### Butterworth Band-Pass Filters

Band-pass filters can also be designed through the use of Table 10. Unfortunately the process is not as straightforward as it is for low- and high-pass filters if a practical design is to be obtained. In essence, a low-pass filter is resonated to some center frequency with the 3.01-dB cutoff frequency being replaced by the filter bandwidth. The ratio of the bandwidth to center frequency must be relatively large; otherwise component values tend to become unmanageable.

While there are many variations of specifying such filters, a most useful approach is to determine an upper and lower frequency for a given attenuation. The center frequency and bandwidth are then given by

$$f_o = \sqrt{f_1 f_2}$$

$$BW = f_2 - f_1$$

Fig. 78 — A Butterworth band-pass filter. Capacitance values are in picofarads.

If the bandwidth specified is not the 3.01-dB bandwidth ( $BW_c$ ) this bandwidth can be determined from

$$BW_c = \frac{BW}{(10^{0.1A} - 1)^{\frac{1}{2k}}}$$

in the case of a Butterworth response or from tables of curves. A is the required attenuation at the cutoff frequencies. The upper and lower cutoff frequencies ( $f_{cu}$  and  $f_{cl}$ ) are then given by

$$f_{cl} = \frac{-BW_c + \sqrt{(BW_c)^2 + 4f_o^2}}{2}$$

and

$$f_{cu} = f_{cl} + BW_c$$

A somewhat more convenient method is to pick a 3.01-dB bandwidth (the wider the better) around some center frequency and compute the attenuation at other frequencies of interest by using the transformation:

$$\frac{f}{f_c} = \left| \left( \frac{f}{f_o} - \frac{f_o}{f} \right) \frac{f_o}{BW_c} \right|$$

which can be substituted into the insertion-loss formula or table of curves.

As an example, suppose you want to build a band-pass filter for the 15-meter Novice band in order to eliminate the possibility of radiation on the 14- and 28-MHz bands. For a starting choice, 16 and 25 MHz will be selected as the 3.01-dB points, giving a 3-dB bandwidth of 9 MHz. For these two points,  $f_o$  will be 20 MHz. It is common practice to equate the number of branch elements or filter resonators to certain mathematical entities called poles, and the number of poles is just the value of k for purposes of discussion here. For a three-pole filter (k of 3) the insertion loss will be 12.79 and 11.3 dB at 14 and 28 MHz, respectively.

C1, C3 and L2 are then calculated for a 9-MHz low-pass filter and the elements for this filter are resonated to 20 MHz as shown in Fig. 78A. The response shape is plotted in Fig. 78B, and it appears to be unsymmetrical about  $f_o$ . In spite of this fact, such filters are called symmetrical band-pass filters and  $f_o$  is the center frequency. If the response is plotted with a

logarithmic frequency scale, the symmetry will become apparent. Consequently, using a logarithmic plot is helpful in designing filters of this type.

Examination of the component values reveals that while the filter is practical, it is a bit untidy from a construction standpoint. Rather than using a single 340.1-pF capacitor, paralleling a number of smaller value units would be advisable. Encountering difficulty of this sort is typical of most filter designs; consequently, some tradeoffs among performance, complexity and ease of construction are usually required.

### Additional Modern Filters

Butterworth filters are used where a flat passband response, well-behaved phase shift characteristics and exact impedance matching are important. They are subject to two limitations, however. For a given number of elements, the rate of attenuation (roll-off) in the transition band is not as great as can be obtained with some other designs of the same complexity. In addition, the ratio of capacitances is fixed at a number that may not result in standard component values. The values can be synthesized by connecting several capacitors in parallel, but this practice may set up parasitic resonances that greatly distort the band-pass and band-stop characteristics.

In applications requiring sharper cutoff or where some response ripple and pass-band impedance mismatch can be tolerated, a Chebyshev design should be considered. A variety of capacitance ratios is possible, depending on the allowable ripple. Many of these ratios result in standard-value capacitors, which greatly simplifies and economizes the circuit.

Another type of modern filter, the elliptic filter, is used in situations requiring extremely sharp cutoff with one or more infinitely deep notches in the stopband. Like the Chebyshev filter, the design parameters can be manipulated to produce circuits having at least some standard-value capacitors.

### PASSIVE LC FILTER DESIGN

The following text by Ed Wetherhold, W3NQN, is adapted from a paper entitled "Simplified Passive LC Filter Design for the EMC Engineer." That work first

appeared in the record of the 1985 IEEE International Symposium on Electromagnetic Compatibility, held August 20-22, 1985, in Wakefield, MA, pp. 575-584. © 1985 IEEE.

The filter design procedure presented here uses eight computer-calculated tables of performance parameters and component values for 5- and 7-branch Chebyshev and 5-branch elliptic 50-ohm filters. The tables permit the quick and easy selection of an equally-terminated passive LC filter for applications where the attenuation response is of primary interest. All of the capacitors in the Chebyshev designs and the three non-resonating capacitors in the elliptic designs have standard, off-the-shelf values to simplify construction. Although the tables cover only the 1- to 10-MHz frequency range, a simple scaling procedure gives standard-value capacitor (SVC) designs for any impedance level and virtually any cutoff frequency.

## Introduction

The radio amateur frequently needs an equally-terminated inductor-capacitor (LC) filter for nonstringent applications such as harmonic attenuation or wideband preamplifier preselection where the amplitude response of sinusoidal signals is of primary concern. Suitable designs are usually obtained by scaling normalized low-pass designs for the desired frequency and impedance. These designs are published in several well-known references by Geffe, White and others.<sup>1,2,3,4,5</sup> The normalized tables in the first two references are based on specific levels of maximum passband ripple attenuation, while tables in the last three references are based on regular increments of reflection coefficient. Although the scaling and transformation procedures used with the normalized low-pass tables are relatively straightforward, the transformation and scaling calculations provide undesired opportunities for error. The calculated capacitor values will invariably be nonstandard, thus complicating the construction.

For most nonstringent filtering applications, it is not necessary that the actual cutoff frequency exactly match the desired cutoff frequency, and a deviation of 5% or so between the actual and desired cutoff frequencies is acceptable. In this case, it is feasible and more convenient to use design tables based on standard capacitor values instead of passband ripple attenuation or reflection coefficient.

## Standard Values Used in Filter Design Calculations

Capacitors are commercially available in special series of preferred values having designations of E12 (10% tolerance) and E24 (5% tolerance).<sup>6</sup> The reciprocal of the E-number is the power to which 10 is raised to give the step multiplier for that particular series. By calculating normalized Chebyshev and elliptic component values based on many ratios of standard capacitor

values, and by using a 50-ohm impedance level, the parameters of a large number of designs can be calculated and tabulated to span the 1-10 MHz decade. Because of the large number of standard-value capacitor (SVC) designs in this decade, the increment in cutoff frequency from one design to the next is sufficiently small so that virtually any cutoff frequency requirement can be satisfied. Using such a table, the selection of an appropriate design consists of merely scanning the cutoff frequency column to find a design having a cutoff frequency that most closely matches the desired cutoff frequency.

## Chebyshev and Elliptic SVC Design Tables

Low-pass and high-pass 5- and 7-element Chebyshev and 5-branch elliptic designs were selected for tabulation because they are easy to construct and will satisfy the majority of nonstringent filtering requirements where the amplitude response is of primary interest. The precalculated 50-ohm designs are presented in eight tables of five low-pass types (Tables 11-15) and three high-pass types (Tables 16-18) with cutoff frequencies covering the 1-10 MHz decade. The applicable filter configuration and attenuation response curve accompany each table. In addition to the component values, attenuation versus frequency data and SWR are also included in the table. The passband attenuation ripples are so low in amplitude that they are swamped by the filter losses and are not measurable. For this reason, they are not shown in the response curves.

## Low-pass Tables

Tables 11 and 12 are for the low-pass 5- and 7-element Chebyshev capacitor input/output configuration. This configuration is generally preferred to the alternate inductor input/output configuration to minimize the number of inductors, and where a decreasing input impedance with increasing frequency in the stopband presents no problems. Tables 13 and 14 are also for low-pass applications, but with an inductor input/output configuration. This configuration is useful when the filter input impedance in the stopband must rise with increasing frequency. For example, some RF transistor amplifiers may become unstable when terminated in a low-pass filter having a stopband response with a decreasing input impedance. In this case, the inductor-input configuration may eliminate the instability.<sup>7</sup> Because only one capacitor value is required in the designs of Table 13, it was feasible to have the inductor value of L1 and L5 also be a standard value. Table 15 is for the low-pass 5-branch elliptic filter with the capacitor input/output configuration in which the nonresonating capacitors (C1, C3 and C5) are standard values. The alternate inductor input/output elliptic configuration is seldom used, and therefore it is not included.

## High-pass Tables

Tables 16, 17 and 18 are for the high-pass 5- and 7-element Chebyshev and the 5-branch elliptic capacitor input/output configurations, respectively. Because the inductor input/output configuration is seldom used, it was not included. As with the low-pass elliptic filter, only capacitors C1, C3 and C5 in the high-pass elliptic filter have standard values.

## Scaling the Tables to Other Frequencies and Impedances

The tables shown are for the 1-10 MHz decade and for a 50-ohm equally terminated impedance. The designs are easily scaled to other frequency decades and to other equally terminated impedance levels, however, making the tables a universal design aid for these specific filter types.

## Frequency Scaling

To scale the frequency and the component values to the 10-100 or 100-1000 MHz decades, multiply all tabulated frequencies by 10 or 100, respectively, and divide all C and L values by the same number. The  $A_s$  and SWR data remain unchanged. To scale the filter tables to the 1-10 kHz, 10-100 kHz or the 0.1-1 MHz decades, divide the tabulated frequencies by 1000, 100 or 10, respectively, and multiply the component values by the same number. By changing the "MHz" frequency headings to "kHz" and the "pF" and "μH" headings to "nF" and "mH," the tables are easily changed from the 1-10 MHz decade to the 1-10 kHz decade, and the table values may be read directly. Because the impedance level is still at 50 ohms, the component values may be awkward, but this can be corrected by increasing the impedance level by ten times using the impedance scaling procedure described below.

## Impedance Scaling

All the tabulated designs are easily scaled to impedance levels other than 50 ohms while keeping the convenience of standard-value capacitors and the "scan mode" of design selection. If the desired new impedance level differs from 50 ohms by a factor of 0.1, 10 or 100, the 50-ohm designs are scaled by inspection by shifting the decimal points of the component values. The other data remain unchanged. For example, if the impedance level is increased by ten or one hundred times (to 500 or 5000 ohms), the decimal point of the capacitor is shifted to the left one or two places and the decimal point of the inductor is shifted to the right one or two places. With increasing impedance the capacitor values become smaller and the inductor values become larger. The opposite is true if the impedance decreases.

When the desired impedance level differs from the standard 50-ohm value by a factor such as 1.2, 1.5 or 1.86, the following scaling procedure is used:

1. Calculate the impedance scaling ratio:  $R = Z_x/50$ , where  $Z_x$  is the desired new impedance level in ohms.

2. Calculate the cutoff frequency ( $F_{50\text{co}}$ ) of a "trial" 50-ohm filter, where  $F_{50\text{co}} = R \times F_{x\text{co}}$ .  $R$  is the impedance scaling ratio and  $F_{x\text{co}}$  is the desired cutoff frequency of the filter at the new impedance level.

3. From the appropriate SVC table select a design having its cutoff frequency closest to the calculated  $F_{50\text{co}}$  value. The tabulated capacitor values of this design are taken directly, but the frequency and inductor values must be scaled to the new impedance level.

4. Calculate the exact  $F_{x\text{co}}$  values, where

$$F_{x\text{co}} = \frac{F'_{50\text{co}}}{R}$$

and  $F'_{50\text{co}}$  is the tabulated cutoff frequency of the selected design. Calculate the other frequencies of the design in the same way.

5. Calculate the inductor values for the new filter by multiplying the tabulated inductor values of the selected design by the square of the scaling ratio,  $R$ .

For example, assume a 600-ohm elliptic low-pass filter is desired with a cutoff frequency of 1.0 kHz. The elliptic low-pass table is frequency scaled to the 1-10 kHz decade by changing the table headings to kHz, nF and mH. A suitable design is then selected for scaling to 60 ohms. The 60-ohm design is then scaled to 600 ohms by shifting the decimal point to complete the scaling procedure. The calculations for this example follow, using the five steps outlined above:

$$1. R = Z_x / 50 = 60/50 = 1.2$$

$$2. F_{50\text{co}} = 1.2 \times 1.0 \text{ kHz} = 1.2 \text{ kHz}$$

3. From the elliptic low-pass table (Table 15), designs 5 and 10 have cutoff frequencies closest to the  $F_{50\text{co}}$  of 1.2 kHz, and either design is suitable. Design 5 is selected because of its better selectivity. The tabulated capacitor values of 2200 nF, 3900 nF, 1800 nF, 271 nF and 779 nF are copied directly.

4. All frequencies of the final design are calculated by dividing the tabulated frequencies (in kHz) of design 5 by the impedance scaling ratio of 1.2:

$$F_{\text{co}} = 1.27/1.2 = 1.06$$

$$F_{3 \text{ dB}} = 1.45/1.2 = 1.21$$

$$F_{\text{As}} = 2.17/1.2 = 1.88$$

Note that a cutoff frequency of 1.0 kHz was desired, but a 1.06 kHz cutoff frequency will be accepted in exchange for the convenience of using an SVC design.

5. The L2 and L4 inductor values of design 5 are scaled to 60 ohms by multiplying them by the square of the impedance ratio where  $R = 1.2$  and  $R^2 = 1.44$ :

$$L2 = 1.44 \times 7.85 \text{ mH} = 11.3 \text{ mH}$$

$$L4 = 1.44 \times 6.39 \text{ mH} = 9.20 \text{ mH}$$

The 60-ohm design is now impedance scaled to 600 ohms by shifting the decimal

points of the capacitor values to the left and the decimal points of the inductor values to the right. The final scaled component values for the 600-ohm filter are:

$$C1 = 0.22 \mu\text{F}$$

$$C4 = 77.9 \text{ nF}$$

$$C3 = 0.39 \mu\text{F}$$

$$L2 = 113 \text{ mH}$$

$$C5 = 0.18 \mu\text{F}$$

$$L4 = 92.0 \text{ mH}$$

$$C2 = 27.1 \text{ nF}$$

### How to Use the Filter Tables

**50-ohm impedance level:** Before selecting a filter design, the important parameters of the filter must be known, such as type (low-pass or high-pass), cutoff frequency, impedance level, preferred input element (for low-pass only), and an approximation of the required stopband attenuation. It is obvious which tables to use for low-pass or high-pass applications, but it is not so obvious which one design of the many possible choices is optimum for the intended application. Generally, the Chebyshev will be preferred over the elliptic because the Chebyshev does not require tuning of the inductors; if the relatively gradual attenuation rise of the Chebyshev is not satisfactory, however, then the elliptic should be considered. For audio filtering, the elliptic designs with high values of SWR are preferred because these designs have a much more abrupt attenuation rise than the Chebyshev. For RF applications, SWR values less than 1.2 are recommended to minimize undesired reflections. Low SWR is also important when cascading high-pass and low-pass filters to achieve a band-pass response more than two octaves wide. Each filter will operate as expected if it is correctly terminated, but this will occur only if both designs have the relatively constant terminal impedance that is associated with low SWR.

Knowing the filter type and the response needed, select the table of designs most appropriate for the application on a trial basis. From the chosen table, scale the 1-10 MHz data to the desired frequency decade, and search the cutoff frequency column for a value nearest the desired cutoff frequency. After finding a possible design, check the stopband attenuation levels to see if they are satisfactory. Then check the SWR to see if it is appropriate for the application. Finally, check the component values to see if they are convenient. For example, in the audio-frequency range, the capacitor values probably will be in the microfarad range, and capacitors in this size are available only in the E12 series of standard values. Then connect them in accordance with the diagram shown in the table from which the design was selected.

**Impedance levels other than 50 ohms:** First calculate a "trial" filter design using the impedance scaling procedure previously explained. Then search the appropriate table for the best match to the trial filter and scale the selected design to the desired impedance level. In this way, the convenient scan mode of filter selection is used regardless of the desired impedance level.

(A)

(B)

The schematic for a 5-element capacitor input/output Chebyshev low-pass filter is shown at A. At B is the typical attenuation response curve.

Table 12

**7-Element Chebyshev Low-pass Filter Designs**  
**50-ohm Impedance, C-In/Out**  
**For Standard E24 Capacitor Values**

Filter

(A)

(B)

The schematic for a 5-element capacitor input/output Chebyshev high-pass filter, is shown at A. At B is the typical attenuation response curve.

Table 17

**7-Element Chebyshev High-pass Filter Designs**  
**50-ohm Impedance, C-In/Out**  
**For Standard E24 Capacitor Values**

Filter No.	Frequency (MHz)				Max. SWR	C1,7 (pF)	L2,6 (μH)	C3,5 (pF)	L4 (μH)

## COUPLED RESONATORS

Coupled resonators are frequently encountered in RF circuits. Applications include simple filters, oscillator tuned circuits and even antennas. The circuit shown in Fig. 79A illustrates the basic principles involved. A series RLC circuit and the external terminals ab are coupled through a common capacitance,  $C_m$ . Applying the formulas for conductance and susceptance in terms of series reactance and resistance gives

$$G_{ab} = \frac{R_r}{R_r^2 + X^2}$$

$$B_{ab} = B_{cm} - \frac{X}{R_r^2 + X^2}$$

The significance of these equations can be understood with the aid of Fig. 79B. At some point, the series inductive reactance will cancel the series capacitive reactance (at a point slightly below  $f_0$  where the conductance curve reaches a peak). Depending on the value of the coupling susceptance,

Fig. 79 — A capacitively coupled resonator is shown at A. See text for explanation of figure shown at B.

$B_{cm}$ , it is possible that a point can be found where the total input susceptance is zero. The input conductance at this frequency,  $f_0$  is then  $G_0$ .

Since  $G_0$  is less than the conductance at the peak of the curve,  $1/G_0$  or  $R_0$  is going to be greater than  $R_r$ . This effect can be applied when it is desired to match a low-value load resistance (such as found in a mobile whip antenna) to a more practical value. Suppose  $R_r$  and  $C_r$  in Fig. 79A are 10 ohms and 21 pF, respectively, and represent the equivalent circuit of a mobile antenna. Find the value of  $L_r$  and  $C_m$  that will match this antenna to a 52-ohm feed line at a frequency of 3900 kHz. Substituting the above values into the formulas for input conductance gives

$$\frac{1}{52} = \frac{10}{10^2 + X^2}$$

Solving for X (the total series reactance) gives a value of the square root of 420 or 20.49 ohms. The reactance of a 21-pF capacitor at 3900 kHz is 1943.3 ohms so the inductive reactance must be  $20.49 + 1943.3 = 1963.8$  ohms. While either a positive or negative reactance will satisfy the equation for  $G_{ab}$  a positive value is required to tune out  $B_{cm}$ . If the coupling element was a shunt inductor, the total reactance would have to be capacitive or negative in value. Thus, the required inductance value for  $L_r$  will be  $80.1 \mu\text{H}$ . In order to obtain a perfect match, the input susceptance must be zero. The value of  $B_{cm}$  can be found from

$$0 = B_{cm} - \frac{20.49}{10^2 + 20.49^2}$$

giving a susceptance value of 0.03941 siemens, which corresponds to a capacitance of 1608 pF.

## Coefficient of Coupling

If the solution to the mobile whip antenna problem is examined, it can be seen that for given values of frequency,  $R_r$ ,  $L_r$ , and  $C_r$  only one value of  $C_m$  results in an input load that appears as a pure resistance. While such a condition might be defined as resonance, the resistance value obtained is not necessarily the one required for maximum transfer of power.

A definition that is helpful in determining how to vary the circuit elements in order to obtain the desired input resistance is called the coefficient of coupling. The coefficient of coupling is defined as the ratio of the common or mutual reactance to the square root of the product of two specially defined reactances. If the mutual reactance is capacitive, one of the special reactances is the sum of the series capacitive reactances of the primary mesh (with the resonator disconnected) and the other one is the sum of the series capacitive reactances of the resonator (with the primary disconnected). Applying this definition to the circuit of Fig. 79A, the coefficient of coupling, k, is given by

$$k = \sqrt{\frac{C_r}{C_r + C_m}}$$

How meaningful the coefficient of coupling will be depends on the particular circuit configuration under consideration and on which elements are being varied. For example, suppose the value of  $L_r$  in the mobile-whip antenna problem was fixed at  $100 \mu\text{H}$ , and suppose  $C_m$  and  $C_r$  were allowed to vary. (Recall that  $C_r$  is 21 pF and represents the antenna capacitance. However, the total resonator capacitance could be changed by adding a series capacitor between  $C_m$  and the antenna. Thus,  $C_r$  could be varied from 21 pF to some lower value but not a higher one.)

A calculated plot of k versus input resistance,  $R_{in}$  is shown in Fig. 80. Notice the rapid change in k for resistance values between 10 ohms and slightly higher resistances.

Fig. 80 — Variation of k with Input resistance for the circuit of Fig. 79.

Similar networks can be designed to work with any ratio of input resistance and load resistance, but it is evident that small ratios are going to pose difficulties. For larger ratios, component tolerances are less critical. For instance,  $C_m$  might consist of switchable fixed capacitors with  $C_r$  being variable. With the given load resistance,  $C_m$  essentially sets the value of the reactance and thus the input resistance, while  $C_r$  and  $L_r$  provide the required reactance for the conductance formula. However, if  $L_r$  is varied,  $k$  varies also. Generally speaking, higher values of  $L_r$  (and consequently circuit  $Q$ ) require lower values of  $k$ .

At this point, the question arises as to the significance and even the merit of such definitions as coefficient of coupling and  $Q$ . If the circuit element values are known, and if the configuration can be resolved into a ladder network, important properties such as input impedance and attenuation can be computed directly for any frequency. On the other hand, circuit information might be obscured or even lost by attempting to attach too much importance to an arbitrary definition. For example, the plot in Fig. 80 merely indicates that  $C_m$  and  $C_r$  are changing with respect to each other. But it doesn't illustrate how they are changing. Such information is important in practical applications, and even a simple table of  $C_m$  and  $C_r$  vs.  $R_{in}$  for a particular  $R_r$  would be much more valuable than a plot of  $k$ .

Similar precautions must be taken with the interpretation of circuit  $Q$ . Selectivity and  $Q$  are simply related for single resonators and circuit components, but the situation rapidly changes with complex configurations. For instance, adding loss or resistance to circuit elements would seem to contradict the idea that low-loss or high- $Q$  circuits provide the best selectivity. However, this is actually done in some filter designs to improve frequency response. In fact, the filter with the added loss has identical characteristics to one with pure elements. The method is called predistortion and is very useful in designing filters where practical considerations require the use of circuit elements with parasitic or undesired resistance.

As the frequency of operation is increased, discrete components must become physically smaller. Eventually a point is reached where other forms of networks have to be used. Here, entities such as  $k$  and  $Q$  are sometimes the only means of describing such networks. Another definition of  $Q$  that is quite useful in this instance is that it is equal to the ratio of  $2\pi$  (energy stored per RF cycle)/(energy lost per RF cycle).

### Mutually Coupled Inductors

A number of very useful RF networks involve coupled inductors. In a previous section, there was some discussion on iron-core transformers which represent a special case of coupled inductance. The formulas

Fig. 81 — Two types of magnetically coupled circuits. At A, only mutual magnetic coupling exists while the circuit at C contains a common inductance also. Equivalents of both circuits at B and D permit the application of the ladder-network analysis discussed in this section. (If the sign of voltage is unimportant,  $T_1$  can be eliminated.)

presented apply to instances where the coefficient of coupling is very close to 1.0. While it is possible to approach this condition at frequencies in the RF range, many practical circuits work at values of  $k$  that are considerably less than 1.0. A general solution is rather complex, but many practical applications can often be simplified and solved through use of the ladder-network method. In particular, the sign of the mutual inductance must be taken into account if there are a number of coupled circuits or if the phase of the voltage between two coupled circuits is important.

The phase consideration is illustrated in Fig. 81. An exact circuit for the two mutually coupled coils at A is shown at B.  $T_1$  is an ideal transformer that provides the isolation between terminals  $ab$  and  $cd$ . If the polarity of the voltages between these terminals can be neglected, the transformer can be eliminated and just the circuit before the terminals  $cd$  substituted. A second circuit is shown in Fig. 81C and D. Here, it is assumed that the winding sense doesn't change between  $L_1$  and  $L_2$ . If so, then the circuit of Fig. 81D can be substituted for the tapped coil shown in Fig. 81C.

Coefficients of coupling for the circuits in Fig. 81 are given by

$$k = \frac{M}{\sqrt{L_1 L_2}}$$

and

$$k = \frac{L_1 + M}{\sqrt{L_1 (L_1 + L_2 + 2M)}}$$

If  $L_1$  and  $L_2$  do not have the same value, an interesting phenomenon takes place as the coupling is increased. A point is reached where the mutual inductance exceeds the inductance of the smaller coil. The interpretation of this effect is illustrated in Fig. 82. While all the flux lines (as indicated

Fig. 82 — Diagram illustrating how  $M$  can be larger than one of the self inductances. This represents the transition from lightly coupled circuits to conventional transformers, since an impedance step-up is possible without the addition of capacitive elements.

by the dashed lines) associated with  $L_1$  also encircle turns of  $L_2$ , there are additional ones that encircle extra turns of  $L_2$ , also. Thus, there are more flux lines for  $M$  than there are for  $L_1$ . Consequently,  $M$  becomes larger than  $L_1$ . Normally, this condition is difficult to obtain with air-wound coils, but the addition of ferrite material greatly increases the coupling. As  $k$  increases so that  $M$  is larger than  $L_1$  (Fig. 82), the network begins to behave more like a transformer. For a  $k$  of 1, the equivalent circuit of Fig. 81B yields the transformer equations of a previous section. On the other hand, for small values of  $k$ , the network becomes merely three coils arranged in a T fashion. One advantage of the circuit of Fig. 81A is that there is no direct connection between the two coils. This property is important from an isolation standpoint and can be used to suppress unwanted currents that are often responsible for RFI difficulties.

## Piezoelectric Crystals

A somewhat different form of resonator consists of a quartz crystal between two conducting plates. If a voltage is applied to the plates, the resultant electric field causes a mechanical stress in the crystal. Depending on the size and cut of the crystal, the crystal begins to vibrate at a certain frequency. The effect of this mechanical vibration is to simulate a series RLC circuit as in Fig. 79A. A capacitance associated with the crystal plates which appears across the terminals ( $C_m$  in Fig. 79A). Consequently, this circuit can also be analyzed with the aid of Fig. 79B. At some frequency ( $f_1$  in Fig. 83), the series reactance is zero and  $G_{ab}$  in the preceding formula will simply be  $1/R_r$ . Typical values for  $R_r$  range from 10 k $\Omega$  and higher. However, the equivalent inductance of the mechanical circuit is normally extremely high (over 10,000 henrys in the case of some low-frequency units), which results in a very high circuit Q (30,000).

Above  $f_1$  the reactance is inductive, and

Fig. 83 — Frequency response of a quartz crystal resonator. The minimum value is only approximate since holder capacitance is neglected.

at  $f_2$  the susceptance of the series resonator is just equal to the susceptance of the crystal holder,  $B_{cm}$ . Here the total susceptance is zero. Since  $B_{cm}$  is usually very small, the equivalent series susceptance is also small. This means the value for X in the susceptance formula will be very large, and consequently  $G_{ab}$  will be small. This corresponds to a high input resistance. A plot of the magnitude of the impedance is shown in Fig. 83. The dip at  $f_1$  is called the series-resonant mode and the peak at  $f_2$  is referred to as the parallel-resonant or anti-resonant mode.

When specifying crystals for oscillator applications, the type of mode must be given along with the external capacitance across the holder or type oscillator circuit to be used. Otherwise, considerable difference in actual oscillator frequency will be observed. The effect can be used to advantage, however. The frequency of a crystal oscillator can be pulled with an external reactive element, or even frequency modulated with a device that converts voltage or current fluctuations into changes in reactance.

## Matching Networks

In addition to filters, ladder networks are frequently used to match one impedance value to another one. While there are many circuits, a few of them offer such advantages as simplicity of design formulas or minimum number of elements. Some of the more popular ones are shown in Fig. 84. Shown at Fig. 84A and 84B, are two variations of an L network. These networks are relatively simple to design. The situation is somewhat more complicated for the circuits shown at Fig. 84C and 84D. For a given value of input and output resistance, there are many networks that satisfy the conditions for a perfect match. The difficulty

can be resolved by introducing the dummy variable labeled N.

From a practical standpoint, N should be selected in order to optimize circuit component values. Either values of N that are too low or too high result in networks that are hard to construct.

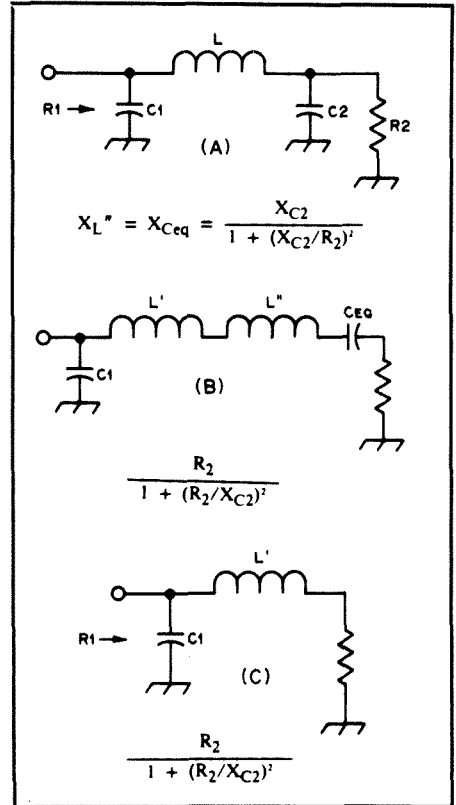

Fig. 85 — Illustration of the manner in which the network of Fig. 84C can be reduced to the one of Fig. 84A, assuming  $C_2$  is assigned some arbitrary value. (The formulas shown are for numerical reactance values.)

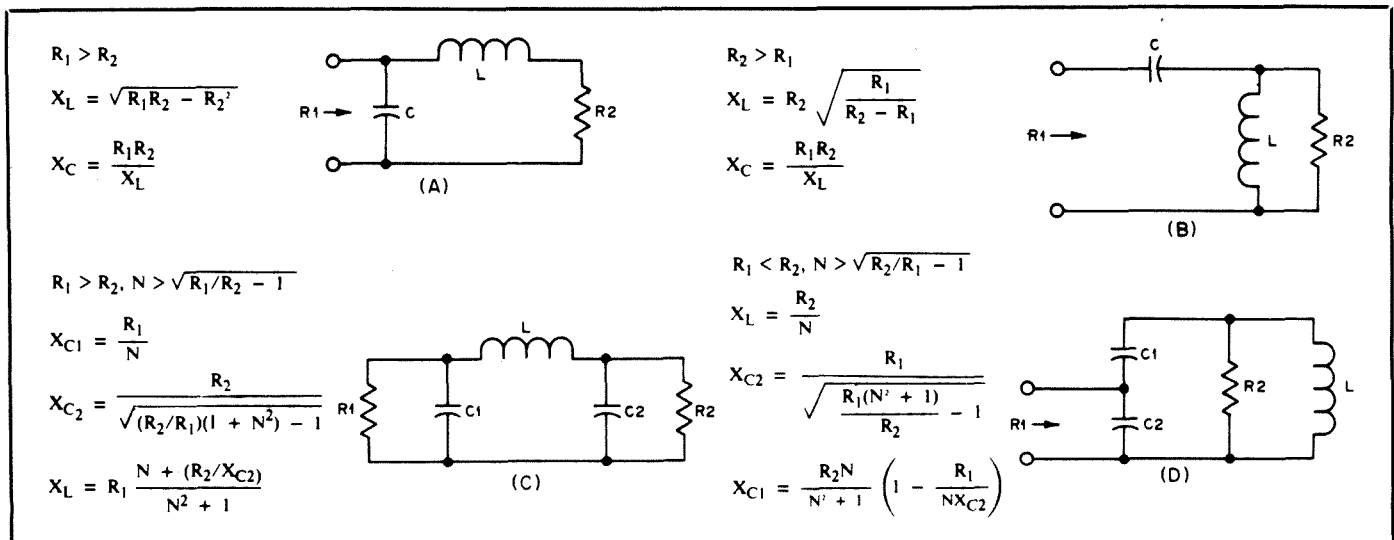

Fig. 84 — Four matching networks that can be used to couple a source and load with different resistance values. (Although networks are drawn with  $R_1$  appearing as the source resistance, all can be applied with  $R_2$  at the source end. Also, all formulas with capacitive reactance are for the numerical or absolute value.)

The reason for this complication is as follows. Only two reactive elements are required to match any two resistances. Consequently, adding a third element introduces a redundancy. This means one element can be assigned a value arbitrarily and the other two components can then be found. For instance, suppose  $C_2$  in Fig. 84C is set to some particular value. The parallel combination of  $C_2$  and  $R_2$  may then be transformed to a series equivalent (see Fig. 85). Then,  $L$  may be found by breaking it down into two components,  $L'$  and  $L''$ . One component ( $L''$ ) would tune out the remaining capacitive reactance of the output series equivalent circuit. The network is then reduced to the one shown in Fig. 84A and the other component of  $L$  ( $L'$ ) along with the value of  $C_1$ , could be determined from formulas (Fig. 84A). Adding the two inductive components gives the actual inductive reactance required for a match in the circuit of Fig. 84C.

As mentioned before, it is evident that an infinite number of networks of the form shown in Fig. 84C exist since  $C_2$  can be assigned any value. Either a set of tables or a family of curves for  $C_1$  and  $L$  in terms of  $C_2$  could then be determined from the method discussed earlier and illustrated in Fig. 87. However, similar data along with other information can be obtained by approaching the problem somewhat differently. Instead of setting one of the element values arbitrarily and finding the other two, a third variable is contrived, and in the case of Figs. 84C and 84D is labeled  $N$ . All three reactances are then expressed in terms of the variable  $N$ .

The manner in which the reactances change with variation in  $N$  for two representative circuits of the type shown in Fig. 84C is shown in Fig. 86. The solid curves are for an  $R_1$  of 3000 ohms and  $R_2$  equal to 52 ohms. The dashed curves are for the same  $R_2$  (52 ohms) but with  $R_1$

Fig. 86 — Network reactance variation as a function of dummy variable  $N$ . Solid curves and values of  $N$  from 8 to 11 are for an input resistance of 3000 ohms and an output resistance of 52 ohms. The dashed curves are for a similar network with an input and output resistance of 75 and 52 ohms, respectively. Values of  $N$  from 1 to 4 are for the dashed curves.

equal to 75 ohms. For values of  $N$  very close to the minimum specified by the inequality (Fig. 84C),  $X_{C2}$  becomes infinite, which means  $C_2$  approaches zero. As might be expected, the values of  $X_L$  and  $X_{C1}$  at this point are approximately those of an  $L$  network (Fig. 84A) and could be determined by means of the formulas in Fig. 84A for the corresponding values of  $R_1$  and  $R_2$ .

The plots shown in Fig. 86 give a general idea of the optimum range of component values. The region close to the left-hand portion should be avoided since there is little advantage to be gained over an  $L$  network, while an extra component is required. For very high values of  $N$ , the

Fig. 87 — Input resistance vs. output reactance for an output resistance of 52 ohms. The curve is for a fixed inductor of 219 ohms (Fig. 84C).  $X_C$  varies from 196 to 206 ohms.

capacitance values become large without producing any particular advantage either. A good design choice is an  $N$  a few percent above the minimum specified by the inequality.

Often, one of the elements is fixed, with either or both of the remaining two elements variable. In many amateur transmitters, it is the inductor that remains fixed (at least for a given band), while  $C_1$  and  $C_2$  (Fig. 84C) are made variable. While this system limits the bandwidth and matching capability somewhat, it is still a very useful approach. For instance, the plot shown in Fig. 87 indicates the range of input resistance values that can be matched for an  $R_2$  of 52 ohms. The graph is for an inductive reactance of 219 ohms.  $X_{C1}$  varies from 196 to 206 ohms over the entire range of  $R_1$  (or approximately 20 percent). However,  $X_{C2}$  varies from 15 to almost 100 ohms, as indicated in the graph.

Since  $C_2$  more or less sets the transformed resistance, it is often referred to as the loading control on transmitters using the network of Fig. 84C, with  $C_1$  usually labeled TUNE. While the meaning of the latter term should be clear, the idea of

loading in a matching application perhaps needs some explanation. For small values of  $X_{C2}$  (very large  $C_2$ ), the transformed resistance is very high. Consequently, a source that was designed for a much lower resistance would deliver relatively little power. However, as the resistance is lowered, increased amounts of current will flow, resulting in more power output. Then the source is said to be loaded more heavily.

Similar considerations such as those discussed for the network of Fig. 84C also exist for the circuit of Fig. 84D. Only the limiting  $L$  network for the latter is the one shown in Fig. 84B. The circuit of Fig. 84C is usually called a pi network and, as pointed out, it is used extensively in the output stage of transmitters. The circuit of Fig. 84D has never been given any special name, but is quite popular in both antenna and transistor matching applications.

The plots shown in Fig. 86 are for fixed input and output resistances with the reactances variable. Similar figures can be plotted for other combinations of fixed and variable elements. An interesting case is for  $X_L$  and  $R_1$  fixed with  $R_2$ ,  $X_{C1}$  and  $X_{C2}$  variable. A lower limit for  $N$  also exists for this plot, except that instead of an  $L$  network, the limiting circuit is a network of three equal reactances. A feature of this circuit is that the output resistance is the ratio of the square of the reactance and the input resistance.

An analogous situation exists with a quarter-wavelength transmission-line transformer. The output resistance is the ratio of the square of the characteristic impedance of the line and the input resistance. Consequently, the special case in which all the reactances are equal in the circuit of Fig. 84C is the lumped-constant analog of the quarter-wavelength transformer. It has identical phase shift ( $90^\circ$ ) along with the same impedance-transforming properties.

## Frequency Response

In many instances, a matching network performs a dual role in transforming a resistance value while providing frequency rejection. Usually the most important considerations are matching versatility, component values and the number of elements. But a matching network might also be able to provide sufficient selectivity for some application, thus eliminating the need for a separate circuit such as a filter.

Recall that  $Q$  and selectivity are closely related for simple RLC series and parallel circuits. Bandwidth and the parameter  $N$  of Fig. 84 are approximately related in this manner. For values of  $N$  much greater than the minimum specified by the inequality,  $N$  and  $Q$  can be considered to mean the same thing for all practical purposes. However, the frequency response of networks that are more complex than simple RLC types is usually more complicated. Consequently, some care is required in the

interpretation of  $N$  or  $Q$  in regard to frequency rejection. For instance, a simple circuit has a frequency response that results in increasing attenuation for increasing excursions from resonance.

That is not true for the pi network, as can be seen from Fig. 88. For slight frequency changes below resonance, the attenuation increases as in the case of a simple RLC network. At lower frequencies, the attenuation decreases and approaches 2.55 dB. This plot is for a resistance ratio of 5:1, and the low-frequency loss is caused only by the mismatch in source and load resistance. Thus, while increasing  $N$  improves the selectivity near resonance, it has little effect on response for frequencies much farther away.

A somewhat different situation exists for the circuit of Fig. 84D. At frequencies far from resonance, either a series capacitance provides decoupling at the lower frequen-

Fig. 88 — Frequency response of the network of Fig. 84C for two values of  $N$ .

cies or a shunt capacitance causes additional mismatch at the higher ones. This circuit, then, has a response resembling those of simple circuits unlike the pi network. Curves A and B of Fig. 89 are for

Fig. 89 — Frequency response of the circuit of Fig. 84D (see text).

a resistance ratio of 5:1, with  $N$  equal to 2.01 for curve A. Curve B is for an  $N$  of 10. Curves C and D are for a resistance ratio of 50:1, with  $N$  equal to 7.04 and 10, respectively.

# Radio Design Technique and Language

Many amateurs desire to construct their own radio equipment, and some knowledge of design procedures becomes important. Even when some commercially manufactured equipment is used, these techniques may still be required in setting up peripheral equipment. Also, an applicant for an Amateur Radio license might be tested on material in this area.

## "Pure" vs. "Impure" Components

In the chapter on electrical laws and circuits, it is assumed that the components in an electrical circuit consist solely of elements that can be reduced to a resistance, capacitance or inductance. However, such elements do not exist in nature. An inductor always has some resistance associated with its windings and a carbon-composition resistor becomes a complicated circuit as the frequency of operation is increased. Even conductor resistance must be taken into account if long runs of cable are required.

In many instances, the effects of these "parasitic" components can be neglected and the actual device can be approximated by a "pure" element such as a resistor, capacitor, inductor or a short circuit in the case of an interconnecting conductor. In other cases, the unwanted component must be taken into account. However, it may be possible to break the element down into a simple circuit consisting of single elements alone. Then the actual circuit may be analyzed by means of the basic laws discussed in the previous chapter. It may also be possible to make a selection so the effects of the residual element are negligible.

There are times when unwanted effects may not only be difficult to remove but will affect circuit operation adversely as well. In fact, such considerations often set a limit on how stringent a design criterion can be tolerated. For instance, it is a common practice to connect small-value capacitors in various parts of a complex circuit, such as a transmitter or receiver, for bypassing purposes. A bypass capacitor permits energy below some specified frequency to

Fig. 1 — Equivalent circuit of a capacitor.

pass a given point while providing rejection to energy at higher frequencies. In essence, the capacitor is used in a single form of filter. In more complicated filter designs, capacitors may be required for complex functions (such as matching) in addition to providing a low reactance to ground.

An equivalent circuit of a capacitor is shown in Fig. 1. Normally, the series resistance,  $R_s$ , can be neglected. On the other hand, the upper frequency limit of the capacitor is limited by the series inductance,  $L_s$ . In fact, above the point where  $L_s$  and  $C_p$  form a resonant circuit, the capacitor actually appears as an inductor at the external terminals. This is why it is common practice to use two capacitors in parallel for bypassing, as shown in Fig. 2. At first inspection, this might appear as superfluous duplication. But the self-resonant frequency of a capacitor is lower for high-capacitance units than it is for smaller value ones. Thus,  $C_1$  in Fig. 2 provides a low reactance for low frequencies such as those in the audio range while  $C_2$  acts as a bypass for frequencies above the self-resonant frequency of  $C_1$ .

## RF Leakage

Although the capacitor combination

shown in Fig. 2 provides a low-impedance path to ground, it may not be very effective in preventing RF energy that travels along the conductor at point 1 from reaching point 2. At dc and low-frequency applications, a circuit must always form a closed path for a current to flow. Consequently, two conductors are required if power is to be delivered from a source to a load. In many instances, one of the conductors may be common to several other circuits and constitutes a local ground.

As the frequency of operation is increased, however, a second type of coupling mechanism is possible. Power may be transmitted along a single conductor. (Although the same effect is possible at low frequencies, unless circuit dimensions are extremely large, such transmission effects can be neglected.) The conductor acts as

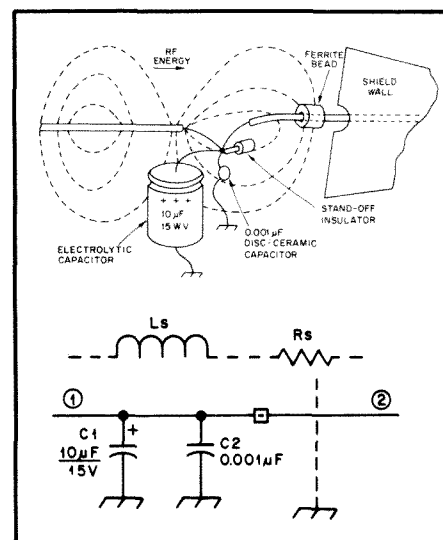

Fig. 2 — A bypassing arrangement that affords some measure of isolation (with the equivalent circuit shown.) Dashed lines indicate a mode of wave travel that permits RF energy to leak past the bypass circuit and that should be taken into account when more stringent suppression requirements are necessary. ( $L_s$  and  $R_s$  in the equivalent circuit represent the ferrite bead.)

a waveguide in much the same manner that a large conducting surface, such as the earth, will permit propagation of a radio wave close to its boundary with the air. A mode similar to ground-wave propagation that can travel along the boundary of a single conductor is illustrated by the dashed lines in Fig. 2. As with the wave traveling close to the earth, a poor conducting boundary will cause attenuation. This is why a ferrite bead is often inserted over the exit point of a conductor from an area where RF energy is to be contained or excluded. In addition to loss (particularly in the VHF range), the high permeability of the ferrite introduces a series-inductive reactance as well. Finally, the shield wall provides further isolation.

While the techniques shown in Fig. 2 get around some of the deficiencies of capacitors that are used for bypass purposes, the resulting suppression is inadequate for a number of applications. Examples would be protection of a VFO to surrounding RF energy, a low-frequency receiver with a digital display, and suppression of radiated harmonic energy from a transmitter. In each of these cases, a very high degree of isolation is required. For instance, a VFO is sensitive to voltages that appear on dc power supply lines and a transmitter output with a note that sounds "fuzzy" or rough may result.

Digital displays usually generate copious RF energy in the low-frequency spectrum. Consequently, a receiver designed for this range presents a situation where a strong source of emission is in close proximity to very sensitive receiving circuits. A similar case exists with transmitters operating on a frequency that is a submultiple of a fringe-area TV station. In the latter two instances, the problem is not so severe if the desired signal is strong enough to override the unwanted energy. Unfortunately, this is not the case normally and stringent measures are required to isolate the sensitive circuits from the strong source.

A different type of bypass-capacitor configuration is often used with associated shielding for such applications, as shown in Fig. 3. To reduce the series inductance of the capacitor, and to provide better isolation between points 1 and 2, either a disc type (Fig. 3A) or a coaxial configuration (Fig. 3B) is employed. The circuit diagram for either configuration is shown in the inset. While such "feedthrough" capacitors are always connected to ground through the shield, this connection is often omitted on drawings. Only a connection to ground is shown, as in Fig. 3C.

#### Dielectric Loss

Even though capacitors are usually high-Q devices, the effect of internal loss can be more severe than in the case of a coil. This is because good insulators of electricity are also usually good insulators of heat. Therefore, heat generated in a capacitor must be conducted to the outside via the

Fig. 3 — A superior type of bypassing arrangement to that shown in Fig. 2. Concentric conductors provide a low-inductance path to ground and better rejection of unwanted single-wire wave modes.

conducting plates to the capacitor leads. In addition, most capacitors are covered with an insulating coating that further impedes heat conduction. The problem is less severe with capacitors using air as a dielectric for two reasons. The first advantage of air over other dielectrics is that the loss in the presence of an alternating electric field is extremely small. Second, any heat generated by currents on the surface of the conducting plates is either drawn away by air currents or through the mass of the metal.

The dielectric loss in a capacitor can be represented by  $R_p$ , as shown in Fig. 1. However, if a dc ohmmeter were placed across the terminals of the capacitor, the reading would be infinite. This is because dielectric loss is an ac effect. Whenever an alternating electric field is applied to an insulator, there is a local motion of the electrons in the individual atoms that make up the material. Even though the electrons are not displaced as they would be in a con-

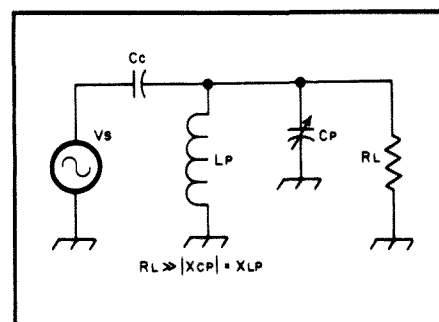

Fig. 4 — Consideration of capacitor voltage and current ratings should be kept in mind in moderate power applications.

Fig. 5 — Equivalent circuit of an inductor.

ductor, this local motion requires the expenditure of energy and results in a power loss.

Consequently, some care is required in the application of capacitors in moderate to high-power circuits. The applied voltage should be such that RF current ratings are not exceeded for the particular frequency of operation. This is illustrated in Fig. 4. A parallel-resonant circuit consisting of  $L_p$ ,  $C_p$  and  $R_L$  is connected to a voltage source,  $V_s$ , through a coupling capacitor,  $C_c$ . It is also assumed the  $R_L$  is much greater than either the inductive or capacitive reactance taken alone. This condition would be typical of that found in most RF power amplifier circuits using vacuum tubes.

Since the inductive and capacitive reactance of  $L_p$  and  $C_p$  cancel at resonance, the load presented to the source would be just  $R_L$ . This would mean the current through  $C_c$  would be much less than the current through either  $C_p$  or  $L_p$ . The effect of such current rise is similar to the voltage rise at resonance discussed in the previous chapter. Even though the current at the input of the parallel-resonant circuit is small, the currents that flow in the elements that make up the circuit can be quite large.

The requirements for  $C_c$ , then, would be rather easy to satisfy with regard to current rating and power dissipation. On the other hand,  $C_p$  would ordinarily be restricted to air-variable types, although

Fig. 6 — Distributed capacitance (indicated by dashed lines) affects the operation of a coil at high frequencies.

some experiments have been successful, using Teflon as a dielectric. Generally speaking, the coupling capacitor should have a low reactance (at the lowest frequency of operation) in comparison to the load presented by the tuned circuit. The effect of the coupling-capacitor reactance could then be compensated by slightly retuning the parallel-resonant circuit.

### Inductors

Similar considerations to those discussed in the previous sections exist with inductors also, as shown in Fig. 5. Since an inductor usually consists of a coil of wire, there will be a resistance associated with the wire material and this component is represented by  $R_s$ . In addition, there is always a capacitance associated with conductors in proximity as illustrated in Fig. 6. While such capacitance is distributed through the coil, it is a convenient approximation to consider that an equivalent capacitance,  $C_p$ , exists between the terminals (Fig. 5). Inductors are often wound on materials that have high permeability in order to increase the inductance. Thus, it is possible to build an inductor with fewer turns and that is smaller in size than an equivalent coil with an air core.

Unfortunately, high-permeability materials presently available have considerable loss in the presence of an RF field. It will be recalled that a similar condition existed with the dielectric in a capacitor. Consequently, in addition to the wire resistance, a loss resistance is associated with the core and represented by  $R_p$  in Fig. 5. Since this loss is more or less independent of the current through the coil but dependent on the applied voltage, it is represented by a parallel resistance.

### RF Transformer

Although the term "transformer" might be applied to any network that transforms a voltage or an impedance from one level to another one, the term is usually reserved

for circuits incorporating mutual magnetic coupling. Examples would be IF transformers, baluns, broadband transformers and certain antenna matching networks (see Chapter 2). Of course, many devices used at audio and power frequencies are also transformers in the sense used here and have been covered in a previous chapter.

Networks that use mutual magnetic coupling exclusively have attractive advantages over other types in many common applications. A principal advantage is that there is no direct connection between the input and output terminals. Consequently, dc and ac components are separated easily, thus eliminating the need for coupling capacitors. Even more importantly, it is also possible to isolate RF currents because of the lack of a common conductor. Often, an HF receiver in an area where strong local broadcast stations are present will suffer from "broadcast harmonics" and possibly even rectified audio signals getting into sensitive AF circuits. In such cases, complicated filters sometimes prove ineffective, while a simple tuned RF transformer will clear up the problem completely. This is because the unwanted BC components are prevented from flowing on the receiver chassis, along with being rejected by the tuned transformer filter characteristic.

A second advantage of circuits using mutual magnetic coupling exclusively is that analysis is relatively simple compared to other forms of coupling, although exact synthesis is complicated. That is, finding a network with some desired frequency response would be difficult in the general case.

However, circuits using mutual magnetic coupling usually have very good out-of-band rejection characteristics when compared to networks incorporating other forms. (A term sometimes applied to transformer or mutual magnetic coupling is indirect coupling. Circuits with a single resistive or reactive element for the common impedance are called direct-coupled networks. Two or more elements in the common impedance are said to comprise complex coupling.) For instance, relatively simple band-pass filters are possible with mutual magnetic coupling and are highly recommended for VHF transmitter-multiplier chains. For receiving, such filters are often the main source of selectivity. Standard AM and FM broadcast receivers would be examples where intermediate-frequency (IF) transformers derive their band-pass characteristics from mutually coupled inductors.

A third advantage of mutually coupled networks is that practical circuits with great flexibility are possible particularly in regard to matching capabilities. For this reason, variable-coupling matching networks or those using link coupling have been popular for many years. In addition to matching flexibility, these circuits are good band-pass filters and can also provide isolation be-

Fig. 7 — Basic magnetically coupled circuit.

Fig. 8 — Equivalent single-mesh network of the two-mesh circuit of Fig. 7.

tween antenna circuits and those of the transmitter.

### Design Formulas

A basic two-mesh circuit with mutual magnetic coupling is shown in Fig. 7. The reactance,  $X$ , is arbitrary and could be either inductive or capacitive. However, it is convenient to combine it with the secondary reactance ( $X_{Ls}$ ) since this makes the equations more compact. Hence, the total secondary reactance is defined by

$$X_s = 2\pi fL_s + X$$

The primary reactance and mutual reactance are also defined respectively as

$$X_p = 2\pi fL_p$$

$$X_m = 2\pi fM$$

A set of equations for the input resistance and reactance is given by

$$R_{in} = \frac{R_s X_m^2}{R_s^2 + X_s^2}$$

$$X_{in} = X_p - \frac{X_m^2 X_s}{R_s^2 + X_s^2}$$

This permits reducing the two-mesh circuit of Fig. 7 to the single-mesh circuit of Fig. 8.

### Double-Tuned Circuits

A special case occurs if the value of  $X_s$  is zero. This could be accomplished easily by tuning out the inductive reactance of the secondary with an appropriate capacitor or

by varying the frequency until a fixed capacitor and the secondary inductance resonated. Under these conditions, the input resistance and reactance would be

$$R_{in} = \frac{X_m^2}{R_s}$$

$$X_{in} = X_p$$

Then, in order to make the input impedance purely resistive, a second series capacitor could be used to cancel the reactance of  $X_p$ . The completed network is shown in Fig. 9 with C1 and C2 being the primary and secondary series capacitors.

If  $X_m$  could be varied, it is evident that the secondary resistance could be transformed to almost any value of input resistance. Usually, the desired resistance would be made equal to the generator resistance,  $R_g$ , for maximum power transfer. It might also be selected to satisfy some design goal, not necessarily related to maximum power transfer. This brings up a minor point but one that can cause considerable confusion. Normally, in transmitter circuits, the unloaded Q of the reactive components would be very high and the series parasitic resistances (discussed in a previous section) could be neglected. However, if it is not desired to do so, how should these resistances be taken into account? If maximum power transfer is the goal, the series resistance of the primary coil would be added to the generator resistance,  $R_g$ , and the transformed secondary resistance would be made equal to this sum.

On the other hand, a more common case requires the total input resistance to be equal to some desired value. For instance, an amplifier might provide optimum efficiency or harmonic suppression when terminated in a particular load resistance. Transmission lines also require a given load resistance in order to be matched. In such cases, the series resistance of the primary coil would be subtracted from the actual resistance desired and the transformed resistance made equal to this difference. As an example, suppose an amplifier required a load resistance of 3000 ohms, and the primary-coil resistance was 100 ohms. Then the transformed resistance must be equal

to 2900 ohms, (In either case, the secondary coil resistance is merely added to the secondary load resistance and the sum substituted for  $R_s$ .)

### Coefficient of Coupling

Although the equations for the input impedance can be solved in terms of the mutual reactance, the transforming mechanism involved becomes clearer if the coefficient of coupling is used instead. The coefficient of coupling,  $k$ , in terms of the corresponding reactances of inductances is

$$k = \frac{X_m}{\sqrt{X_p X_s}} = \frac{L_m}{\sqrt{L_p L_s}}$$

Then, the input resistance becomes

$$R_{in} = \frac{k^2 X_p X_s}{R_s}$$

The primary and secondary Q values are defined as

$$Q_p = \frac{X_p}{R_g}$$

$$Q_s = \frac{X_s}{R_s}$$

where a loaded Q is assumed. This would mean  $R_s$  includes any secondary-coil loss. For maximum power transfer,  $R_g$  would be the total primary resistance, which consists of the generator and coil resistance.

The coefficient of coupling under these conditions reduces to a simple formula

$$k_c = \frac{1}{\sqrt{Q_p Q_s}}$$

However, if it is desired to make the input resistance some particular value (as in the case of the previous example), the coefficient of coupling is then

$$k_c = \sqrt{\frac{R_{in} - R_p}{X_p Q_s}}$$

If the primary "loss" resistance is zero, both formulas are identical.

At values of  $k$  less than  $k_c$ , the input resistance is lower than either the prescribed value or for conditions of maximum power transfer. Higher values of  $k$  result in a higher input resistance. For this reason,  $k_c$  is called the critical coefficient of coupling. If  $k$  is less than  $k_c$  the circuit is said to be undercoupled, and for  $k$  greater than  $k_c$  an overcoupled condition results. A plot of attenuation vs. frequency for the three cases is shown in Fig. 10. Critical coupling gives the flattest response, although greater bandwidth can be obtained by increasing  $k$  to approximately 1.5  $k_c$ . At higher values, a pronounced dip occurs at the center or resonant frequency.

In the undercoupled case, a peak occurs at the resonant frequency of the primary and secondary circuit but the transformed resistance is too low and results in a mis-

match. As the coupling is decreased still further, very little power is transferred to the secondary circuit and most of it is dissipated in the primary-loss and generator-source resistances. On the other hand, an interesting phenomenon occurs with the overcoupled case. It will be recalled that the transformed resistance is too high at resonance because the coefficient of coupling is greater than the critical value. However, a special case occurs if the primary and secondary circuits are identical, which also means the transformed resistance  $R_{in}$  must equal  $R_s$ .

The behavior of the circuit under these conditions can be analyzed with the aid of Fig. 8. Assuming the Q of both circuits is high enough, the reactance,  $X_s$ , increases very rapidly on either side of resonance. If this variation is much greater than the variation of  $X_m$  with frequency, a frequency exists on each side of resonance where the ratio of  $X_m^2$  to  $R_s^2 + X_s^2$  is 1.0. Consequently,  $R_{in}$  is equal to  $R_s$  and the transformed reactance is  $-X_s$ . Since the primary and secondary resonators are identical, the reactances cancel because of the minus sign. The frequency plot for a  $k$  of 0.2 ( $k_c$  is 0.1) is shown in Fig. 10. If the primary and secondary circuits are not identical, a double-humped response still occurs, but at the points where the transformed resistance is equal to the desired

Fig. 9 — Double-tuned series circuits with magnetic coupling.

Fig. 10 — Response curves for various degrees of coupling coefficient,  $k$ . The critical coefficient of coupling for the network shown in the circuit diagram is 0.1. Lower values give a single response peak (but less than maximum power transfer) while "tighter" coupling results in a double-peak response.

value, the reactances are not the same numerically. Consequently, there is attenuation at peaks, unlike the curve of Fig. 10.

### Other Circuit Forms

While the coupled network shown in Fig. 9 is the easiest to analyze, it is not commonly encountered in actual circuits. As the resistance levels are increased, the corresponding reactances become very large also. In transmitter circuits, extremely high voltages are then developed across the coils and capacitors. For high-impedance circuits, the circuit shown in Fig. 11 is often used.

Although the frequency response for the circuit of Fig. 11 is somewhat different than the circuit of Fig. 9 (in fact, the out-of-band rejection is greater), a matching network can be designed based upon the previous analysis for the series circuit. This is accomplished by changing the parallel primary and secondary circuits to series equivalents. (It should be emphasized that this transformation is good at one frequency only.) The equivalent circuit of the one shown in Fig. 11 is illustrated in Fig. 12, where the new resistance and reactance of the secondary are given by

$$R_{eq}(S) = \frac{R_s}{1 + \gamma^2}$$

$$X_{eq}(C_s) = \frac{-R_s \gamma}{1 + \gamma^2}$$

$$\gamma = R_s / X_c$$

A similar set of transformations exists for the primary circuit also. In most instances, where one high-impedance load is matched to another,  $R_s$  in Fig. 11 is much greater than the reactance of  $C_s$  and  $C_p$ . This simplifies the transformations, and approximate relations are given by

$$R_{eq}(S) \approx \frac{X_c^2}{R_s}$$

$$X_{eq}(C_s) \approx X_c$$

As an example, suppose it was desired to match a 3000-ohm load to a 5000-ohm source using a coupled inductor with a 250-ohm (reactance) primary and secondary coil. Assume the coupling can be varied. Determine the circuit configuration and the critical coefficient of coupling.

Since the load and source resistance have a much higher numerical value than the reactance of the inductors, a parallel-tuned configuration must be used. In order to tune out the inductive reactance, the equivalent series capacitive reactance must be  $-250$  ohms. Since both  $R_s$  and  $R_p$  are known, the exact formulas could be solved for  $\gamma$  and  $R_{eq}$ . However, because the respective resistances are much greater than the reactance, the simplified approximate formulas can be used. This means the primary and secondary equivalent

capacitive reactances are  $-250$  ohms. The equivalent secondary resistance is  $250^2/3000$  or  $20.83$  ohms, resulting in a secondary  $Q$  of  $250/20.83$  or  $12$ . (A formula could be derived directly for the  $Q$  from the approximate equations.) The equivalent primary resistance and  $Q$  are  $12.5$  ohms and  $20$ , respectively. Substituting the values for  $Q$  into the formula for the critical coefficient of coupling gives  $1/\sqrt{(20)(12)}$  or  $0.065$ .

Double-tuned coupled circuits of the type shown in Fig. 11 are used widely in radio circuits. Perhaps the most common example is the IF transformer found in AM and FM BC sets. Many communications receivers have similar transformers, although the trend has been toward somewhat different circuits. Instead of obtaining selectivity by means of IF transformers (which may require a number of stages), a single filter with quartz-crystal resonators is used instead. The subject of receivers is treated in a later chapter.

### Single-Tuned Circuits

In the case of double-tuned circuits, separate capacitors are used to tune out the inductive components of the primary and secondary windings. However, examination of the equivalent circuit of the coupled coil shown in Fig. 8 suggests an alternative. Instead of a separate capacitor, why not detune a resonant circuit slightly and reflect a reactance of the proper sign into the primary in order to tune out the primary inductance. Since the transformation function (shown in the box in Fig. 8) reverses the sign of the secondary reactance, it is evident that  $X_s$  must be inductive in order to tune out the primary inductance.

This might seem to be a strange result but it can be explained with the following reasoning. From a mathematical point of view, the choice of the algebraic sign of the transformed reactance is perfectly arbitrary. That is, a set of solutions to the equations governing the coupled circuit is possible, assuming either a positive or negative sign for the transformed reactance. However, if the positive sign is chosen, the transformed resistance would be negative. But from a physical point of view, this is a violation of the law of conservation of energy since it would imply the secondary resistance acts as a source of energy rather than an energy sink. Consequently, the solution with the negative resistance does not result in a physically realizable network.

This phenomenon has implications for circuits one might not normally expect to be related to coupled networks. For instance, consider coil 1 (Fig. 13) in proximity to the one-turn shorted coil 2. A time-varying current in coil 1 will induce a current in coil 2. In turn, the induced current will set up a magnetic field of its own. The question is, will the induced field aid or oppose the primary field. Since the energy in

Fig. 11 — Coupled network with parallel-tuned circuits of IF transformer.

Fig. 12 — Equivalent series circuit of the parallel network shown in Fig. 11. This transformation is valid only at a single frequency and must be revalued if the frequency is changed.

Fig. 13 — A coil coupled magnetically to a shorted turn provides insight to coils near solid shield walls.

a magnetic field is proportional to the square of the flux, the induced field must oppose the primary field. Otherwise the principle of the conservation of energy would be violated as it was with the "negative" resistance. Consequently, the induced current must always be in a direction such that the induced field opposes changes in the generating field. This result is often referred to as Lenz's Law.

If, instead of a one-turn loop, a solid shield wall was substituted, a similar phenomenon would occur. Since the total flux (for a given current) would be less with the shield present than it would in the absence of the shield, the equivalent coil inductance is decreased. That is why it is important to use a shield around a coil that is big enough to reduce the effect of such coupling. Also, a shield made from a metal with high conductivity such as copper or aluminum is advisable; otherwise a loss resistance will be coupled into the coil as well.

### Link Coupling

An example of a very important class of

Fig. 14 — Link coupling can be used to analyze a number of important circuits.

Fig. 15 — A VHF/UHF circuit which can be approximated by a link-coupled network using conventional components.

Fig. 16 — Equivalent low-frequency analog of the circuit shown in Fig. 15.

Fig. 17 — The network of Fig. 16 can be reduced with the transformation shown in Fig. 8.

single-tuned circuits is shown in Fig. 14. The primary inductor consists of a small coil either in close proximity to or wound over one end of a large coil. Two resonators can be coupled in this manner, although there may be considerable separation (and no mutual coupling between the larger coils). Hence the term, link coupling. While this particular method is seldom used nowadays, the term is still applied to the basic configuration shown in Fig. 14. Ap-

plications would be antenna-matching networks, output stages for amplifiers, and especially important, many circuits used at VHF that have no direct HF equivalent.

The cavity resonators used in repeater duplexers are one form of VHF circuit that uses link coupling. A cross-sectional view of a representative type is shown in Fig. 15. Instead of ordinary coils and capacitors, a section of coaxial transmission line comprises the resonant circuit. The frequency of the resonator may be varied by adjusting the tuning screw that changes the value of the capacitor. Energy is coupled into and out of the resonator by means of two small, one-turn loops. Current in the input loop causes a magnetic field (shown by dashed lines). If the frequency of the generating field is near one of the resonant modes of the configuration, an electric field will also be generated (shown by solid lines). Finally, energy may then be coupled out of the resonator by means of a second loop.

A low-frequency equivalent circuit of the resonator is shown in Fig. 16. However, the circuit can be used only to give an approximate idea of the actual frequency response of the cavity. At frequencies not close to the resonant frequency, the mathematical laws governing resonant circuits are different from those of discrete components used at HF. Over a limited frequency range, the resonator can be approximated by the series LC circuit shown in Fig. 16.

By applying the formulas for coupled networks shown in Fig. 8 to the two-link circuit of Fig. 16, the output link and load can be transformed to an equivalent series resistance and reactance. This is shown in Fig. 17. In most instances the reactance,  $X_s$  in the formula, is just the reactance of the output link. Since the two-link network has been reduced to a single coupled circuit, the formulas can be applied again to find the input resistance and reactance.

### Analysis of Single-Tuned Circuits

Single-tuned circuits are very easy to construct and adjust experimentally. The tuned circuit consisting of  $L_s$ ,  $C_s$ , and perhaps the load,  $R_s$ , can be constructed first and tuned to the natural resonant frequency

$$f_o = \frac{1}{2\pi \sqrt{L_s C_s}}$$

Then the primary inductor, which may be a link or a larger coil, is brought into proximity of the resonant circuit. The resonant frequency will usually shift upward. For instance, a coil and capacitor combination was tuned to resonance by means of a dip oscillator (see the chapter on measurements) at a frequency of 1.8 MHz. When a two-turn link was wound over the coil and coupled to the dip oscillator, the resonant frequency had increased to 1.9 MHz. A three-turn link caused a change to 2 MHz.

Often an actual load may be an unknown

quantity, such as an antenna, and insight into the effects of the various elements is helpful in predicting single-tuned circuit operation. Usually, as in the case of most matching networks,  $R_s$  (Fig. 8) and the input resistance are specified with the reactive components being the variables. Unfortunately, the variables in the case of mutually coupled networks are not independent of each other, which complicates matters.

Examination of the equivalent circuit shown in Fig. 8 would indicate the first condition is that the reactance reflected from the secondary into the primary be sufficient to tune out the primary reactance. Otherwise, even though the proper resistance transformation is obtainable, a reactive component would always be present. A plot of the reflected reactance as a function of  $X_s$  is shown in Fig. 18. From mathematical considerations it can be shown that the maximum and minimum of the curve have a value equal to  $X_m^2/2R_s$ . Consequently, this value must be greater than or equal to  $X_p$  so a value of  $X_s$  may exist such that the reflected reactance will cancel  $X_p$ . In the usual case where  $X_m^2/2R_s$  is greater than  $X_p$ , it is interesting to note that two values of  $X_s$  exist where  $X_p$  and the reflected reactance cancel. This means there are two cases where the input impedance is purely resistive, and  $R_s$  could be matched to either one of two source resistances if so desired. The value of  $X_s$  at these points is designated as  $X_{s1}$  and  $X_{s2}$ .

On the other hand, a high value of  $R_s$  requires  $X_m$  to be large also. This could be accomplished by increasing the coefficient of coupling or by increasing the turns on the secondary coil. Increasing the turns on the primary also will cause  $X_m$  to be higher, but  $X_p$  will increase also. This is self-defeating, since  $X_{m2}$  is proportional to  $X_p$ .

An alternative approach is to use the parallel configuration of Fig. 19. The approximate equivalent series resistance of the parallel combination is then  $X(C_s)^2/R_s$  and the reactance is approximately  $X(C_s)$ . (See diagram and text for Fig. 12.) This approach is often used in multiband antenna systems. On some frequencies the impedance at the input of the feed line is high, so the circuit of Fig. 18 is employed. This is referred to as parallel tuning. If the impedance is very low, the circuit of Fig. 14 is used and is called series tuning.

As an example, suppose a single-tuned circuit is to be used to match a 1-ohm load to a 50-ohm source, as shown in Fig. 20. It might be pointed out here that networks using mutual magnetic coupling can be scaled in the same manner that filter networks are scaled (as discussed in Chapter 2). For instance, the circuit of Fig. 20 could be scaled in order to match a 50-ohm load to a 2500-ohm source merely by multiplying all the reactances by a factor of 50.

The input resistance and reactance of the

Fig. 18 — Reflected reactance into the primary of a single-tuned circuit places restraints on resistances that can be matched. This gives rise to a general rule that high-Q secondary circuits require a lower coefficient of coupling than low-Q ones.

Fig. 19 — Single-tuned circuit with a parallel RC secondary.

Fig. 20 — Example of a single-tuned circuit.

Fig. 21 — Input resistance of the circuit of Fig. 20 as a function of frequency.

circuit of Fig. 20 are plotted in Figs. 21 and 22, respectively. As pointed out earlier, there are two possible points where the reactance is zero, and this circuit could be used to match the 1-ohm load to either a 50-ohm or 155-ohm source. Assuming a 50-ohm source is being used, the attenuation plot as a function of frequency is given

Fig. 22 — Input reactance of the network of Fig. 20. Note two resonant frequencies (where reactance is zero).

by the solid curve of Fig. 23.

With slight modification to include the effect of the source, the transformation of Fig. 8 can be applied to the primary side of the coupled circuit shown in Fig. 20. This is illustrated in Fig. 24. The complete circuit is shown at Fig. 24A and the network with the transformed primary resistance and reactance is shown in Fig. 24B.

In a lossless transformer, the maximum available power at the secondary must be the same as that of the original source on the primary side, neglecting the effects of reactance. That is, the power delivered to a 1-ohm resistance (shown as a dashed line in Fig. 24B) must be the same as that delivered to a 50-ohm load in Fig. 24A.

Fig. 23 — Response of the circuit shown in Fig. 20.

Fig. 24 — The transformation of Fig. 8 applied to the primary side of the circuit of Fig. 20.

This assumes that the rest of the circuit has been disconnected in either case. In order to fulfill this requirement, the original source voltage must be multiplied by the square root of the ratio of the new and old source resistance.

The single-mesh transformed network is shown in Fig. 24C. It is interesting to compare the response of an RLC series circuit that actually possesses these element values at resonance with the circuit of Fig. 20. For comparison, the response of such a circuit is shown in Fig. 23 as a dashed curve; this curve differs only slightly from the coupled-

circuit curve (solid line). The reason for the similarity is that even though the transformation of the primary resistance and reactance also changes with frequency, the effect is not that great in the present case.

### Broadband RF Transformers

The sensitivity of the frequency characteristic of the transformation shown in Fig. 8 depends mostly on the ratio of  $X_s$  to  $R_s$ . However, if  $X_s$  is much greater than  $R_s$ , the transformed reactance can be approximated by

$$\frac{-X_m^2 X_s}{R_s^2 + X_s^2} \approx \frac{-X_m^2}{X_s}$$

and the resistance becomes

$$\frac{R_s X_m^2}{R_s^2 + X_s^2} \approx R_s \frac{X_m^2}{X_s^2}$$

Applying this approximation to the general coupled circuit shown in Fig. 25A results in the transformed network of Fig. 25B. The coefficient of coupling for the circuit of Fig. 25A is

$$k = \frac{X_m}{\sqrt{X_1 X_2}}$$

and the network shown in Fig. 25B in terms of the coefficient of coupling is illustrated in Fig. 25C. If  $k$  equals 1.0, the input reactance is zero and the input resistance is given by

$$R_{in} = \left( \frac{X_1}{X_2} \right) R_2 = \left( \frac{L_1}{L_2} \right) R_2 \approx \left( \frac{N_1}{N_2} \right) R_2$$

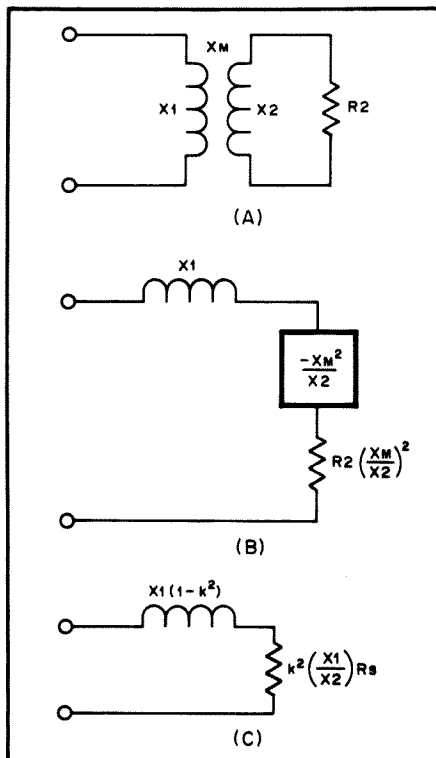

Fig. 25 — Equivalent-circuit approximation of two coupled coils.

Fig. 26 — Input resistance and reactance as a function of output load resistance for  $X_1$  and  $X_2$  equal to 100 ohms and 10 ohms, respectively (Fig. 25).

where  $N_1$  and  $N_2$  are the number of turns on coil 1 and 2, respectively. From maximum-power transfer considerations such as those discussed for the circuit of Fig. 24, the voltage transfer ratio becomes

$$e_2 = \left( \frac{N_2}{N_1} \right) e_1$$

It will be recalled the above equations occurred in the discussion of the "ideal transformer" approximation in Chapter 2. It was assumed then that the leakage reactance and magnetizing current were negligible. The effects on circuit operation of these variables are shown in Fig. 26. The curves were computed for various load resistances ( $R_s$ ) using the exact equations shown in Fig. 8.

$X_1$  and  $X_2$  are assumed to be 100 and 10 ohms, respectively, with the solid curves for a  $k$  of 1.0 and the dashed reactance curve for  $k$  equal to 0.99 (the resistance curve for the latter values is the same as the one for  $k$  equal to 1.0). The ideal-transformer representation can be modified slightly to approximate the curve of Fig. 26 as shown in Fig. 27. The shunt reactance,  $X_{mag}$ , is called the magnetizing reactance and  $X_L$  is referred to as the leakage reactance.

Unfortunately, the two reactances are not independent of each other. That is, attempts to change one reactance so that its effect is suppressed causes difficulties in eliminating the effects of the other reactance. For instance, increasing  $X_1$ ,  $X_m$ , and  $X_2$  will increase  $X_{mag}$ , which is desirable. However, examination of Fig. 25C reveals that the coefficient of coupling,  $k$ , will have to be made closer to 1.0. Otherwise, the leakage reactance increases since it is proportional to  $X_1$ .

### High-Permeability Cores

As a consequence of the interaction between the leakage reactance and the

magnetizing reactance, transformers that approach ideal conditions are extremely difficult (if not impossible) to build using techniques common in air-wound or low-permeability construction. In order to build a network that will match one resistance level to another one over a wide range of frequencies, ideal transformer conditions have to be approached quite closely. Otherwise, considerable inductive reactance will exist along with the resistance component, as shown in Fig. 26.

One approach is to use a core with a higher permeability than air. Familiar examples would be power transformers and similar types common to the AF range. However, when an inductor configuration contains materials of more than one permeability, the analysis relating to Fig. 25C has to be modified somewhat. The manner in which the core affects the circuit is a bit complicated although even a qualitative idea of how such transformers work is very useful.

First, consider the coupled coils shown in Fig. 28. For a given current,  $I_1$  a number of flux lines are generated that link both coil 1 and coil 2. Note that in coil 1, not all of the flux lines are enclosed by all the turns. The inductance of a coil is equal to the ratio of the sum of flux linkages each turn and the generating current or

$$L_1 = \frac{\Lambda_{TOTAL}}{I_1}$$

where for the example shown in Fig. 28,  $\Lambda_{TOTAL}$  is given by

$$\Lambda_{TOTAL} = \Lambda_1 + \Lambda_2 + \Lambda_3 + \Lambda_4 + \Lambda_5$$

Counting up the number of flux linkages in coil 1 gives

$$\Lambda_{TOTAL} = 5 + 5 + 7 + 7 + 5 = 29$$

If all the flux lines linked all the turns,

Fig. 27 — Approximate network for the curves of Fig. 26.

Fig. 28 — Coupled coils showing magnetic flux lines.

Fig. 29 — Toroidal transformer.

$\Lambda_{TOTAL}$  would be 35 so  $L_1$  is  $29 / 35$  or 83 percent of its maximum possible value. Likewise, if all the flux (7 lines) generated in coil one linked all the turns of coil 2, the maximum number of flux linkages would be the number of turns on coil 2 times 7 or 28. Since only three lines link coil 2, the mutual inductance is  $3 \times 4/28$  or 43 percent of maximum.

Assuming both coils are perfect, if a current  $I_1$  produced 7 flux lines in a five-turn

coil, then the same current in a four-turn coil would produce  $(4/5)(7)$  flux lines, since the flux is proportional to the magnetizing current times the number of turns. Consequently, the maximum flux linkages in coil 1 from a current of the same value as  $I_1$  but in coil 2 instead would be  $(4/5)(7)(5)$  or 28. Therefore, it can be seen that the mutual inductance is independent of the choice of coil used for the primary or secondary. That is, a voltage produced in one coil by a current in the other one would be the same if the coils were merely interchanged. (This result has been used implicitly on a number of previous occasions without proof.) In addition, the maximum flux linkages in coil 2 produced by a current,  $I_1$ , would be  $(4/5)(7)(4)$ . As an exercise, substitute the maximum inductance values into the formula for the coefficient of coupling and show that  $k$  is 1.0.

The next step is to consider the effect of winding coils on a form with a magnetic permeability much higher than that of air. An example is illustrated in Fig. 29, and the configuration shown is called a toroidal transformer. Since the flux is proportional to the product of the permeability and the magnetizing current, the flux in the core shown in Fig. 29 will be much greater than the coil configuration of Fig. 28. However, not all of the flux is confined to the core. As can be seen in Fig. 29, some of the flux lines never penetrate the core (see lines marked A in Fig. 29) while others enclose all the windings of coil 1 but not coil 2 (see line marked B). The significance of these effects is as follows. The total flux linkage produced by the current,  $I_1$ , is

$$\Lambda_{TOTAL} = \Lambda_{air} + \Lambda_{core}$$

and dividing both sides of the equation by  $I_1$  gives

$$L_T = L_{air} + L_{core}$$

Consequently, the circuit of Fig. 25 can be represented as shown in Fig. 30A. For values of  $X_2$  much greater than the load resistance, the approximate network of Fig. 30B can replace the one of Fig. 30A.

At first sight, it might seem as though little advantage has been gained by introducing the core since the formulas are much the same as those of Fig. 25C. However, the reactances associated with the core can be made very high by using a material with a high permeability. Also, even though there may be some leakage from the core as indicated by line B in Fig. 29, it is ordinarily low and the coefficient of coupling in the core can be considered 1.0 for all practical purposes. This is especially true at AF and power frequencies with transformers using iron cores where the permeability is extremely high. This means the magnetizing reactance can be made very high without increasing the leakage reactance accordingly as is the case with the circuit in Fig. 25C. Therefore, ideal transformer conditions are considered to exist in the core, and the final circuit can

be approximated by the one shown in Fig. 30C.

### Bifilar and Twisted-Pair Windings

Although the core helps alleviate some of the problems with leakage and magnetizing reactance, the residual parasitic elements must still be made as low as possible. This is especially important in matching applications, as the following example illustrates. A transformer has a primary and secondary leakage reactance of 1 ohm and 0.1 ohm, respectively, with a coefficient of coupling of 1.0 in the core.  $X_1$  and  $X_2$  are 1000 ohms and 100 ohms.

A plot similar to the one of Fig. 26 is shown in Fig. 31, along with a curve for voltage standing wave ratio (VSWR). These results are based on the exact equations and it can be seen that the approximate relations shown in Fig. 30C are valid up to 1 ohm or so. Curve A (Fig. 31) includes only the effect of the secondary reactance and illustrates the manner in which the reactance is transformed. Curve B shows the total input reactance, which merely requires the addition of 1 ohm. The VSWR curve includes the effect of the input reactance. The useful range of the transformer is between 1 and 10 ohms, with rapid deterioration in VSWR outside of these values. (The VSWR curve is for a characteristic impedance equal to 10 times the secondary resistance. For instance, the transformer would be useful in matching a 5-ohm load to a 50-ohm line.)

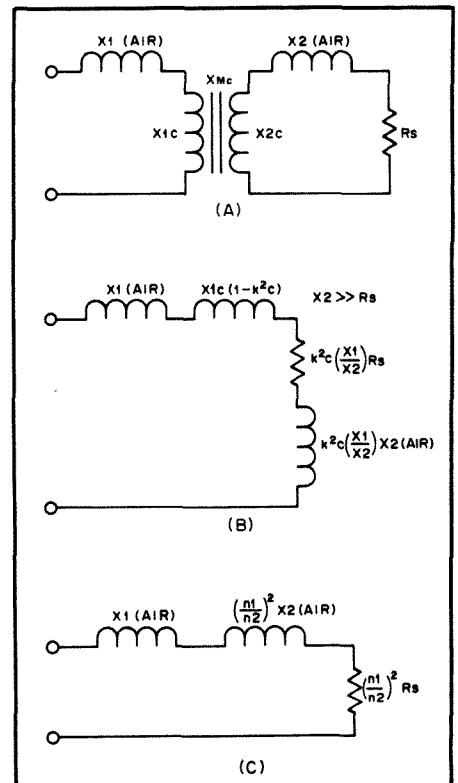

Fig. 30 — Effect of a high-permeability core on transformer equivalent circuit.

Fig. 31 — Curve for transformer problem discussed in the text.

Fig. 32 — Bifilar-wound transformer on toroidal core.

Fig. 33 — Effect of distributed capacitance on transformer action.

As mentioned previously, these difficulties are less pronounced at audio frequencies since the permeabilities normally encountered in iron-core transformers are so high. The actual inductance of the winding itself is therefore small in com-

parison to the component represented by the core. That is, a small number of turns of wire wound on a core may actually be the equivalent of a very large coil. However, materials suitable for RF applications have much lower permeabilities, and a narrower range of matching values is likely to be the result (such as in the example of Fig. 31). Therefore, other means are required in keeping the parasitic elements as low as possible. Either that, or less conventional transformer designs are used.

One approach is shown in Fig. 32. Instead of separating the windings on the core as shown in Fig. 29, they are wound in parallel fashion. This is called a bifilar winding, although a more common approach to achieve the same purpose is to twist the wires together. Either way, there are a number of advantages to be gained (and some disadvantages). With reference to Fig. 28, the fact that not all the flux lines linked all of the turns of a particular coil meant the self inductance was lower than if all the turns were linked. Since the separation between turns of a particular coil is quite large in the configuration of Fig. 32, the flux linkage between turns is quite low. This means the corresponding leakage inductance is reduced accordingly. However, the coupling between both coils is increased because of the bifilar winding (flux line A) in Fig. 32 which also tends to reduce the leakage inductance of either coil.

On the other hand the capacitance between windings is increased considerably as indicated by B in Fig. 32. As a result, the coupling between windings is both electrical and magnetic in nature. Generally speaking, analysis of the problem is complicated. However, a phenomenon usually associated with such coupling is that it

Fig. 34 — Basic configuration for a directional-coupler type of VSWR detector.

tends to be directional. That is, energy transferred from one winding to the other propagates in a preferred direction rather than splitting equally.

### Directional Coupling

Two conductors are oriented side by side over a conducting plane as shown in Fig. 33. The current  $I$  in conductor 1 will induce a current  $I_m$  in conductor 2 because of magnetic coupling. The actual value of the current will depend on the external circuitry attached to the conductors but it will be assumed that the two of them extend to infinity in both directions.

Since capacitive coupling exists also, a second set of current components denoted by  $I_c$  will flow. The result is that a wave traveling toward the right in conductor 1 will produce a wave traveling toward the left in conductor 2. Such coupling is called contradirectional coupling, since the induced wave travels in the opposite direction to the generating wave.

This is the principle behind many practical devices and ones that are quite common in amateur applications. In adjusting a load such as an antenna, it is desirable to ensure that energy is not reflected back to the transmitter. Otherwise, the impedance presented to the transmitter output may not be within range of permissible values. A directional coupler is useful in determining how much power is reflected, as indicated in Fig. 34. Energy originating from the transmitter and flowing to the right causes a voltage to be produced across the resistor at the left. On the other hand, a wave traveling from the right to the left produces a voltage across the right-hand resistor. If both of these voltages are sampled, some idea of the amount of power reflected can be determined. (The subject of reflected power is taken up in more detail in the chapter on transmission lines.)

In some situations, the coupling described can be very undesirable. For instance, the lines shown in Fig. 34 might be conductors on a circuit board in a piece of equipment. As a result, the coupling between lines can cause feedback and, because of its directional nature, can be very difficult to sup-

Fig. 35 — Directional-coupler hybrid combiner.

Fig. 36 — Transmission-line transformer with ferrite cores.

press with conventional methods. Therefore, it is good design practice to use double-sided board (board with conductive foil on both sides) so a ground plane of metal is in close proximity to the conductors. This tends to confine the fields to the region in the immediate vicinity of the wires.

### Transmission-Line Transformers

In effect, sections of transmission line in close proximity act as transformers with the unique feature that the coupling is directional. For instance, if only magnetic coupling were present in the configuration of Fig. 34, power would be divided equally between the resistors at either end of the secondary section of transmission line. As another example of directional effects, the network shown in Fig. 35 can be used to couple two sources to a common load without cross-coupling of power from one

Fig. 37 — Equivalent circuit of transmission-line transformer in the presence of the core. Dots indicate winding sense of coils. A positive current into a dotted end of one coil will produce a voltage in the other coil because of mutual coupling. The polarity of this voltage will be such that dotted end of the "secondary" coil will be positive. The crossed-arrows symbol in the middle of the parallel lines is the standard symbol for a directional coupler.

source to the other one. (This assumes the sources have the same frequency and phase. Otherwise, a resistance of value  $2R$  must be connected from point a to d.) Such a configuration is called a hybrid combiner and is often used to combine the outputs of two solid-state amplifiers in order to increase the power-handling capability. This permits the use of less expensive low-power devices rather than very expensive high-power ones. Even though more devices are required, it is still simpler since the difficulties in producing a high-power transistor increase in a greater proportion as the power level is raised.

The manner in which the circuit shown in Fig. 35 operates is as follows. A wave from the generator on the left end of line 1 travels toward the right and induces a wave in line 2 that travels toward the left and on into the load. No wave is induced in line 2 that travels toward the right except for a small fraction of power.

A similar situation exists with the second generator connected at the right end of line 2. A wave is induced in line 1 that travels toward the right. Since the load is also connected to the right end of line 1, power in the induced wave will be dissipated here with little energy reaching the generator at the left end of line 1. In order to simulate a single load (since there are two generators involved), the value of the load resistance must be half of the generator resistance. Assuming that two separate resistors of value  $R$  were connected to the ends of the line, it would be possible to connect them together without affecting circuit operation. This is because the voltage across both resistors is of the same phase and amplitude. Consequently, no additional current would flow if the two resistors were paralleled or combined into a single resistor of  $R/2$ .

### Extending the Low-Frequency Range

As might be expected, the coupling

mechanism illustrated in Figs. 32 through 34 is highly dependent on dimensions such as conductor spacing and line length. For instance, maximum coupling of power from the primary wave to the induced wave occurs when the secondary line is a quarter-wavelength long<sup>1</sup> or some odd multiple of a quarter-wavelength. This would normally make such couplers impractical for frequencies in the HF range. However, by running the leads through a ferrite core as shown in Fig. 36, lower frequency operation is possible. Although the transformer of Fig. 36A is seldom used, it illustrates the manner in which the conductors are employed electrically in the more complicated configurations of Fig. 32 and 36B. Also, the relationship between the parallel-line coupler in Fig. 35 and the loaded version of Fig. 36A is easier to visualize.

As covered in an earlier problem discussion (Fig. 29), a set of coupled coils wound on a high-permeability core can be broken down into combinations of two series inductances. One inductance represents the path in air while the other includes the effects of the flux in the core. As before, it is assumed that the coefficient of coupling in the core is 1.0.

If the hybrid combiner of Fig. 35 is wound on a core (such as those of Fig. 32 or Fig. 36), the low-frequency range of the entire system is increased considerably. The equivalent circuit showing the effect of the core on the air-wound coupler is illustrated in Fig. 37. (The symbol in the middle of the parallel lines is the standard for a directional coupler.) At the higher frequencies, most core materials decrease in permeability. The operation approaches that of the original air-wound coupler, and

<sup>1</sup>Oliver, "Directional Electromagnetic Couplers," *Proceedings of the I.R.E.*, Vol. 42, pp. 1686-1692, November 1954.

Fig. 38 — Low-frequency equivalent circuit of hybrid combiner showing isolation of sources.

Fig. 39 — Desired coupling mode of hybrid combiner.

the inductance produced by the core can be neglected. At the low end of the frequency range, the line lengths are usually too short to provide much coupling or isolation. Therefore, the circuit can be represented by the set of coupled coils shown in Figs. 38 and 39.

For a current  $I_2$  flowing from a source 1 over to the mesh that includes source 2, the mutual-reactance components add to the self-inductance of each coil. Consequently, a large reactance appears in series between the two sources, which effectively isolates them. On the other hand, currents from both sources that flow through the load resistor,  $R/2$ , produce fluxes that cancel, and the voltages produced by the self- and mutual-reactance terms subtract. If both sources have the same amplitude and phase, currents  $I_1$  and  $I_2$  must be identical because of the symmetry involved. However, if the coefficient of coupling is 1.0, the self- and mutual-reactance must be equal. Therefore the voltage across either coil is zero, since the terms subtract, and a low-impedance path exists between both sources and the load.

### Other Transformer Types

The hybrid combiner is only one application of a combination transmission-line or directional-coupler transformer and conventional coupled-coil arrangement. With other variations, the low-frequency isolation is accomplished in the same manner. Mutual-reactance terms add to the self-reactance to provide isolation for some purpose with cancellation of reactive components in the path for the desired coupling. Very good bandwidth is possible

with a range from BC frequencies to UHF in the more esoteric designs. Models that cover all the amateur HF bands can be constructed easily.<sup>2</sup>

Unfortunately, there is also a tendency to expect too much from such devices. Misapplication or poor design often results in inferior performance. For instance, as indicated in an earlier example (Fig. 31), actual impedance levels are important, along with the desired transforming ratio. Using a transformer for an impedance level that was not intended results in undesirable reactive components and an improper transforming ratio. However, when applied properly, the transformers discussed in the previous sections can provide bandwidth characteristics that are obtainable in no other way.

Another transformer type is shown in Fig. 40A. The windings of the coils are such that the voltages across the inductors caused by the desired current are zero. This is because the induced voltages produced by the current in the mutual-reactance terms just cancel the voltage drop caused by the current flowing in the self-reactances of either coil, (assuming the coefficient of coupling is 1.0) However, an impedance connected to ground at point c would be in series with the self-reactance ( $X_L$ ) of the coil connected between points a and c. But there would be no induced voltage to counter the voltage drop across this coil. Therefore, if  $X_L$  is large, very little current would flow in the impedance Z and it would be isolated effectively from the source.

In fact, terminal c could be grounded as shown in Fig. 40B. The voltage drop across the coil from a to c would then be equal to  $V_1$ . However, the induced voltage in the coil connected between points b and d would also be  $V_1$ , assuming unity coupling ( $k$  equal to 1.0). Although the voltage drop produced by the inductors around the mesh through which  $I_1$  flows is still zero, point d is now at potential  $-V_1$  and a phase reversal has taken place. For this reason, the configuration shown in Fig. 40B is called a phase-reversal transformer.

### Baluns

The circuit shown in Fig. 40A is useful in isolating a load from a grounded source. This is required in many applications, and the device that accomplishes this goal is called a balun (balanced to unbalanced) transformer. Baluns may also be used to transform impedances and to provide isolation. A 1:1 balun such as the one shown in Fig. 40A means the impedance at the input terminals ab will be the same as the load connected across terminals cd. Other transforming ratios, such as 4:1, are possible with the appropriate circuit connections.

<sup>2</sup>Ruthroff, "Some Broad-Band Transformers," *Proceedings of the I.R.E.*, Vol. 97, pp. 1337-1342, August 1959.

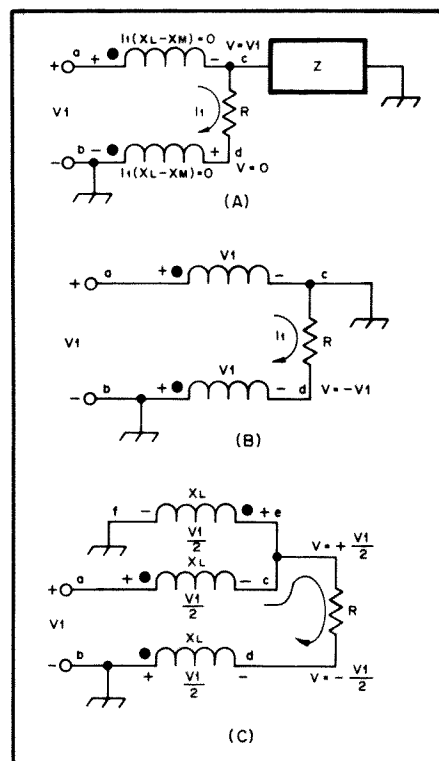

Fig. 40 — Applications of transmission-line transformers. See text.

One disadvantage of the network of Fig. 40A is that although the load is isolated from the source, the voltages at the output are not balanced. This is important in some applications such as diode-ring mixers, where a push-pull input is required, and so the circuit of Fig. 40C is used. A third coil connected between points e and f is wound on the same core as the original transformer (Fig. 40A). This coil is connected so a voltage across it produces a flux that adds to that produced by the coil between a and c. Assuming both coils are identical, the voltage drop across either one must be the same, or half the applied voltage. However, since the coil between b and d is also coupled to this combination (and is an identical coil), the induced voltage must also be  $-V_1/2$ . Consequently, the end of the load connected to points c and e is at a potential of  $+V_1/2$  with respect to ground, while point d is  $-V_1/2$  with respect to ground when the input voltage has the polarity shown. Therefore, this circuit not only isolates the load from the source but provides a balanced voltage.

Either the circuit of Fig. 40A or Fig. 40C can be used if only isolation is desired. However, the network shown in Fig. 40C is more difficult to design and construct since the reactance of the coils between points a and f must be very high throughout the frequency range of the transformer. With both transformers, the coefficient of coupling must also be very close to 1.0 in order to prevent undesirable reactance in

series with the load. This problem can be offset somewhat by reducing  $X_L$  slightly (by fewer turns) but this is counter to the requirement of a large  $X_L$  in the circuit of Fig. 40C. Isolation is reduced in both cases, although no detrimental effect on input impedance results in the transformer of Fig. 40A by reducing  $X_L$ .

### Twisted Pairs — Impedance and Attenuation

Twisted pairs of wire are often used in the construction of broadband RF transformers. The question often arises as to what size conductors and what number of twists per inch should be used. To help answer these questions the information contained in Tables 1 and 2 was developed. Table 1 illustrates the approximate impedance for various size conductors with different numbers of twists per inch. These values are based on measurements in the ARRL laboratory, and should be accurate to within an ohm or two. Enameled copper wire was used for each pair. The information shown in Table 2 is the attenuation per foot for the same twisted pairs of wire. Information is not included for twists per inch greater than  $7\frac{1}{2}$  for the no. 20 wire

since this results in an unusable tight pair. Likewise, the information for twists per inch less than  $7\frac{1}{2}$  for no. 30 wire is omitted since these pairs are extremely loose.

As a general rule the wire size can be selected based on the core size to be used and the required number of turns. The number of twists per inch can be selected according to the impedance level of

transmission line that is needed. For applications where moderate levels of power are to be handled (such as in the low- and medium-level stages of a solid-state transmitter), smaller wire sizes should be avoided. For receiver applications, very small wire can be used. It is not uncommon to find transformers wound with pairs of no. 32 wire and smaller.

## Nonlinear and Active Networks

Almost all the theory in previous sections has dealt with so-called passive components. Passive networks and components can be represented solely by combinations of resistors, capacitors and inductors. As a consequence, the power output at one set of terminals in a passive network cannot exceed the total power input from sources connected to other terminals in the circuit. This assumes all the sources are at one frequency. Similar considerations hold true for any network, but, it is possible for energy to be converted from one frequency (including dc) to other ones. While the total power input must still be equal to the total power output, it is convenient to consider certain elements as controllable sources of power. Such devices are called amplifiers and are part of a more general class of circuits called active networks. An active network generally possesses characteristics that are different from those of simple RLC circuits, although the goal in many instances is to attempt to represent them in terms of passive elements and generators.

### Nonlinearity

Two other important attributes of passive RLC elements are that they are linear and bilateral. A two-terminal element such as a resistor is said to be bilateral since it doesn't matter which way it is connected in a circuit. Semiconductor and vacuum-

tube devices such as triodes, diodes, transistors and integrated circuits (ICs) are all examples where the concept of a bilateral element no longer holds true. The manner in which the device is connected in a circuit and the polarity of the voltages involved are very important.

An implication of the failure to satisfy the bilateral requirements is that such devices are nonlinear in the strictest sense. Linearity means that the amplitude of a voltage or current is related to other voltages and currents in a circuit by a single proportionality constant. For instance, if all the voltages and currents in a circuit were doubled, a single remaining voltage or current would be doubled also. That is, it couldn't change by a factor of one half, or three, no matter how complex the network might be. Likewise, if all the polarities of the currents and voltages in a circuit are reversed, the polarity of a remaining voltage or current must be reversed also. Finally, if all the generators or sources in a linear network are sine waves at a single frequency, any voltage or current produced by these sources must also be a sine wave at the same frequency.

Consequently, if a device is sensitive to the polarity of the voltage applied to its terminals, it doesn't meet the requirements of either a bilateral element or a linear one. Because of the extreme simplicity of the

mathematics of linear circuits as compared to the general nonlinear case, however, there is tremendous motivation in being able to represent a nonlinear circuit by a linear approximation. Many devices exhibit linear properties over part of their operating range or may satisfy some but not all of the requirement of linear circuits. Such devices in these categories are sometimes termed piece-wise linear (or, simply, as linear). For instance, a linear mixer doesn't satisfy the rule that a voltage or current must be at the same frequency as the generating source(s). Since the desired output voltage (or current) varies in direct proportion to the input voltage (or current), however, the term linear is applied to distinguish the mixer from types without this quasi-linear property.

### Harmonic Frequency Generation

In a circuit with nothing but linear components, the only frequencies present are those generated by the sources themselves. This is not true with nonlinear elements. One of the properties of nonlinear networks mentioned earlier is that energy at one frequency (including dc) may become converted to other frequencies. In effect, this is how devices such as transistors and vacuum tubes are able to amplify radio signals. Energy from the dc power supply is converted to energy at the desired signal

Fig. 41 — Nonlinear transfer characteristic (see text discussion).

Fig. 42 — Harmonic analysis and spectrum.

frequency. Therefore, a greater amount of signal power is available at the output of the network of an active device than at the input.

On the other hand, such frequency generation may be undesirable. For instance, the output of a transmitter may have energy at frequencies that could cause interference to nearby receiving equipment. Filters and similar devices must be used to suppress this energy as much as possible.

The manner in which this energy is produced is shown in Fig. 41. A sine wave at the input of a nonlinear network ( $V_{in}$ ) is "transformed" into the output voltage waveform ( $V_{out}$ ) illustrated. If the actual device characteristic is known, the waveform could be constructed graphically. It could also be tabulated, if the output voltage as a function of input voltage was available in either tabular or equation form. (Only one-half of the period of a sine wave is shown in Fig. 41 for clarity.)

Although the new waveform retains many of the characteristics of the original sine wave, some transformations have taken place. It has zero value when  $t$  is either 0 or  $T/2$ , and attains a maximum at  $T/4$ . However, the fact that the curve is flattened somewhat means energy at the original sine-wave frequency has been converted to other frequencies. It will be recalled that the sum of a number of sine waves at one frequency result in another sine wave at the same frequency. Therefore, the waveform of Fig. 41 must have more than one frequency component present since it is no longer a sine wave.

One possible model for the new waveform is shown in Fig. 42A. Instead of one sine wave at a single frequency, there are two generators at three times the "fundamental" frequency  $\omega$ , where  $\omega$  is  $2\pi f$  (Hz). If the two sine waves are plotted point by point, the dashed curve of Fig. 42B results. While this curve doesn't resemble the one of Fig. 41 very closely, the general symmetry is the same. It would take an infinite number of generators to represent the desired curve exactly, but it is evident that all the frequencies must be odd multiples of the fundamental. Even multiples would produce a lopsided curve that might be useful for representing other types of waveforms.

In either case, the multiples have a specific name and are called harmonics. There is no first harmonic. By definition, the second, third and fourth multiples are designated as the second, third and fourth harmonics. Thus the dashed curve of Fig. 42 is the sum of the fundamental and third harmonic.

Analyzing waveforms such as those of Fig. 41 is a very important procedure. A plot of harmonic amplitude such as that shown in Fig. 42C is called the spectrum of the waveform and can be displayed on an instrument called a spectrum analyzer. If the mathematical equation or other data for the curve is known, the harmonics can also be determined by means of a mathematical process called Fourier analysis.

### Linear Approximations of Nonlinear Devices

Nonlinear circuits may have to be analyzed graphically as in the previous example. There are many other instances where only a graphical method may be practical, such as in power-amplifier prob-

lems. However, a wide variety of applications permit a different approach. A model is derived from the nonlinear characteristics using linear elements to approximate the more difficult nonlinear problem. This model is then used in more complicated networks instead of the nonlinear characteristics, which simplifies analysis considerably.

The following example illustrates how this is accomplished. Although a vacuum-tube application is considered, a similar process is employed in solving semiconductor problems as well. However, there are some additional factors involved in semiconductor design that do not apply to vacuum tubes. In fact, much of the analysis required with vacuum tubes is unnecessary with modern solid-state components since many of the problems have already been "solved" before the device leaves the counter at the radio store. That is, amplifiers such as those in integrated circuits have the peripheral elements built in, and there is no need to determine the gain or other parameters such as the values of bias resistors.

### The Triode Amplifier

A simple network using a triode vacuum tube is shown in Fig. 43A, and a typical set of characteristic curves is illustrated in Fig. 44A. The first chore in finding a suitable linear approximation for the triode is to determine an optimum operating point. Generally speaking, a point in the center of the set of curves is desirable and is indicated by point Q in Fig. 44A. (Other areas are often picked for power-amplifier operation, but the goal here is to find a point where the maximum voltage swing is possible without entering regions where the nonlinearities affect the linear approximation.)

In the particular operating point chosen, the cathode to grid voltage is  $-3$ , the cathode to plate voltage is 280, and the plate current is 10 mA. It is assumed that the input signal source in Fig. 43A is a short-circuit at dc, and a 3-V battery connected as shown results in a dc voltage of  $-3$  being applied to the grid at all times. Such a battery is called a bias battery or bias supply.

The next step is to determine how the plate voltage varies with grid voltage ( $e_g$ ) for a constant plate current. Assuming that the characteristic curves were completely linear, this would permit evaluation of an equivalent ac voltage generator as shown in Fig. 43B. For a constant plate current of 10 mA, the plate voltage changes from 325 (point b) to 230 (point a) when the grid voltage is changed from  $-4$  to  $-2$  (Fig. 44A).

These numbers can be used to compute the amplification factor ( $\mu$ ) of the triode which is

$$\mu = \frac{325 - 230}{(-4) - (-2)} = -47.5$$

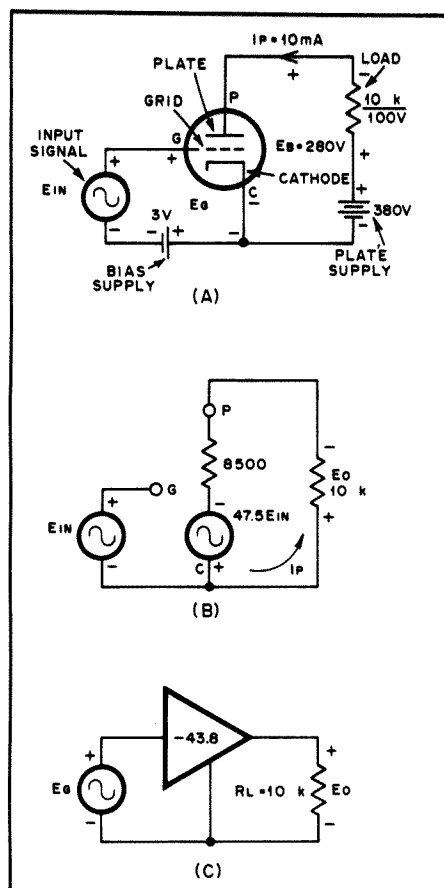

Fig. 43 — Basic triode amplifier and equivalent circuit.

Fig. 44 — Triode characteristics and derivations of small-signal parameters.

Quite often a set of characteristics will not be published for a triode, and only the

amplification factor will be given along with a typical operating point. However, note that the amplification factor is negative. This means that for an increase in the signal voltage ( $e_{in}$ ), the controlled generator decreases in voltage. Consequently, there is a  $180^\circ$  phase shift between the input voltage and the controlled source. (Note the polarity of the generator shown in Fig. 43B.)

In order to complete the equivalent generator circuit, the source impedance must be computed. This is accomplished by determining how the plate voltage varies with plate current at constant grid voltage as shown in Fig. 44B. The plate resistance is then

$$r_p = \frac{325 - 240}{(15 - 5) \times 10^{-3}} = 8500 \text{ ohms}$$

which must be considered to be in series with the controlled source of Fig. 43B.

It should be pointed out that the reasoning why this procedure is valid has not been presented. That is, why was the amplification factor defined as the ratio of a change in plate voltage to change in grid voltage at constant current? Unfortunately, the calculations involved, although not difficult, are somewhat sophisticated. Some knowledge of the subject of partial differential equations is required for the theoretical derivation of these parameters. However, an intuitive idea can be obtained from the following.

If the characteristics were completely linear, instead of being nonlinear as shown, the equivalent generator would not be affected by changes in plate current, but only by changes in grid voltage. For instance, if the plate current was increased from 10 to 17 mA (Fig. 44A), the amplification factor would be the equivalent of the change in voltage represented by the line cd divided by  $-2$ . However, since the length of cd is almost the same as that of ab (the difference in plate voltage for a  $-2$ -V change at 10 mA), it can be concluded  $\mu$  doesn't change very much — at least not in the center region of the characteristics.

Similar considerations hold for the plate resistance,  $r_p$ . It wouldn't matter if the curve for  $-4$  or  $-2$  V was picked (Fig. 44B), since the change in plate voltage vs. plate current would be approximately the same. Entities such as  $\mu$  and  $r_p$  are often called incremental or small-signal parameters. This means they are valid for small ac voltages or currents around some operating point, but less so for large variations in signal or for regions removed from the specified operating point. Also, such parameters are not closely related to dc voltage characteristics. For instance, a static plate resistance could be defined as the ratio of plate voltage to plate current. For the  $-3$ -V operating point chosen, the static plate resistance would be 280 divided by  $10 \times 10^{-2}$  or 28 k $\Omega$ . This is considerably different from the small-signal

plate resistance determined previously, which was 8500 ohms.

### Amplifier Gain

The ratio of the variation in voltage across the load resistance to change in input voltage is defined as the gain of the amplifier. For the equivalent circuit shown in Fig. 43B, this ratio would be

$$A = \frac{e_o}{e_{in}}$$

To solve for the gain, the first step is to determine the incremental plate current. This is just the source voltage divided by the total resistance of the circuit mesh or

$$i_p = \frac{47.5e_{in}}{10 + 8.5} \text{ mA}$$

The output voltage is then

$$e_o = i_p 10.$$

Combining these two equations gives

$$A = \frac{e_o}{e_{in}} = \frac{(47.5)(10)}{10 + 8.5} = 25.67$$

It is inconvenient to have the input and output voltages defined with opposite polarities as shown in Fig. 43B. Therefore, the gain becomes negative as illustrated in the triangle in Fig. 43C. A triangle is the standard way of representing an amplifier stage in block diagram form. The amplifier gain depends on the load resistance,  $R_L$ . A general formula for the gain of the circuit of Fig. 43B is

$$A = \frac{-\mu R_L}{r_p + R_L}$$

### Feedback

Being able to eliminate the equivalent circuit and use only one parameter such as the gain permits analysis of more complicated networks. A very important application occurs when part of the output energy of an amplifier is returned to the input circuit and gets amplified again. Since energy is being fed back into the input, the general phenomenon is called feedback. The manner in which feedback problems are analyzed is illustrated in Fig. 45. The output voltage is sampled by a network in the box marked beta and is multiplied by this term. This transformed voltage then appears in series with the input voltage,  $e_{in}$  which is applied to the input terminals of the amplifier (triangle with  $A_o$ ).  $A_o$  is defined as the open-loop gain. It is the ratio of the voltage that appears between terminals 3 and 4 when a voltage is applied to terminals 1 and 2. The circuit of Fig. 45 is an example of voltage feedback; a similar analysis holds for networks incorporating current feedback.

The closed-loop gain,  $A_c$ , can then be found by inspection of Fig. 45. From the

diagram, the output voltage must be

$$e_o = A_o(e_{in} + \beta e_o)$$

Rearranging terms gives

$$e_o(1 - \beta A_o) = A_o e_{in}$$

The closed-loop gain is defined by

$$A_c = \frac{A_o}{1 - \beta A_o} = \frac{e_o}{e_{in}}$$

### Cathode Bias

As an application of the feedback concept, consider the amplifier circuit shown in Fig. 46. It will be recalled that a bias battery was required in the previous example. A method of eliminating this extra source is to insert a small-value resistor in series with the cathode lead to ground (Fig. 46A). In terms of the amplifier block diagram, the circuit of Fig. 46B results. The next task is to evaluate the open-loop gain and the value of  $\beta$ .

With the exception of the cathode resistor, the circuit of Fig. 46 is the same as that of Fig. 43. Consequently, the ac plate current must be

$$i_p = \frac{-\mu e_{12}}{r_p + R_L + R_c}$$

The open-loop gain can then be determined from

$$\frac{e_o}{e_{12}} = A_o = \frac{-\mu R_L}{r_p + R_L + R_c}$$

Next,  $\beta$  is determined from the expression for output voltage

$$e_o = i_p R_L$$

and the feedback voltage, which is

$$e_f = i_p R_c$$

Then  $\beta$  is

$$\beta = \frac{e_f}{e_o} = \frac{i_p R_c}{i_p R_L} = \frac{R_c}{R_L}$$

Note that  $\beta$  is positive since if the path 1 to 2 is considered, the feedback voltage is added to the input signal. Substituting the values of  $\beta$  and  $A_o$  into the feedback equation gives

$$A_c = \frac{A_o}{1 - \frac{R_c}{R_L} A_o}$$

which after some manipulation becomes

$$A_c = \frac{-\mu R_L}{r_p + R_L + (1 + \mu) R_c}$$

Comparison of this equation with the one for the previous circuit with no cathode resistor reveals that the gain has decreased

because of the term  $(1 + \mu) R_c$  in the denominator. Such an effect is called negative or degenerative feedback.

On the other hand, if the feedback was such that the gain increased, regenerative or positive feedback would result. Positive feedback can be either beneficial or detrimental in nature, and the study of feedback is an important one in electronics. For instance, frequency generation is possible in a circuit called an oscillator. But on the other hand, unwanted oscillation or instability in an amplifier is very undesirable.

### Oscillators

A special case of feedback occurs if the term  $1 - \beta A_o$  becomes zero. This would mean the closed-loop gain would become infinite. An implication of this effect is that a very small input signal would be amplified and fed back and amplified again until the output voltage became infinite. Either that, or amplifier output would exist with no signal input. Random noise would trigger the input into producing output.

Of course, an infinite output voltage is a physical impossibility and circuit limitations such as the nonlinearities of the active device would alter the feedback equation. For instance, at high output voltage swings, the amplifier would either saturate (be unable to supply more current) or limit (be cut off because the grid was too negative), and  $A_o$  would decrease.

It should be stressed that it is the product of  $\beta A_o$  that must be 1.0 for oscillations to occur. In the general case, both  $\beta$  and  $A_o$  may be complex numbers unlike those of the cathode-bias problem just discussed. That is, there is a phase shift associated with  $A_o$  and  $\beta$  with the phase shift of the product being equal to the sum of the individual phase shifts associated with each entity.

Therefore, if the total phase shift is  $180^\circ$  and if the amplitude of the product is 1.0, oscillations will occur. At low frequencies, these conditions normally are the result of the effect of reactive components. A typical example is shown in Fig. 47; the configuration is called a tuned-plate tuned-grid oscillator. If the input circuit consisting of  $L_1$  and  $C_1$  is tuned to a frequency  $f_o$ , with the output circuit ( $L_2$ ,  $C_2$ ) tuned to the same frequency, a high impedance to ground will exist at the input and output of the amplifier. Consequently, a small capacitance value represented by  $C_f$  is capable of supplying sufficient voltage feedback from the plate to the grid.

At other frequencies, or if either circuit is detuned, oscillations may not occur. For instance, off-resonant conditions in the output tank will reduce the output voltage and in effect, reduce the open-loop gain to the point where oscillations will cease. On the other hand, if the input circuit is detuned far from  $f_o$ , it will present a low impedance in series with the relatively high reactance of  $C_f$ . The voltage divider thus formed will result in a small value for  $\beta$  and

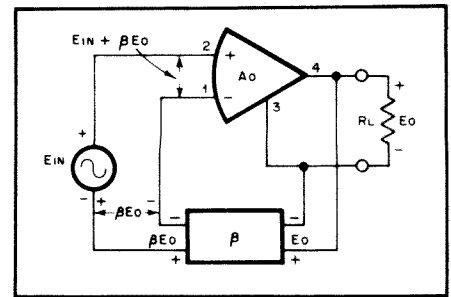

Fig. 45 — Network illustrating voltage feedback.

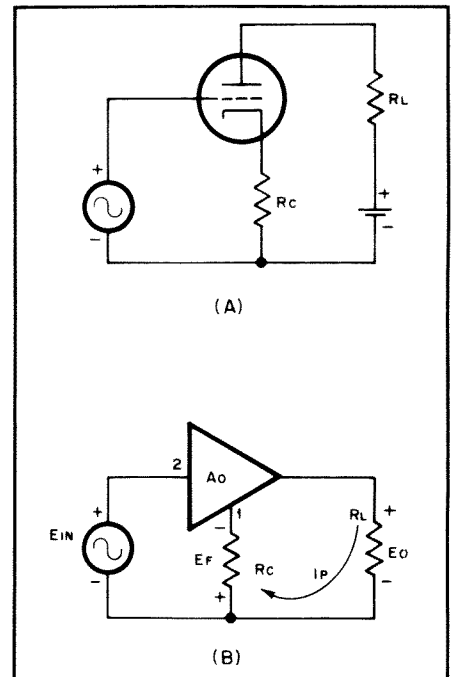

Fig. 46 — Feedback example of an amplifier with cathode bias.

Fig. 47 — Tuned-plate tuned-grid oscillator.

the conditions for oscillations will not be fulfilled. However, for conditions near  $f_o$ , both the amplitude and phase of the  $\beta A_o$  product will be correct for oscillations to occur.

Under some conditions, the voltage across the tank circuit may be sufficient to cause the grid to be driven positive with respect to the cathode, and grid current will flow through  $C_g$ . During the rest of the RF cycle,  $C_g$  will discharge through  $R_g$ , causing a negative bias voltage to be ap-

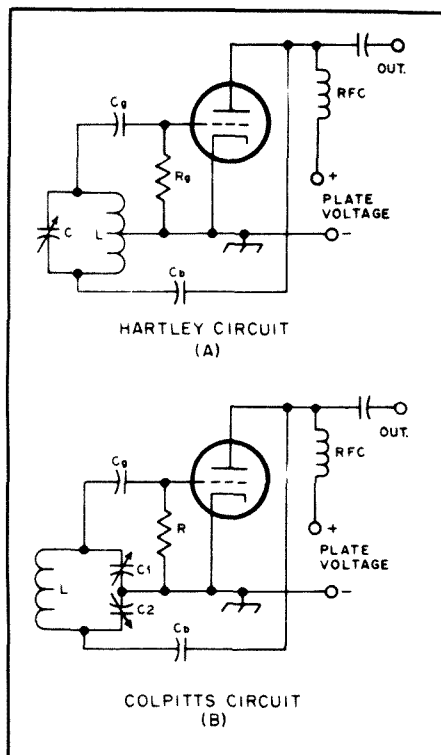

Fig. 48 — Hartley and Colpitts oscillators.

plied to the grid. This bias voltage sets the operating point of the oscillator and prevents excessive current flow.

Two other common type of oscillators are shown in Fig. 48. In Fig. 48A, feedback voltage is applied across a tapped inductor while in Fig. 48B, the voltage is applied across a capacitor instead. Quite often, a tuned plate circuit is not employed and an RF choke coil provides a high impedance load instead.

### Classes of Amplifier Service

The amplifiers discussed so far have been described mostly in terms of ideal linear gain blocks. Class-A amplifiers, with or without negative feedback, reproduce the input signal with the greatest fidelity or least distortion. They accomplish this at the expense of poor power efficiency, meaning the signal power delivered to the load is usually only a small fraction of the dc power taken from the power supply. The remainder must be dissipated as heat. The maximum theoretical efficiency for a class-A amplifier is 50 percent, with 25 percent being a more typical figure. One factor preventing the theoretical maximum efficiency from being realized is that a practical amplifying device cannot be a perfect conductor — it will have a finite minimum voltage drop that prevents the full power supply potential from being impressed across the load. The operating point for a class-A amplifier is chosen to permit power supply current to flow over the entire 360° of the input signal cycle, and the average supply current does not vary with the signal level.

An advantage of a class-A amplifier, aside from nearly perfect input waveform reproduction (linearity), is that it requires minimal energy from the signal source. So while the power efficiency is poor, the power gain can be extremely high. The amplifier described in Figs. 43 and 44 operates in class-A.

An amplifier operating in class-B is biased so that no power supply current flows without an input signal applied. Current is taken from the supply over exactly 180° of the input signal cycle. A single-ended class-B amplifier that works only into a resistor for a load is, in effect, a half-wave rectifier (see Chapter 6), because one half of the input cycle is duplicated in the output and the other half is absent. This type of circuit finds some application as a rectifier or detector in radio work, but the distortion would be intolerable if it were used as an audio amplifier.

Class-B amplifiers can be used in low-distortion applications, however. Two class-B devices can be combined in a push-pull circuit. The two input terminals are driven 180° out of phase, so the amplifying devices conduct on opposite half cycles of the input signal. The output terminals are similarly coupled out of phase (usually by means of a transformer) to reproduce the input waveform faithfully.

A single-ended class-B stage is suitable for linear RF amplification if the load is a tuned circuit having a Q of five or better. The flywheel (ringing) effect of the tank circuit supplies the missing half of the output cycle. The efficiency of this type of amplifier is typically 60 percent.

An amplifier that is biased so as to conduct over the entire cycle for small input signals but at a reduced angle for large signals is a class-AB amplifier. The operating point is adjusted for the desired compromise among efficiency, power gain and linearity.

The output terminal of a single-device class-A, AB or B amplifier operated without negative feedback acts as a current source. This means that the instantaneous power supply current is essentially independent of the supply potential and is determined by the input signal amplitude. When an amplifying device is driven into saturation, that is, increasing the input amplitude causes no further increase in output, the output terminal no longer approximates a current source. Instead, the output terminal becomes "ohmic," meaning that the supply current varies approximately linearly with the supply voltage.

The signal output voltage also varies linearly with the supply voltage. This effect is highly useful in an important mode of radiotelephony. The saturated amplifier just described is called class-C. Its operating point is selected to allow power supply current to flow only in narrow pulses corresponding to the peaks of the input signal. Class-C amplifiers are extremely

nonlinear, and the harmonics produced in the wave form distortion process make the class-C amplifier useful as a frequency multiplier. High-Q tank circuits are required to suppress unwanted frequency components generated by a class-C stage.

Apart from its utility as an amplitude modulated amplifier or a frequency multiplier, the principal asset of a class-C amplifier is high power efficiency. The practical efficiency in straight amplifier service can run as high as 85 percent, but considerable drive power is required from the signal source, so the power gain is not as high as can be obtained in class-A or B. In multiplier service the maximum theoretical efficiency is the reciprocal of the harmonic number.

Still higher efficiency can be obtained from class-D and class-E amplifiers. In these circuits the active devices act as saturated switches that are controlled by the input signal. The class-E RF circuit is a recent development (1970s) by WA1HQC that yields high efficiency in an interesting way: The single active device switches the supply current through the load at critical points of the waveform. The output waveform is such that the electronic switch does not conduct current and withstand voltage simultaneously, resulting in very little energy waste. As in the class-C case, this output waveform is rich in harmonics, which must be filtered carefully.

### Glossary of Radio Terms

- active — As used in active filter or active device: A device or circuit that requires an operating voltage. (See passive.)
- analog — A term used in computer work, meaning a system which operates with numbers represented by directly measurable quantities (analog readout mechanical dial system. See digital).
- attenuator — A passive network that reduces the power level of a signal without introducing appreciable distortion.
- balun — Balanced to unbalanced-line transformer.
- bank wound — Pertaining to a coil (inductor) that has two or more layers of wire, each being wound over the top of the preceding one. (See solenoid.)
- bandpass — A circuit or component characteristic that permits the passage of a single band of frequencies while attenuating those frequencies above and below that frequency band.
- band-reject — A circuit or device that rejects a specified frequency band while passing those frequencies that lie above and below the rejected band (opposite of band-pass). Sometimes called band-rejection, as applied to a filter.
- bandwidth — The frequency width of circuit or component, such as a band-pass filter or tuned circuit. Usually measured at the half-power points of the response curve (−3 dB points).
- base loading — Applies to vertical anten-

- nas for mobile and fixed-location use; an inductance placed near the ground end of a vertical radiator to change the electrical length. With variations the inductor aids in impedance matching.
- bifilar — Two conducting elements used in parallel; for example, two parallel wires wound on a coil form.
- bilateral — Having two symmetrical sides or terminals; a filter (as one example) that has a 50-ohm characteristic at each port, with either port suitable as the input or output one.
- bias — To influence current to flow in a specified direction by means of dc voltage; forward bias on a transistor stage, or grid bias on a tube type of amplifier.
- blanker — A circuit or device that momentarily removes a pulse or signal so it is not passed to the next part of a circuit; a noise blanker. Not to be confused with clipper, which clips part of a pulse or waveform.
- bridge — An electrical instrument used for measuring or comparing inductance, impedance, capacitance or resistance by comparing the ratio of two opposing voltages to a known ratio; to place one component in parallel with another; to join to conductors or components by electrical means.
- broadband — A device or circuit that is broadband has the capability of being operated over a broad range of frequencies. A broadband antenna is one example.
- cascade — One device or circuit that directly follows another; two or more similar devices or circuits in which the output of one is fed to the input of the succeeding one (tandem).
- cascode — Two-stage amplifier having a grid-driven (or common-emitter or source) input circuit and a grounded-grid (or common base or gate) output circuit.
- chip — Slang term for an integrated circuit, meaning a chip of semiconductor material upon which an IC is formed.
- clamp — A circuit that maintains a predetermined characteristic of a wave at each occurrence so that the voltage or current is clamped or held at a specified value.
- clipper — A device or circuit that limits the instantaneous value of a wave form or pulse to a predetermined value (see blanker).
- closed loop — A signal path that includes a forward route, a feedback path, and a summing point which provides a closed circuit. In broad terms, an amplifying circuit providing voltage or power gain while being terminated correctly at the input and output ports, inclusive of feedback.
- cold end — The circuit end of a component that is connected to ground or is bypassed for ac or RF voltage (the grounded end of a coil or capacitor).
- common-mode signal — The instantaneous algebraic average of two signals applied to a balanced circuit, both signals being referred to a common reference.
- composite — Made of a collection of distinct components; a complete (composite) circuit rather than a discrete part of an overall circuit.
- conversion loss/gain — Relating to a mixer circuit from which less output energy is taken than is supplied at the input-signal port (loss); when a mixer delivers greater signal output than is supplied to the input-signal port (gain).
- converter — A circuit used to convert one frequency to another. In a receiver the converter stage converts the incoming signals to the intermediate frequency.
- core — An element made of magnetic material, serving as part of a path for magnetic flux.
- damping — A progressive reduction in amplitude of a wave with respect to time (usually referenced to microseconds or milliseconds); a device or network added to a circuit to damp unwanted oscillations.
- decay time — The period of time during which the stored energy or information decays to a specified value less than its initial value, such as the discharge time of a timing network.
- decibel (dB) — A logarithmic expression of power ratio; also used as an expression of voltage ratios, provided the voltages appear across identical values of resistance or impedance. A decibel is 1/10 of a bel, and represents the smallest change in the power level of an audio tone that the human ear can detect.
- decoder — A device or circuit that translates a combination of signals into a single signal representing that combination. One such circuit is that used for decoding the output signal of a DTMF pad.
- differential amplifier — An amplifier with an output signal that is proportional to the algebraic difference between two input signals (sometimes called a difference amplifier).
- digital — Refers to signals having or circuits that work with a finite number of discrete levels or states, as opposed to an analog signal which may have an infinite number of levels.
- diplexing — The simultaneous transmission or reception of two signals while using a common antenna, made possible by using a device called a diplexer. Used in TV broadcasting to transmit visual and aural carriers by means of a single antenna.
- discrete — A single device or circuit (a transistor as opposed to an IC). (See composite.)
- dish — An antenna reflector for use at VHF and higher that has a concave shape. For example, a part of a sphere or paraboloid.
- Doppler — The phenomenon evidenced by the change in the observed frequency of a wave in a transmission system caused by a time rate of change in the effective length of the path of travel between source and the point of observation.
- drift — A change in component or circuit operation over time.
- drive — RF energy applied at the input of an RF amplifier (RF driving power or voltage).
- DTMF — Dual-tone multifrequency, such as a DTMF pad, which is sometimes called a Touch-Tone® pad.
- duplex — Simultaneous two-way independent transmission and reception in both directions.
- duplexer — A device that permits simultaneous transmission and reception of related signal energy while using a common antenna (see diplexing).
- dynamic range — Difference in decibels between the overload level and minimum discernible signal level (MDS) in a system, such as a receiver. Parameters include desensitization point and distortion products as referenced to the receiver noise floor.
- EME — Earth-moon-earth. Communications carried on by bouncing signals off the lunar surface. Commonly referred to as moonbounce.
- empirical — Not based on mathematical procedures; experimental endeavor during design or modification of a circuit. Founded on case-history experience or intuition.
- enabling — The preparation of a circuit for a subsequent function (enabling pulse or signal).
- encoder — A circuit or device which changes discrete inputs into coded combinations of outputs. A DTMF pad is an encoder.
- excitation — Signal energy used to drive a transmitter stage (see drive). Voltage applied to a component to actuate it, such as the field coil or a relay.
- Faraday rotation — Rotation of the plane of polarization of an electromagnetic wave when traveling through a magnetic field. In space communications this effect occurs when signals traverse the ionosphere.
- feedback — A portion of the output voltage being fed back to the input of an amplifier. Description includes ac and dc voltage which can be used separately or together, depending on the particular circuit.
- feedthrough — Energy passing through a circuit or component, but not usually desired. A type of capacitor which can be mounted on a chassis or panel wall to permit feeding through a dc voltage while bypassing ac or RF to ground. Sometimes called a coaxial capacitor.
- ferromagnetic — Material that has a relative permeability greater than unity and requires a magnetizing force. (Ferrite and powdered-iron rods and toroids).
- finite — Having a definable quantity; a

- finite value of resistance or other electrical measure.
- flip-flop** — An active circuit or device that can assume either of two stable stages at a given time, as dictated by the nature of the input signal.
- floating** — A circuit or conductor that is above ac or dc ground for a particular reason. Example: A floating ground bus which is not common to the circuit chassis.
- gate** — A circuit or device, depending on the nature of the input signal, which can permit the passage or blockage of a signal or dc voltage.
- GDO** — Abbreviation for a grid-dip or gate-dip oscillator (test instrument).
- ground loop** — A circuit-element condition (PC board conductor, metal chassis or metal cabinet wall) that permits the unwanted flow of ac from one circuit point to another.
- half-power point** — The two points on a response curve that are 3 dB lower in level than the peak power. Sometimes called the 3dB bandwidth.
- Hall effect** — The change of the electric conduction caused by the component of the magnetic field vector normal to the current density vector, which instead of being parallel to the electric field, forms an angle with it.
- high end** — Refers generally to the hot (RF or dc) end of a component or circuit; the end opposite the grounded or bypassed end (see cold end).
- high level** — The part of a circuit which is relatively high in power output and consumption as compared to the small signal end of a circuit. Example: A transmitter PA stage is the high-level amplifier, as might be the driver also.
- high pass** — Related mainly to filters or networks which are designed to pass energy above a specified frequency, but attenuate or block the passage of energy below that frequency.
- high-Z** — The high-impedance part of a circuit; a high-impedance microphone; a high-impedance transformer winding.
- hot end** — see high end.
- hybrid** — A combination of two generally unlike things; a circuit that contains transistors and tubes, for example.
- ideal** — A theoretically perfect circuit or component; a lossless transformer or device that functions without any faults.
- insertion loss** — That portion of a signal current or voltage that is lost as it passes through a circuit or device. The loss of power through a filter or other passive network.
- interpolate** — To estimate a value between two known values.
- leakage** — The flow of signal energy beyond a point at which it should not be present. Example: Signal leakage across a filter because of poor layout (stray coupling) or inadequate shielding.
- linear amplification** — The process by which a signal is amplified without altering the characteristic of the input waveform. Class-A, AB and B amplifiers are generally used for linear amplification.
- load** — A circuit or component that receives power; the power delivered to such a circuit or component. Example: A properly matched antenna is a load for a transmitter.
- loaded** — A circuit is said to be loaded when the desired power is being delivered to a load.
- logic** — Decision-making circuitry of the type found in computers.
- long wire** — A horizontal wire antenna that is one wavelength or greater in size. A long piece of wire (less than one wavelength) does not qualify as a long wire.
- low end** — see cold end.
- low level** — Low-power stage or stages of a circuit as referenced to the higher-power stages (see high level).
- low pass** — A circuit property that permits the passage of frequencies below a specified frequency but attenuates or blocks those frequencies above that frequency (see high pass).
- low-Z** — Low impedance (see high-Z).
- mean** — A value between two specified values; an intermediate value.
- master oscillator** — The primary oscillator for controlling a transmitter or receiver frequency. Can be a VFO (variable-frequency oscillator), VXO (variable crystal oscillator), PTO (permeability-tuned oscillator), PLL (phase-locked loop), LMO (linear master oscillator) or frequency synthesizer.
- microwaves** — AC signals having frequencies greater than about 1000 MHz.
- modulation index** — The ratio of the frequency deviation of the modulated wave to the frequency of the modulating signal.
- narrowband** — A device or circuit that can be operated only over a narrow range of frequencies. Low-percentage bandwidth.
- network** — A group of components connected together to form a circuit that will conduct power, and in most examples effect an impedance match. Examples: An LC matching network between stages of a transistorized transmitter.
- noise figure** — Of a two-port transducer the decibel ratio of the total noise power to the input noise power, when the input termination is at the standard temperature of 290 K.
- nominal** — A theoretical or designated quantity that may not represent the actual value. Sometimes referred to as the ball-park value.
- op amp** — Operational amplifier. A high-gain, feedback-controlled amplifier. Performance is controlled by external circuit elements.
- open loop** — A signal path that does not contain feedback (see closed loop).
- parameter** — The characteristic behavior of a device or circuit, such as the current gain of a 2N5109 transistor.
- parametric amplifier** — Synonym for reactance amplifier. An inverting parametric device for amplifying a signal without frequency translation from input to output. Used for low-noise UHF and microwave amplification.
- parasitic** — Unwanted condition or quantity, such as parasitic oscillations or parasitic capacitance; additional to the desired characteristic.
- passive** — Operating without an operating voltage. Example: An LC filter that contains no amplifier, or a diode mixer.
- PEP** — Peak envelope power; maximum amplitude that can be obtained with any combination of signals.
- permeability** — A term used to express relationships between magnetic induction and magnetic force.
- pill** — Slang expression for a transistor or an IC.
- PL** — Private Line, such as a repeater accessed by means of a specified tone.
- PLL** — Phase-locked loop.
- port** — The input or output terminal of a circuit or device.
- prototype** — A first full-scale working version of a circuit design.
- Q<sub>L</sub>** — Loaded Q of a circuit.
- Q<sub>u</sub>** — Unloaded Q of a circuit.
- quagi** — An antenna consisting of both full-wavelength loops (quad) and Yagi elements.
- resonator** — A general term for a high-Q resonant circuit, such as an element of a filter.
- return** — That portion of a circuit which permits the completion of current flow, usually to ground; a ground return.
- ringing** — The generation of an audible or visual signal by means of oscillation or pulsating current; the annoying sound developed in some audio filters when the Q is extremely high.
- ripple** — Pulsating current. Also, the gain depressions that exist in the flat portion of a band-pass response curve (above the -3 dB points on the curve). Example: Passband ripple in the nose of an IF filter response curve.
- rise time** — The time required for a pulse or waveform to reach a specified value from some smaller specified value. The specified values are typically 10 and 90 percent of the peak amplitude.
- RMS** — Root mean square. The square root of the mean of the square of the voltage or current during a complete cycle.
- rotor** — A moving rotary component within a rotation-control device. Examples include the moving plates of a variable capacitor and the armature of an alternator. Not to be confused with an antenna rotator, which is the total assembly.
- saturation** — A condition that exists when a further change in input produces no additional output (a saturated amplifier).
- selectivity** — A measure of circuit capability

- ty to separate the desired signal from those at other frequencies.
- shunt** — A device placed in parallel with or across part of another device. Examples: meter shunts, shunt-fed vertical antennas and a capacitor placed (shunted) across another capacitor.
- solenoidal** — A single-layer coil of wire wound to form a long cylinder.
- spectral purity** — The relative freedom of an emission from harmonics, spurious signals and noise.
- standing-wave ratio** — The ratio of the maximum to minimum voltage or current on a transmission line at least a quarter-wavelength long.
- strip** — General term for two or more stages of a circuit that in combination perform a particular function. Examples: a local-oscillator strip, an audio strip or an IF strip.
- subharmonic** — A frequency that is an integral submultiple of a frequency to which it is referred. A misleading term that implies that subharmonic energy can be created along with harmonic energy (not true). More aptly, a 3.5-MHz VFO driving a 40-meter transmitter, with 3.5-MHz leakage at the output, qualifying as a subharmonic.
- tank** — A circuit consisting of inductance and capacitance, capable of storing electrical energy over a band of frequencies continuously distributed about a single frequency at which the circuit is said to be resonant, or tuned.
- toroidal** — Doughnut-shaped physical format, such as a toroid core.
- transducer** — A device which is used to transport energy from one system (electrical, mechanical or acoustical) to another. Example: A loudspeaker or phonograph pickup.
- transceiver** — A combination transmitter and receiver that uses some parts of the circuit for both functions.
- Transmatch** — An LC network used to effect an impedance match between a transmitter and a feed line to an antenna.
- transmission line** — One or more conductors used to convey ac energy from one point to another, as from a radio station to its antenna.
- transverter** — A converter that permits transmitting and receiving at a specified frequency apart from the capability of the transceiver to which it is connected as a basic signal source. Example: a 2-meter transverter used in combination with an HF-band transceiver.
- trap** — A device consisting of L and C components that permits the blockage of a specified frequency while allowing the passage of other frequencies. Example: a wave trap or an antenna trap.
- trifilar** — Same as bifilar, but with three parallel conductors.
- trigger** — To initiate action in a circuit by introducing an energy stimulus from an external source, such as a scope trigger.
- U** — Symbol for unrepairable assembly, such as an integrated circuit (U1, U2, etc.).
- unloaded** — The opposite condition of loaded.
- varactor** — A two-terminal semiconductor device (diode) which exhibits a voltage-dependent capacitance. Used primarily as a tuning device or frequency multiplier at VHF and UHF.
- VCO** — Voltage-controlled oscillator. Uses tuning diodes that have variable dc applied to change their junction capacitances.
- VSWR** — Voltage standing-wave ratio. (See standing-wave ratio).
- VU** — Volume unit.
- VXO** — Variable crystal oscillator.
- wave** — A periodically varying electromagnetic field radiated from a conductor.
- waveguide** — A hollow conducting tube used to convey microwave energy.
- wavelength** — The distance between the two points of corresponding phase of two consecutive cycles of an electromagnetic signal.
- X** — The symbol for reactance.
- Zener diode** — A diode used to regulate voltage or function as a clamp or clipper. Named after the inventor.
- Z** — Symbol for a device or circuit that contains two or more components. Example: A parasitic suppressor that contains a resistor and an inductor in parallel (Z1, Z2, etc.). Z is also the symbol for impedance.

# Solid-State Basics

**S**olid-state devices are also called semiconductors. The prefix semi means half. They have electrical properties between those of conductors and those of insulators.

The conductivity of a material is proportional to the number of free electrons in the material. Pure germanium and pure silicon crystals have relatively few free electrons. If, however, carefully controlled amounts of impurities (materials having a different atomic structure, such as arsenic or antimony) are added, the number of free electrons, and consequently the conductivity, is increased. When certain other impurities are introduced (such as aluminum, gallium or indium), an electron deficiency, or hole, is produced. As in the case of free electrons, the presence of holes encourages the flow of electrons in the semiconductor material, and the conductivity is increased. Semiconductor material that conducts by virtue of the free electrons is called N-type material; material that conducts by virtue of an electron deficiency is called P-type.

## Electron and Hole Conduction

If a piece of P-type material is joined to a piece of N-type material as at A in Fig. 1 and a voltage is applied to the pair as at B, current will flow across the boundary or junction between the two (and also in the external circuit) when the battery has the polarity indicated. Electrons, indicated by the minus symbol, are attracted across the junction from the N material through the P material to the positive terminal of the battery. Holes, indicated by the plus symbol, are attracted in the opposite direction across the junction by the negative potential of the battery. Thus, current flows through the circuit by means of electrons moving one way and holes the other.

If the battery polarity is reversed, as at C, the excess electrons in the N material are attracted away from the junction and the holes in the P material are attracted by the negative potential of the battery away from the junction. This leaves the junction region without any current carriers; consequently, there is no conduction.

In other words, a junction of P- and N-type materials constitutes a rectifier. It differs from the vacuum-tube diode rectifier

in that there is a measurable, although comparatively very small, reverse current. The reverse current results from the presence of some carriers of the type opposite to those that principally characterize the material.

With the two plates separated by practically zero spacing, the junction forms a capacitor of relatively high capacitance. This places a limit on the upper frequency at which semiconductor devices of this construction will operate, as compared with vacuum tubes. Also, the number of excess electrons and holes in the material depends on temperature, and since the conductivity in turn depends on the number of excess holes and electrons, the device is more temperature sensitive than is a vacuum tube.

Capacitance may be reduced by making the contact area very small. This is done by means of a point contact, a tiny P-type region being formed under the contact point during manufacture when N-type material is used for the main body of the device.

## SEMICONDUCTOR DIODES

The vacuum-tube diode has been replaced in modern equipment designs. Semiconductor diodes are more efficient because they do not consume filament power. They are much smaller than tube diodes. In low-level applications they operate cooler than tubes do. Solid-state diodes are superior to tube types in that solid-state diodes operate into the microwave region, while most vacuum-tube diodes are not practical at frequencies above 50 MHz.

Semiconductor diodes fall into two main categories, structurally. Although they can be made from silicon or germanium crystals, they are usually classified as PN junction diodes or point-contact diodes. These formats are illustrated in Fig. 2. Junction diodes are used from dc to the microwave region, but point-contact diodes are intended primarily for RF applications. The internal capacitance of a point-contact diode is considerably less than that of a junction diode designed for the same circuit application. As the operating frequency is increased the unwanted internal and external capacitance of a diode becomes

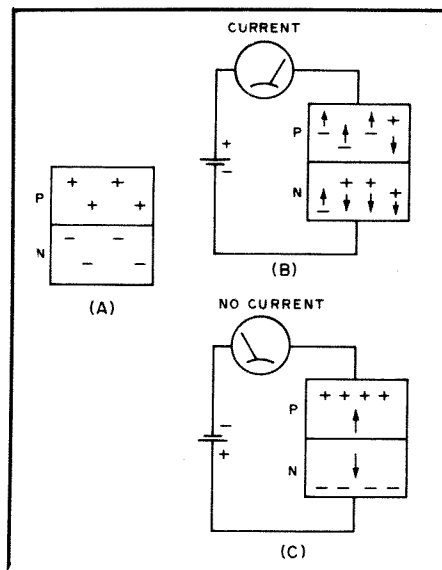

Fig. 1 — A PN junction (A) and its behavior when conducting (B) and nonconducting (C).

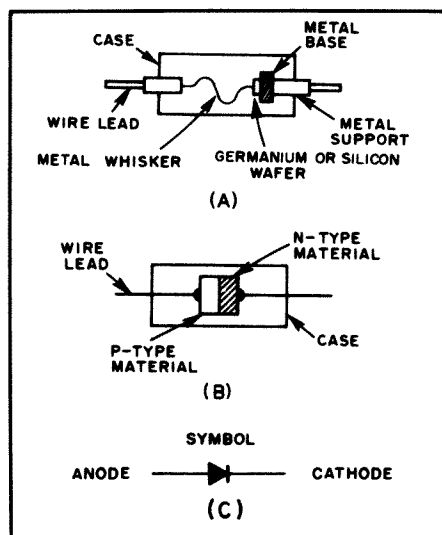

Fig. 2 — A point-contact type of diode is shown at A. A junction diode is depicted at B and the diode symbol is at C. The cathode end is usually indicated by a band on the body of the device.

more troublesome to the designer. Where a given junction type of diode may exhibit a capacitance of several picofarads, the

point-contact device will have an internal capacitance of 1 pF or less.

### Selenium Diodes

Power rectifiers made from selenium were in common use in ac power supplies before 1965. Selenium diodes are characterized by high forward voltage drop (which increases with diode age) and high reverse leakage current. The voltage drop causes the device to dissipate power, and a typical rectifier stack has large cooling fins. An additional shortcoming of selenium rectifiers is that they sometimes emit toxic fumes when they burn out. When replacing selenium diodes with silicon units, be certain that the filter capacitors (and the entire equipment) can withstand the higher output voltage. Some early solar cells were made of selenium, but silicon devices have taken over this area, too.

### Germanium Diodes

The germanium diode is characterized by a relatively large current flow when small amounts of voltage are applied in the forward direction (Fig. 1). Small currents will flow in the reverse (back) direction for much larger applied voltages. A representative curve is shown in Fig. 3. The dynamic resistance in either the forward or back direction is determined by the change in current that occurs, at any given point on the curve, when the applied voltage is changed by a small amount. The forward resistance will vary somewhat in the region of very small applied voltages. However, the curve is mostly straight, indicating a relatively constant dynamic resistance. For small applied voltages the resistance is on the order of 200 ohms or less.

The back resistance exhibits considerable variation and depends on the specific applied voltage during the test. It may vary from a few thousand ohms to well over a megohm. The back resistance of a germanium diode is considerably lower than that of a silicon diode. The back resistance for silicon is greater than a megohm in most instances, but the germanium diode is normally less than a megohm.

### Common Silicon Diodes

Apart from the fact that silicon P and N materials are used in the formation of a silicon junction diode, the characteristics of these devices are similar to those of germanium diodes. The voltage/current curves of Fig. 3 are representative.

The junction barrier voltage for silicon diodes is somewhat higher (approximately 0.7 volt) than that of a germanium diode (about 0.3 volt). The majority of the diodes in use today fall into the silicon class. They are rugged and reliable from RF small-signal applications to dc power use.

Silicon diodes are available in ratings of 1000 volts (PIV) or greater. Many of these diodes can accommodate dc in excess of 100 amperes. The primary rule in pre-

venting damage to any diode is to operate the device within the maximum ratings specified by the manufacturer. The device temperature is one of the important parameters. Heat sinks are used with diodes that must handle large amounts of power, thereby holding the diode junction temperature at a safe level.

The behavior of junction diodes under varying temperatures is of interest to designers of circuits that must perform over some temperature range. The relationship between forward bias current, forward bias voltage and temperature is defined by the classic diode equation:

$$I_f = I_s \left( e^{\frac{qV}{kT}} - 1 \right)$$

where  $q$  is the fundamental electronic charge ( $1.6 \times 10^{-19}$  coulombs),  $V$  is the bias potential,  $k$  is Boltzmann's constant ( $1.38 \times 10^{-23}$  joules/kelvin), kelvin = °Celsius + 273),  $t$  is the junction temperature in kelvins,  $I_s$  is the reverse-bias saturation current,  $I_f$  is the forward-bias current and  $e$  is the natural logarithmic base (2.718). The ratio  $q/k$  is approximately 11,600, so the diode equation can be written:

$$I_f = I_s \left( e^{\frac{11,600V}{t}} - 1 \right) \quad (\text{Eq. 1})$$

It is useful to have an expression for the voltage developed across the junction when the forward current is held constant. To obtain such an expression we must solve the diode equation for  $V$ . Expanding the right side of Eq. 1 yields:

$$I_f = I_s e^{\frac{11,600V}{t}} - I_s \quad (\text{Eq. 2})$$

Adding  $I_s$  to both sides gives:

$$I_f + I_s = I_s e^{\frac{11,600V}{t}} \quad (\text{Eq. 3})$$

Dividing through by  $I_s$  produces:

$$\frac{I_f}{I_s} + 1 = e^{\frac{11,600V}{t}} \quad (\text{Eq. 4})$$

which implies

$$\frac{11,600V}{t} = \ln \left( \frac{I_f}{I_s} + 1 \right) \quad (\text{Eq. 5})$$

Multiplying each term by  $\frac{t}{11,600}$

leaves:

$$V = \frac{t}{11,600} \ln \left( \frac{I_f}{I_s} + 1 \right) \quad (\text{Eq. 6})$$

The undetermined quantity in Eq. 6 is  $I_s$ , the reverse saturation current. In ordinary silicon signal diodes this current approximately doubles with each 4.5 kelvin-temperature increase. A mathematical ex-

Fig. 3 — Typical point-contact diode (germanium) characteristic curve. Because the back current is much smaller than the forward current, a different scale is used for back voltage and current.

pression for this behavior as a function of temperature is:

$$I_{s(t)} = 2I_{s(t-4.5)} \quad (\text{Eq. 7})$$

At room temperature (300 kelvins), the reverse saturation current is on the order of  $10^{-13}$  amperes. Eq. 7 describes a phenomenon similar to radioactive decay, where the 4.5-kelvin current-doubling interval is analogous to the half-life of a radioactive substance. This equation with the given initial condition sets up an initial-value problem, the solution of which is:

$$I_{s(t)} = 10^{-13} e^{\frac{(t-300)\ln 2}{4.5}} \quad (\text{Eq. 8})$$

Substituting this expression for  $I_s$  into Eq. 6 produces the diode voltage drop as a function of temperature for a constant current:

$$V(t) = \frac{t}{11,600} \times \ln \left[ \frac{I_f}{10^{-13} e^{\frac{(t-300)\ln 2}{4.5}}} + 1 \right] \quad (\text{Eq. 9})$$

The temperature coefficient of the junction potential can be obtained from the partial derivative of  $V$  with respect to  $t$ , but it's a simple matter (with the aid of a pocket calculator) to extract the information directly from Eq. 9. If the forward current is fixed at 1 milliamperes, the diode drop at room temperature is 0.5955 volts. This potential decreases at an initial rate of 2 millivolts per kelvin. The temperature coefficient gradually increases to 3 millivolts per kelvin at 340 kelvins. While the temperature curve isn't linear, it is gradual enough to be considered linear over small intervals. When the bias current is increased to 100 milliamperes, the room temperature junction potential increases to 0.7146 volts as might be expected, but the temperature coefficient stays well-behaved. The initial potential decrease is 1.6 millivolts per

kelvin, and this value increases to 2.5 millivolts per kelvin at 340 kelvins.

The significance of the very minor dependence of temperature coefficient on bias current is that it isn't necessary to use an elaborate current regulator to bias diodes used in temperature-compensation applications. The equations defining the behavior of junction diodes are approximations. Some of the voltages were expressed to five significant figures so the reader can verify his calculations, but this much precision exceeds the accuracy of the approximations.

### Diodes as Switches

Solid-state switching is accomplished easily by using diodes or transistors in place of mechanical switches or relays. The technique is not a complicated one at dc and audio frequencies when large amounts of power are being turned on and off, or transferred from one circuit point to another.

Examples of shunt and series diode switching are given in Fig. 4. The illustration at A shows a 1N914 RF-switching diode as a shunt on-off element between C1 and ground. When +12 volts is applied to D1 through R1, the diode saturates and effectively adds C1 to the oscillator tank circuit. R1 should be no less than 2200 ohms in value to prevent excessive current flow through the diode junction ( $I_{\max} = 12 \text{ V} / 2200 \Omega$ ).

Series diode switching is shown in Fig. 4B. In this example the diode, D1, is inserted in the audio signal path. When S1 is in the ON position the diode current path is to ground through R2, and the diode saturates to become a closed switch. When S1 is in the OFF state R1 is grounded and +12 volts is applied to the diode cathode. In this mode D1 is back biased (cut off) to prevent audio voltage from reaching the transistor amplifier. This technique is useful when several stages in a circuit are controlled by a single mechanical switch or relay. RF circuits can also be controlled by means of series diode switching.

A significant advantage to the use of diode switching is that long signal leads are eliminated. The diode switch can be placed directly at the circuit point of interest. The dc voltage that operates it can be at some convenient remote point. The diode recovery time (switching speed) must be chosen for the frequency of operation. In other words, the higher the operating frequency the faster the switching speed required. For dc and audio applications one can use ordinary silicon power-supply rectifier diodes.

### Diodes as Gates

Diodes can be placed in series with dc leads to function as gates. Specifically, they can be used to allow current to flow in one direction only. An example of this technique is given in Fig. 5A.

A protective circuit for the solid-state transmitter is effected by the addition of

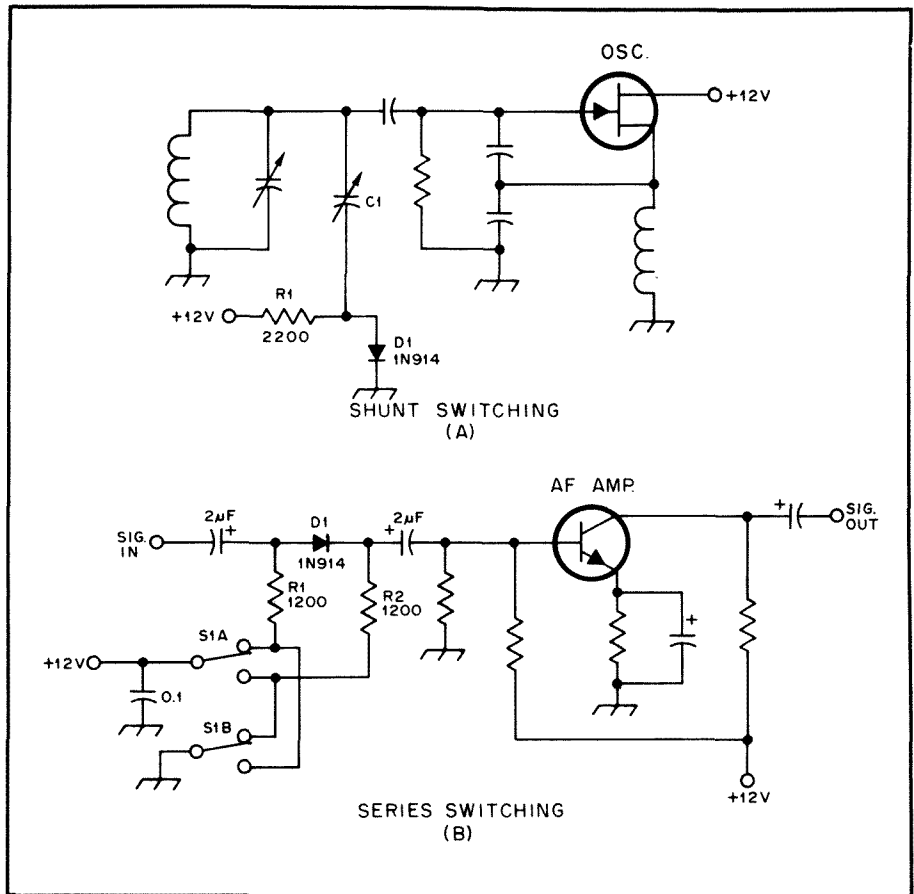

Fig. 4 — A silicon-switching diode, D1, is used at A to place C1 in the circuit. At B is shown a series switch with D1 in the signal path.

D1 in the 13.6-volt dc line to the equipment. The diode allows the flow of positive current, but there will be a drop of approximately 0.7 volt across the diode, requiring a supply voltage of 14.3. Should the operator mistakenly connect the supply leads in reverse, current will not flow through D1 to the transmitter. In this application the diode acts as a gate. D1 must be capable of passing the current taken by the transmitter without overheating.

A power type of diode can be used in shunt with the supply line to the transmitter for protective purposes. This method is illustrated in Fig. 5B. If the supply polarity is crossed accidentally, D1 will draw high current and cause F1 to open. This is sometimes referred to as a crowbar protection circuit. The primary advantage of circuit B over circuit A is that there is no voltage drop between the supply and the transmitter.

### Diodes as Voltage References

Zener diodes are discussed later in this chapter. They are used as voltage references or regulators. Conventional junction diodes can be used for the same purposes by taking advantage of their barrier-voltage characteristics. The greater the voltage needed, the higher the number of diodes

Fig. 5 — D1 at A protects the equipment if the supply leads are cross-polarized in error. At B the fuse will blow if the power supply is connected for the wrong polarity.

used in series. Some examples of this technique are given in Fig. 6. At A the diode (D1) establishes a fixed value of forward bias (0.7 V) for the transistor, thereby functioning as a regulator. R1 is chosen to permit a safe amount of current to flow through the diode junction while it is conducting at the barrier voltage.

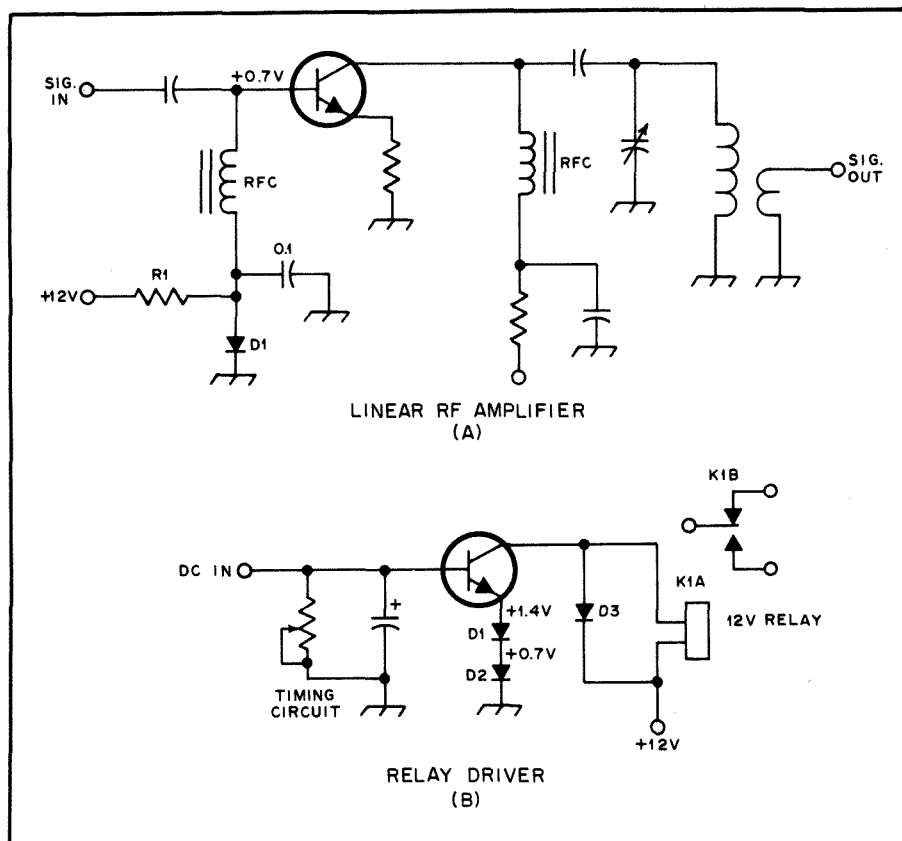

Fig. 6 — D1 establishes a 0.7-volt bias reference at A. Approximately 1.4 volts of emitter bias is established by connecting D1 and D2 in series at illustration B.

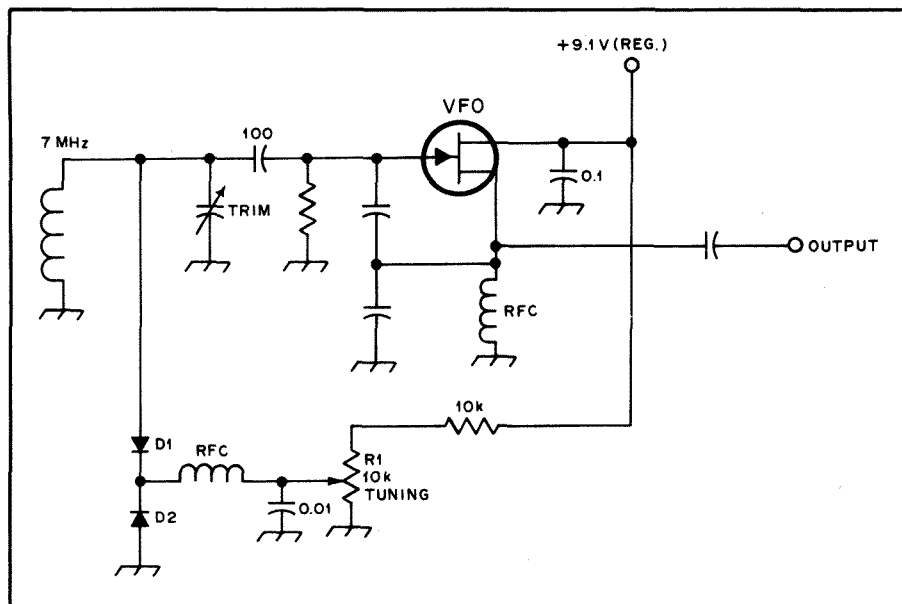

Fig. 7 — High-speed switching diodes of the 1N914 variety can be connected back to back and used as tuning diodes. As the reverse voltage is varied by means of R1, the internal capacitance of the diodes will change.

The circuit of Fig. 6B shows two diodes inserted in the emitter return of a relay-driver transistor. D1 and D2 set up a cutoff voltage of approximately 1.4. This reduces the static current of the transistor when for-

ward bias is not provided at the transistor base. If too much static current flows, the relay may not drop out when the forward bias decays across the timing network. The more sensitive the relay the greater the

chance for such a problem. D1 and D2 prevent relay dropout problems of this variety. D3 is used as a transient suppressor. A spike will occur when the relay coil field collapses. If the amplitude of the spike is great enough, the transient, while following the dc bus in a piece of equipment, can destroy transistors and diodes elsewhere in the circuit. In this application the diode (D3) can be regarded as a clamp, since it clamps the spike at approximately 0.7 volt.

#### Using Diodes as Capacitors

Later in this chapter there is a discussion about VVC (voltage-variable capacitor) diodes. They are known also as tuning diodes and Varicap diodes. It is possible, however, to use ordinary silicon diodes as voltage-variable capacitors. This is accomplished by taking advantage of the inherent changes in diode junction capacitance as the reverse bias applied to them is changed. The primary limitation in using high-speed switching diodes of the 1N914 variety is a relatively low maximum capacitance. At a sacrifice to low minimum capacitance, diodes can be used in parallel to step up the maximum available capacitance.

An example of two 1N914 silicon diodes in a diode tuning circuit is given in Fig. 7. As R1 is adjusted to change the back bias on D1 and D2, there will be a variation in the junction capacitance. That change will alter the VFO operating frequency. The junction capacitance increases as the back bias is lowered. In the circuit shown here the capacitance will vary from roughly 5 pF to 15 pF as R1 is adjusted. The diodes used in circuits of this kind should have a high Q and excellent high-frequency characteristics. Generally, tuning diodes are less stable than mechanical variable capacitors are. This is because the diode junction capacitance will change as the ambient temperature varies. This circuit is not well suited to mobile applications because of its lack of stability.

#### Diode Clippers and Clamps

The previous mention of diode clamping action (D3 in Fig. 6) suggests that advantage can be taken of the characteristic barrier voltage of diodes to clip or limit the amplitude of a sine-wave. Although there are numerous applications in this general category, diode clippers are more familiar to the amateur in noise limiter, audio limiter and audio compressor circuits. Fig. 8 illustrates some typical circuits that use small-signal diodes as clamps and clippers. D1 in Fig. 8A functions as a bias clamp at the gate of the FET. It limits the positive sine-wave swing at approximately 0.7 V. Not only does the diode tend to regulate the bias voltage, it limits the transconductance of the FET during the positive half of the cycle. This action restricts changes in transistor junction capacitance. As a result, frequency stability of the oscillator is enhanced and the generation of harmonic

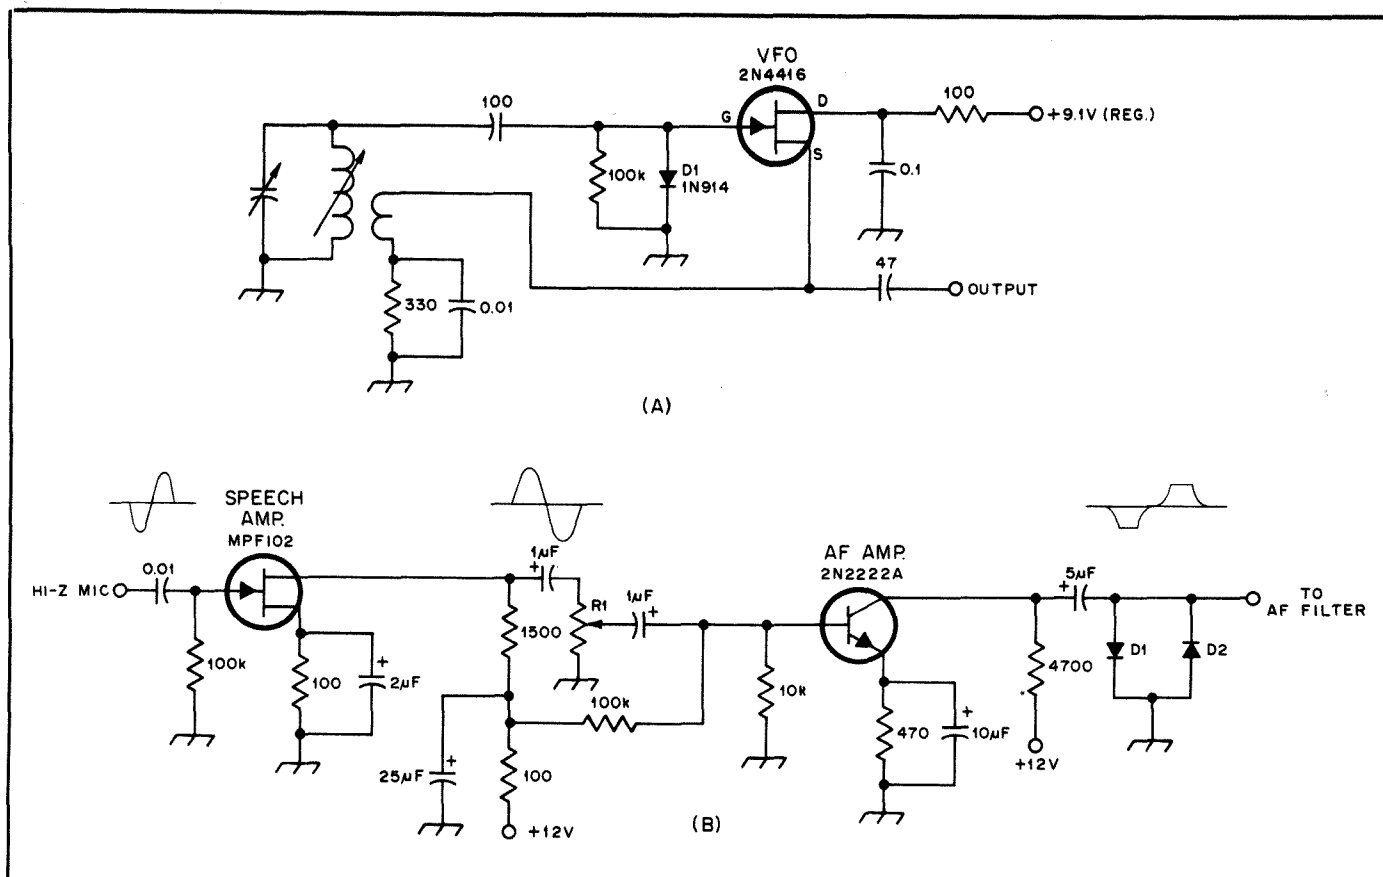

Fig. 8 — D1 serves as a bias stabilization device at A (see text). At B, D1 and D2 are employed as clippers to flatten the positive and negative AF peaks. Clipping will occur at roughly 0.7 volt if silicon diodes are used. Audio filtering is required after the clipper to remove the harmonic currents caused by the diode action.

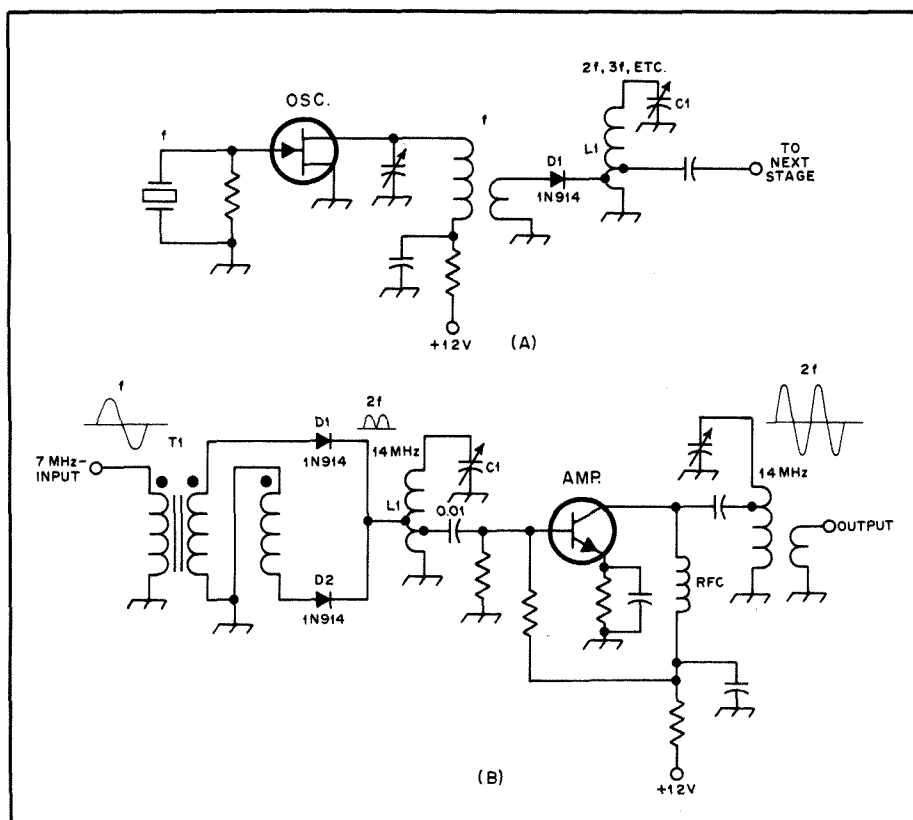

Fig. 9 — A simple diode frequency multiplier is shown at A. A balanced diode frequency doubler is at B. T1 is a trifilar-wound broadband toroid transformer.

currents is greatly minimized.

The circuit of Fig. 8B shows how a pair of diodes can be connected in back-to-back fashion for the purpose of clipping the negative and positive sine-wave peaks in an audio amplifier. If germanium diodes are used at D1 and D2 (1N34As or similar) the audio will limit at roughly 0.3 V. With silicon diodes (1N914 or rectifier types) the voltage will not exceed 0.7 V. R1 serves as the clipping-level control. An audio gain control is normally used after the clipper filter, along with some additional gain stages. The output of the clipper must be filtered to restore the sine wave if distortion is to be avoided. Diode clippers generate considerable harmonic currents, thereby requiring an RC or LC type of audio filter.

### Diode Frequency Multipliers

Designers of RF circuits use small-signal diodes as frequency multipliers when they want to minimize the number of active devices (tubes or transistors) in a circuit. The primary disadvantage of diode multipliers is a loss of signal compared to that available from an active multiplier. Fig. 9 contains examples of diode frequency multipliers. The circuit at A is useful for obtaining odd or even multiples of the driving voltage. The efficiency of this circuit is not high, requiring that an amplifier

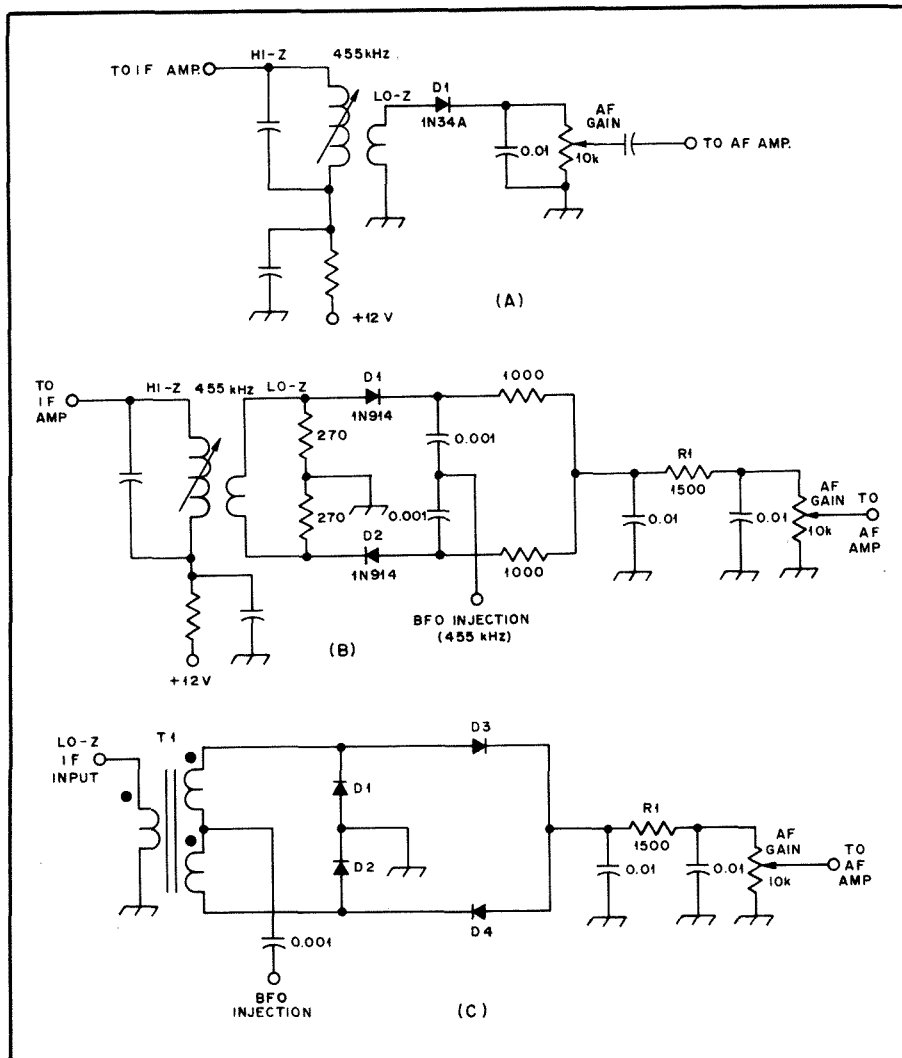

Fig. 10 — D1 at A is used as a simple AM detector. Two versions of diode product detectors are illustrated at B and C. BFO injection for B and C should be approximately 19 volts P-P for best detector performance.

be used after the diode multiplier in most applications. Resonator L1/C1 must be tuned to the desired output frequency.

A diode frequency doubler is shown at B in Fig. 9. It functions like a full-wave power-supply rectifier, where 60-Hz energy is transformed to 120-Hz by virtue of the diode action. This circuit will cause a loss of approximately 8 dB. Therefore, it is shown with a succeeding amplifier stage. If reasonable circuit balance is maintained, the 7-MHz energy will be down some 40 dB at the output of D1 and D2 — prior to the addition of L1 and C1. Additional suppression of the driving energy is realized by the addition of resonator L1/C1. T1 is a trifilar-wound toroidal transformer. At this frequency (7 MHz) a 0.5-inch-diameter ferrite core (permeability of 125) will suffice if the trifilar winding contains approximately 10 turns. Additional information on this subject is given in the ARRL publication, *Solid State Design for the Radio Amateur*.

#### Diode Detectors and Mixers

Diodes are effective as detectors and

mixers when circuit simplicity and strong-signal-handling capability are desired. Impedance matching is an important design objective when diodes are used as detectors and mixers. The circuits are lossy, just as is the case with diode frequency multipliers. A diode detector or mixer will exhibit a conversion loss of 7 dB or more in a typical example. Therefore, the gain before and after the detector or mixer must be chosen to provide an acceptable noise figure for the overall circuit in which the diode stage is used. This is a particularly critical factor when diode mixers are used at the front end of a receiver.

A significant advantage in the use of diode mixers and detectors is that they are broadband in nature, and they provide a wide dynamic range. Hot-carrier diodes are preferred by some designers for these circuits, but the 1N914 class of switching diodes provides good performance if they are matched for a similar resistance before being placed in the circuit.

Fig. 10 illustrates some examples of diode detectors. A basic AM detector is shown at A. The circuit at B is that of a

two-diode product detector. R1 and the two bypass capacitors serve as an RF filter to keep signal and BFO energy out of the following AF amplifier stage. A four-diode product detector is illustrated at C. T1 is a trifilar-wound broadband transformer. The characteristic input impedance of T1 is 50 ohms. An RF filter follows this detector also. BFO injection voltage for the detectors at B and C should be between 8 and 10 volts P-P for best detector performance.

Circuits for typical diode mixers are given in Fig. 11. Product detectors are also mixers except for the frequencies involved. The output energy is at audio frequencies rather than at some RF intermediate frequency. The examples at A and B can be compared to those at C and D for the purpose of illustrating the similarity between balanced modulators and mixers. It is evident that product detectors, balanced modulators and mixers are of the same family. The diodes in all examples can be hot-carrier types or matched silicon switching diodes of the 1N914 class.

C1 and C2 in Fig. 11C and D are used for balancing purposes. They can be employed in the same manner with the circuits at A and B. The transformers in each illustration are trifilar-wound toroidal types. They provide a broadband circuit characteristic.

#### Hot-Carrier Diodes

One of the more recent developments in the semiconductor field is the hot-carrier diode, or HCD. It is a metal-to-semiconductor, majority-carrier conducting device with a single rectifying junction. The carriers are typically high-mobility electrons in an N type of semiconductor material. The HCD is particularly useful in mixers and detectors at VHF and higher. Notable among the good features of this type of diode are its higher operating frequency and lower conduction voltage compared to a PN junction diode such as the 1N914.

When compared to a point-contact diode, the HCD is mechanically and electrically superior. It has lower noise, greater conversion efficiency, larger square-law capability, higher breakdown voltage and lower reverse current. The internal capacitance of the HCD is markedly lower than that of a PN junction diode and it is less subject to temperature variations.

Fig. 12 shows how the diode is structured internally. A typical set of curves for an HCD and a PN junction diode is given in Fig. 13. The curves show the forward and reverse characteristics of both diode types.

Fig. 14 illustrates the noise figure and conversion loss of an HCD with no bias applied. When forward bias is applied to the diode, the noise figure will change from that shown in Fig. 14. Curves for various bias amounts are given in Fig. 15. The numbers at the ends of the curves signify the amount of current (in milliamperes) flowing into the test circuit at point A.

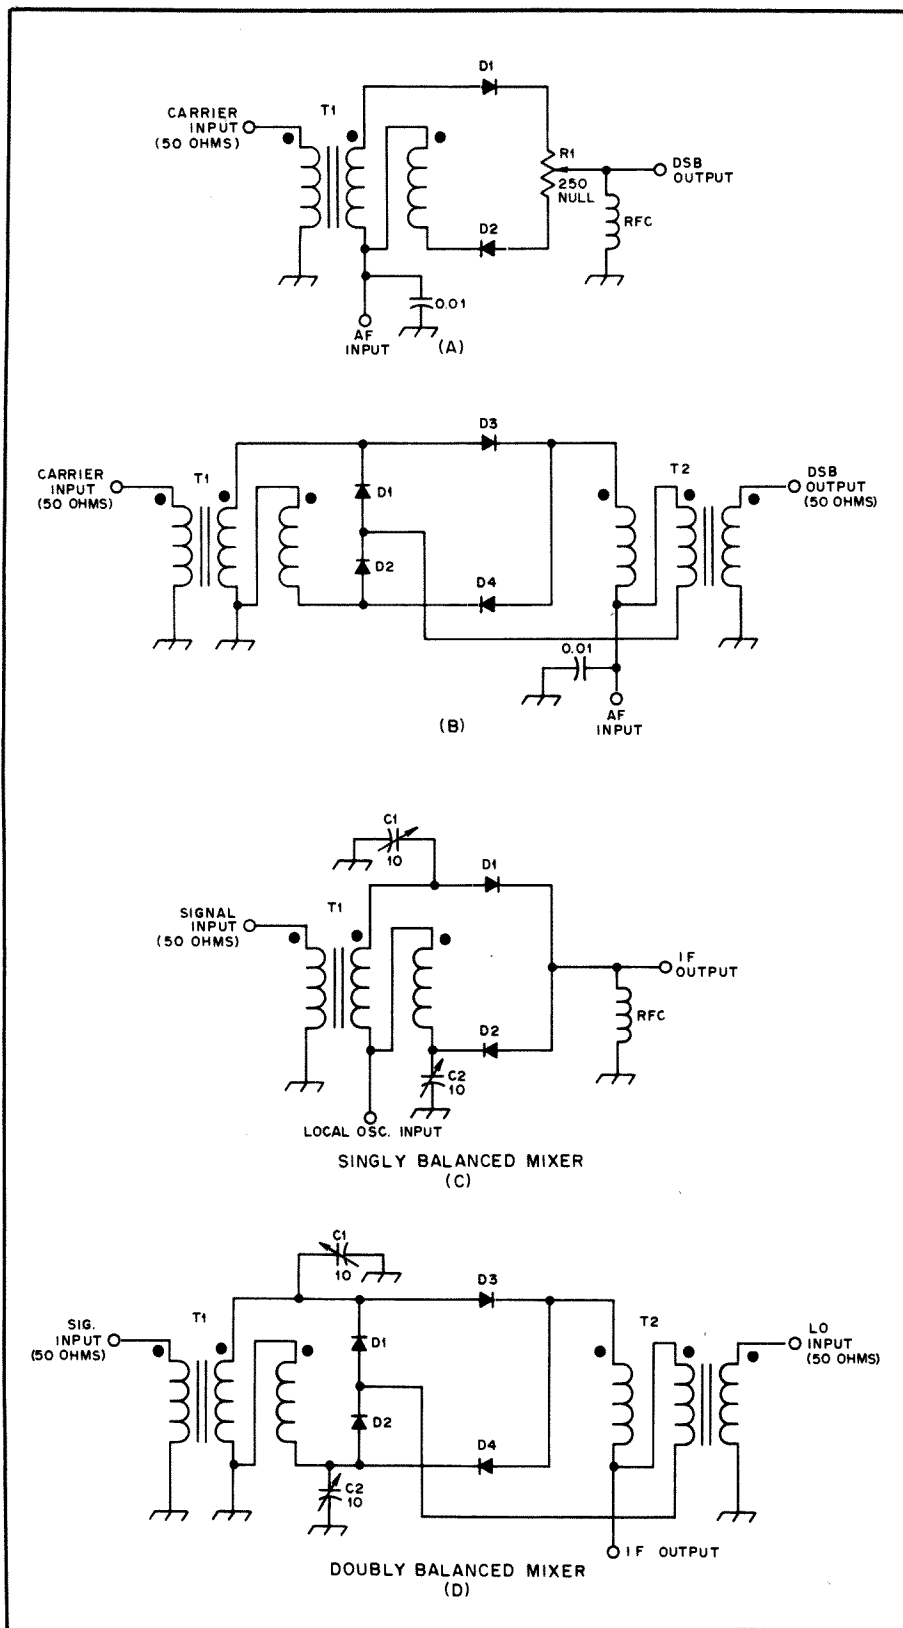

Fig. 11 — The circuits at A and B are for use in balanced modulators. The similarity between these and balanced mixers is shown at C and D.

A set of curves showing conversion loss versus LO drive for an HCD mixer are given in Fig. 16. The test circuit used for the curve of Fig. 15 applies. The curve numbers indicate milliamperes measured at point A.

### Varactor Diodes

Mention was made earlier in this chapter of diodes being used as voltage-variable capacitors, wherein the diode junction capacitance can be changed by varying the reverse bias applied to the diode. Manufac-

Fig. 12 — Cross-sectional representation of a hot-carrier diode (HCD).

Fig. 13 — Forward and reverse characteristics of a hot-carrier diode as compared to a PN junction diode.

Fig. 14 — Noise figure and the conversion loss of a typical HCD that has no bias applied.

turers have designed certain diodes for this application. They are called Varicaps (variable capacitor diodes) or varactor diodes (variable reactance diodes). These diodes depend on the change in capacitance that occurs across their depletion layers. They are not used as rectifiers.

Fig. 15 — Curves for hot-carrier diode noise figure versus local-oscillator drive power. The bias currents are in milliamperes as measured at point A in the representative test circuit.

Fig. 16 — Local-oscillator drive power versus conversion loss for a specified bias amount. Bias currents are in milliamperes as measured at point A of the circuit in Fig. 15.

Varactors are designed to provide various capacitance ranges from a few picofarads to more than 100 pF. Each one has a specific minimum and maximum capacitance, and the higher the maximum amount the greater the minimum value. Therefore, the amateur finds it necessary to tailor circuits for the midrange of the capacitance curve. Ideally, he will choose the most linear portion of the curve. Fig. 17A shows typical capacitance-voltage curves for three varactor diodes.

A representative circuit of a varactor diode is presented in Fig. 18. In this equivalent circuit the diode junction consists of  $C_j$  (junction capacitance) and  $R_j$  (junction resistance). The bulk resistance is shown as  $R_s$ . For the most part  $R_j$  can be neglected. The performance of the diode junction at a particular frequency is determined mainly by  $C_j$  and  $R_s$ . As the operating frequency is increased, the diode performance degrades, owing to the transit time established by  $C_j$  and  $R_s$ .

An important characteristic of the varactor diode is the  $Q$ , or figure of merit. The  $Q$  of a varactor diode is determined by the ratio of its capacitive reactance ( $X_c$ ) and its bulk resistance,  $R_s$ , just as is true of other circuit elements such as coils and capacitors, where  $Q = X/R_s$  at a specified frequency. Fig. 17B characterizes the  $Q$  of three Motorola varactor diodes (versus reverse bias) at 50 MHz.

Fig. 17 — Reverse voltage respective to diode capacitance of three Motorola varactor diodes (A). Reverse voltage versus diode Q for the varactors at A are shown at B.

Fig. 18 — Representative circuit of a varactor diode showing case resistance, junction resistance and junction capacitance.

Present-day varactor diodes operate into the microwave part of the spectrum. They are quite efficient as frequency multipliers at power levels as great as 25 watts. The efficiency of a correctly designed varactor multiplier exceeds 50 percent in most instances. Fig. 19 illustrates the basic circuit of a frequency multiplier that contains a varactor diode. D1 is a single-junction device that serves as a frequency tripler in this example. FL1 is required to ensure reasonable purity of the output energy. It is a high-Q strip-line resonator. Without FL1 in the circuit there would be considerable output energy at 144, 288 and 864 MHz. Similar circuits are used as doublers, quadruplers and higher.

A Motorola MV104 tuning diode is used in the circuit of Fig. 20. It contains two varactor diodes in a back-to-back arrangement. The advantage in using two diodes is reduced signal distortion, as compared to a one-diode version of the same circuit. Reverse bias is applied equally to the two diodes in the three-terminal device. R1 functions as an RF isolator for the tuned circuit. The reverse bias is varied by means of R2 to shift the operating frequency. Regulated voltage is as important to the varactor as it is to the FET oscillator if reasonable frequency stability is to be ensured. Varactor diodes are often used to tune two or more circuits at the same time (receiver RF amplifier, mixer and oscillator), using a single potentiometer to control the capacitance of the diodes.

It is worth mentioning that some Zener diodes and selected silicon power-supply rectifier diodes will work effectively as varactors at frequencies as high as 144 MHz. If a Zener diode is used in this manner it must be operated below its reverse breakdown voltage point. The stud-mount variety of power supply diodes (with glass headers) are reported to be the best candidates as varactors, but not all diodes of this type will work effectively; experimentation is necessary.

#### Gunn Diodes

Gunn diodes are named after the developer, J. B. Gunn, who was studying carrier behavior at IBM Corp. in 1963. Basically, the Gunn effect is a microwave oscillation that occurs when heavy current is passed through bulk semiconductor material. A Gunn device is a diode only in

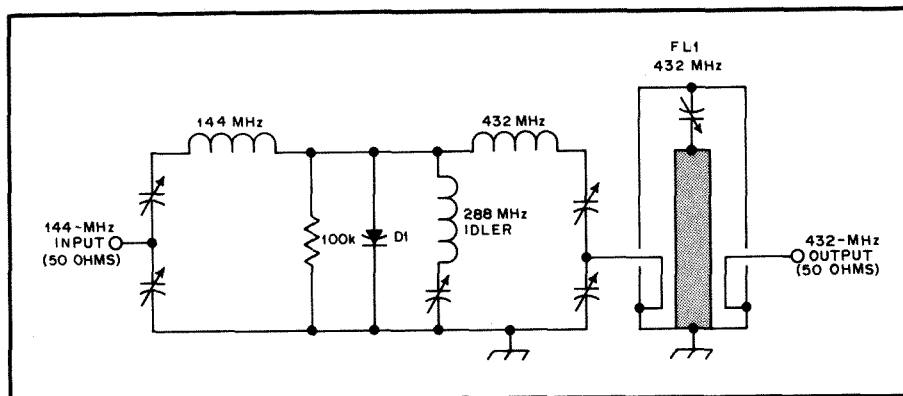

Fig. 19 — Typical circuit for a varactor-diode frequency tripler.

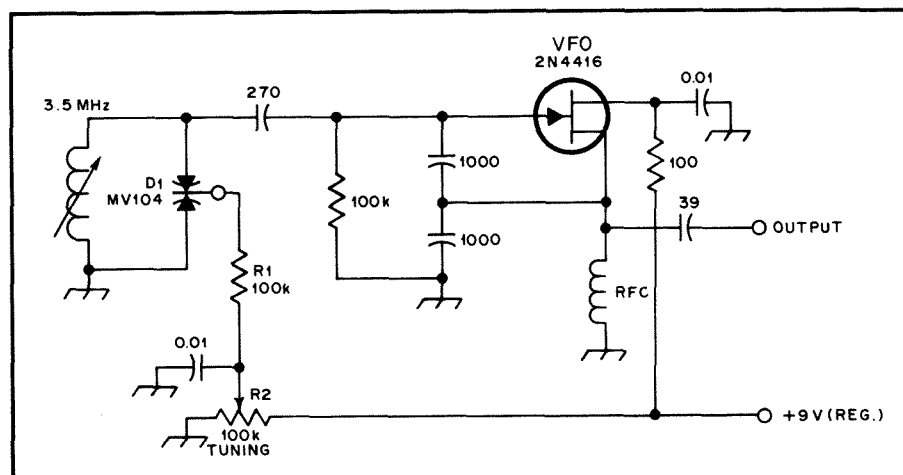

Fig. 20 — Example of a varactor-tuned VFO. D1 contains two varactors, back to back (see text).

Fig. 21 — Cross-sectional illustration of Gunn diode.

Fig. 22 — Active region thickness versus frequency of a Gunn diode.

Fig. 23 — Equivalent circuit of a Gunn diode. The parasitic reactances of the diode package are included.

the sense that it has two electrodes; it has no rectifying properties.

Amateurs have been using Gunn oscillators at 10 and 24 GHz, but these devices are employed commercially from 4 to 100 GHz and beyond. In high-power (>100 mW) or relatively narrow-bandwidth applications, a varactor diode is used to adjust the oscillation frequency. Gunn oscillators in octave-bandwidth systems such as laboratory sweep generators use YIG tuning. In this method, the volume of a resonant cavity is varied by the magnetic expansion of an yttrium iron garnet sphere. The magnetic force for tuning is generated by a coil external to the cavity, and the oscillation frequency is very nearly a linear function of the coil current.

YIG tuning produces a much cleaner harmonic and close-in oscillation spectrum than that obtainable with varactor tuning, because of the higher Q. The output power of YIG-tuned oscillators must be limited to about 100 mW. This is because the YIG sphere becomes a nonlinear circuit element at higher powers and can cause spurious emissions. An in-depth treatment of the

technology and physics of Gunn devices is provided in the *Gunn Diode Circuit Handbook* by Microwave Associates, Inc. Chapter 32 of this book contains a section on practical applications of Gunn technology for radio amateurs.

Fig. 21 shows a cross-sectional representation of a slice of the material (gallium arsenide) from which Gunn diodes are made. Layer no. 1 is the active region of the device. The thickness of this layer depends on the chosen frequency of operation. For the 10-GHz band it is approximately 10  $\mu\text{m}$  ( $10^{-5}$  meters) thick. The threshold voltage is roughly 3.3 volts. At 16 GHz the layer would be formed to a thickness of 8  $\mu\text{m}$ , and the threshold voltage would be about 2.6 volts.

Layer no. 2 is grown epitaxially and is doped to provide low resistivity. This layer is grown on the active region of the semiconductor, but it is not essential to the primary operation of the diode. It is used to ensure good ohmic contact and to prevent metalization from damaging the N layer of the diode.

The composite wafer of Fig. 21 is

metalized on both sides to permit bonding into the diode package. This process of metalization also ensures a low electrical and thermal resistance. The completed chip is bonded to a gold-plated copper pedestal, with layer no. 2 next to the heat sink. A metal ribbon is connected to the back side of the diode to provide for electrical contact.

The curve in Fig. 22 shows the relationship of the diode active-region thickness to the frequency of operation. The curve illustrates an approximation because the actual thickness of the active region depends on the applied bias voltage and the particular circuit used. The input power to the diode must be 20 to 50 times the desired output power. Thus the efficiency from dc to RF is on the order of two to five percent.

The resonant frequency of the diode assembly must be higher than the operating frequency to allow for parasitic C and L components which exist. Fig. 23 shows the equivalent circuit of a packaged Gunn

Fig. 24 — Illustration of a packaged Gunn diode as presented in literature from Microwave Associates.

diode. Assuming a diode natural resonant frequency of 17 GHz, the following approximate values result:  $L_p = 0.25$  nH,  $C_a = 0.15$  pF and  $C_b = 0.15$  pF. Additional components exist within the diode chip. They are represented by  $C_d$  (capacitance) and  $-R_d$  (negative resistance). These quantities, plus the stray resonances in the diode holder and bias leads in the microwave cavity, have a direct bearing on the electrical behavior of the Gunn oscillator. A cross-sectional representation of a packaged Gunn diode is shown at Fig. 24.

Presently, Gunn diodes are useful for generating powers between 0.1 and 1 watt. As the technology advances these power limits will increase. IMPATT (impact-avalanche transit time) diodes are useful as microwave amplifiers after a Gunn diode signal source. IMPATT diodes are also capable of providing power output in the 0.1- to 1-watt class.

Fig. 25 shows block diagrams of two Gunn-diode systems. In each example an IMPATT diode is used as an amplifier. Fig. 25A shows a direct FM transmitter which employs a varactor-deviated Gunn-diode oscillator as a signal source. FM is provided by applying audio to the bias lead of the varactor diode. The latter is coupled to the Gunn-diode cavity. Fig. 25B illustrates a microwave relay system in which a Gunn diode is used as an LO source. Essentially, the equipment is set up as a heterodyne up-converter transmitter. The upper sideband from the mixer is amplified at microwave frequency by means of an IMPATT diode.

#### PIN Diodes

A PIN diode is formed by diffusing heavily doped P+ and N+ regions into an almost intrinsically pure silicon layer, as illustrated in Fig. 26. In practice it is impossi-

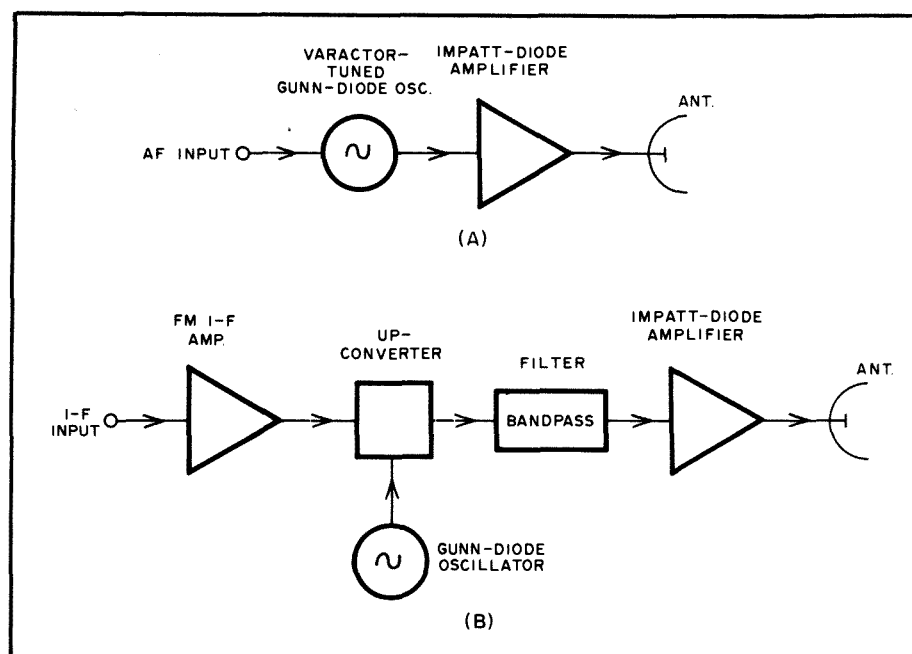

Fig. 25 — Block diagram of a simple Gunn-diode transmitter for FM (A) and an up-converter Gunn-diode transmitter (B).

Fig. 26 — The PIN diode is constructed by diffusing P+ and N+ regions into an almost intrinsically pure silicon layer. Thus the name PIN diode.

ble to obtain intrinsically pure material, and the I layer can be considered to be a lightly doped N region. Characteristics of the PIN diode are primarily determined by the thickness, area and semiconductor nature of the chip, especially that of the I region. Manufacturers design for controlled-thickness I regions having long carrier lifetime and high resistivity. Carrier lifetime is basically a measure of the delay before an average electron and hole recombine. In a pure silicon crystal the theoretical delay is on the order of several milliseconds, although impurity doping can reduce the effective carrier lifetime to microseconds or nanoseconds.

When forward bias is applied to a PIN diode, holes and electrons are injected from the P+ and N+ regions into the I region. These charges do not immediately recom-

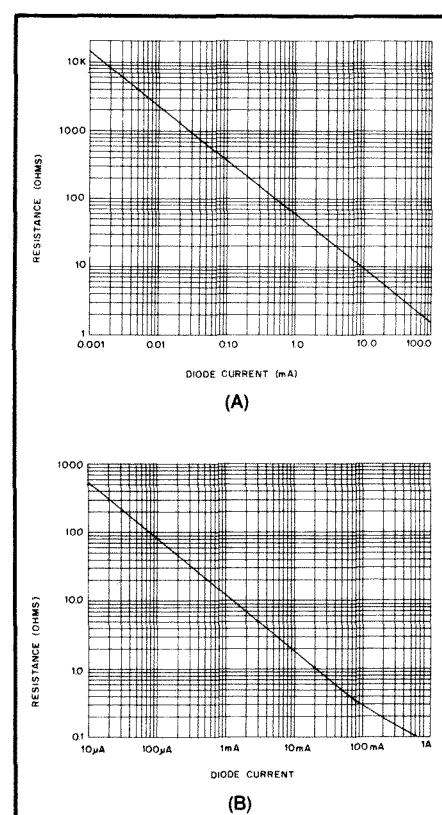

Fig. 27 — At A is a graph comparing diode resistance to forward-bias current for a PIN diode intended for low-level receiver applications. At B is a similar graph for a diode capable of handling over 100 watts of RF.

bine. Rather, a finite quantity of charge always remains stored and results in a lowering of the I-region resistivity. The amount of stored charge depends on the

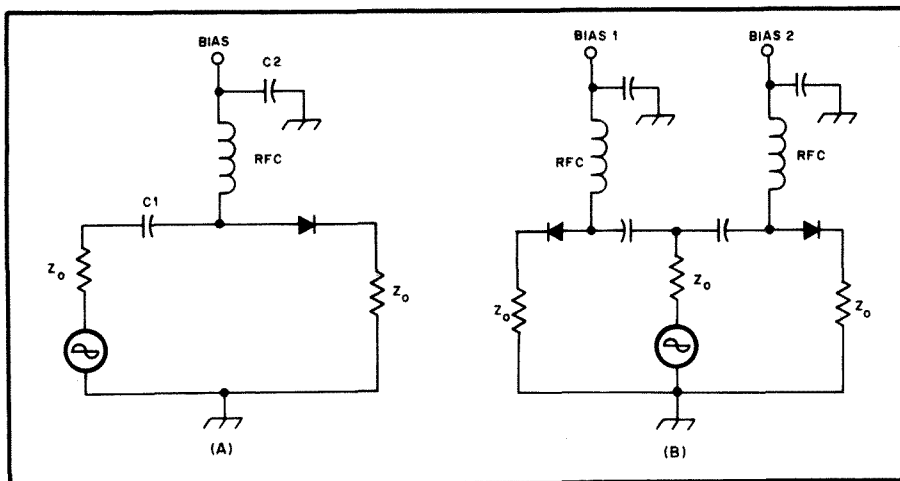

Fig. 28 — At A a PIN diode is used as an SPST switch. At B, two diodes form an SPDT switching arrangement.

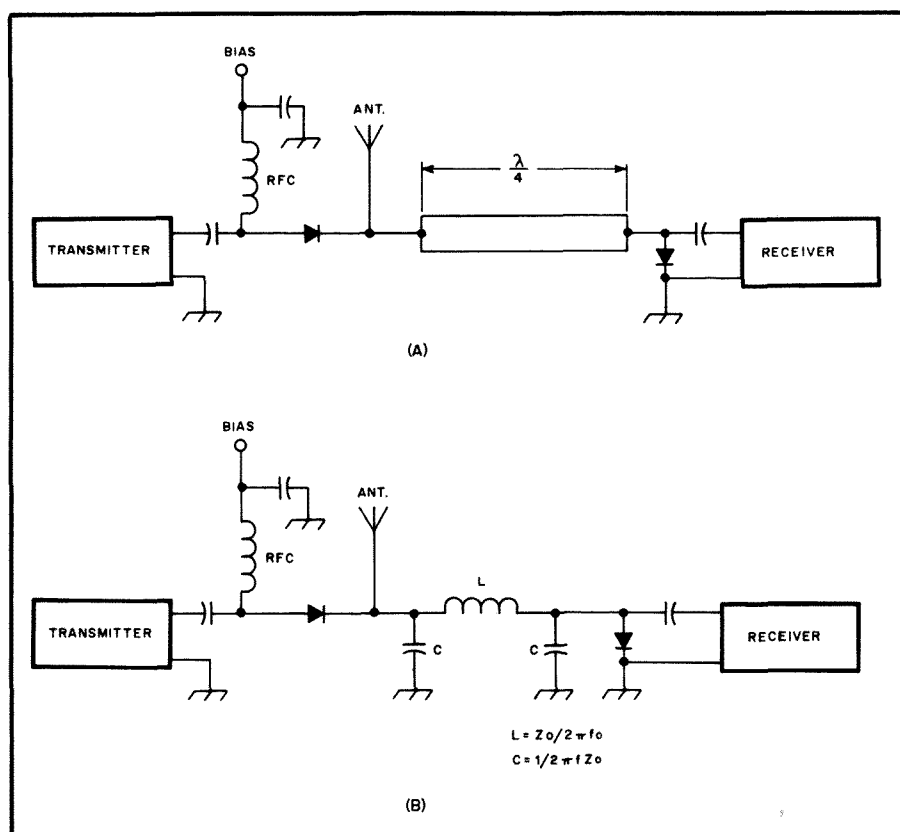

Fig. 29 — PIN diodes are used to transfer a common antenna to either a transmitter or receiver. A voltage applied to the bias terminal will switch the system to the transmit mode, connecting the output of the transmitter to the antenna. At the same time the diode across the receiver input is forward biased to a low-resistance state to protect the input stage of the receiver. The quarter-wave line isolates the low resistance of the receiver diode from the common antenna connection. At B the quarter-wave line is replaced with a lumped-element equivalent.

recombination time (carrier lifetime) and the level of the forward-bias current. The resistance of the I region under forward-bias conditions is inversely proportional to the charge and depends on the I-region width and mobility of the holes and electrons of the particular semiconductor material. Representative graphs of

resistance vs. forward bias level are shown in Fig. 27A and B for low-level receiving and high-power transmitting PIN diodes.

When a PIN diode is at zero or reverse bias, there is essentially no charge, and the intrinsic region can be considered as a low-loss dielectric. As with an ordinary PN junction there is a reverse breakdown or

Zener region where the diode current increases rapidly as the reverse voltage increases. For the intrinsic region to remain in a low-loss state, the maximum instantaneous reverse or negative voltage must not exceed the breakdown voltage. Also, the positive voltage excursion must not cause thermal losses to exceed the diode dissipation rating.

At high radio frequencies, when a PIN diode is at zero or reverse bias, the diode appears as a parallel plate capacitor, essentially independent of reverse voltage. It is the value of this capacitance that limits the effective isolation the diode can provide. PIN diodes intended for high isolation and not power-handling capability are designed with as small a geometry as possible to minimize the capacitance.

Manufacturers of PIN diodes supply data sheets with all necessary design data and performance specifications. Key parameters are diode resistance (when forward biased), diode capacitance, carrier lifetime, harmonic distortion, reverse voltage breakdown and reverse leakage.

PIN diodes are used in many applications, such as RF switches, attenuators and various types of phase-shifting devices. Our discussion will be confined to switch and attenuator applications since these are the most likely to be encountered by the amateur. The simplest type of switch that can be created with a PIN diode is the series SPST type. The circuit is shown in Fig. 28A. C1 functions as a dc blocking capacitor and C2 is a bypass capacitor. In order to have the signal from the generator flow to the load, a forward bias must be applied to the bias terminal. The amount of insertion loss caused by the diode is determined primarily by the diode bias current.

Fig. 28B illustrates an SPDT switch arrangement that uses essentially two SPST switches with a common connection. For a generator current to flow into the load resistor at the left, a bias voltage is applied to bias terminal 1. For signal to flow into the load at the right a bias must be applied to terminal 2. In practice it is usually difficult to achieve more than 40 dB isolation with a single diode switch at UHF and microwaves. Better performance, in excess of 100 dB, is achievable using compound switches. Compound switches are made up of two or more diodes in a series/shunt arrangement. Since not all diodes are biased for the same state, some increase in bias-circuit complexity results.

One general class of switches used in connection with transceive applications requires that a common antenna be connected to either the receiver or transmitter during the appropriate receive or transmit states. When PIN diodes are used as switching elements in these applications, higher reliability, better mechanical ruggedness and faster switching speeds are achieved relative to the electromechanical relay.

Fig. 30 — Two types of PIN diode attenuator circuits. The circuit at A is called a bridged T and the circuit at B is a pi type. Both exhibit very broadband characteristics.

Fig. 31 — A solar-energy diode cell. Electrons flow when light strikes the upper surface. The bottom of the cell is coated with foil to collect current for the load, or for the succeeding cell in series-connected arrays of cells.

A basic approach is shown in Fig. 29A and B where a PIN diode is used in series with the transmit line and another diode in shunt with the receive line. A single bias supply is used to turn on the series diode during transmit while also turning on the shunt diode to protect the receiver. The quarter-wave line between the two diodes is necessary to isolate the low resistance of the receiver diode from the antenna connection. During receive periods both diodes are effectively open circuited, allowing signal energy to be applied to the receiver. At B is the same basic circuit, although the quarter-wave line has been replaced with a lumped element section.

Two of the more common types of attenuators using PIN diodes are shown in Fig. 30. The type at A is referred to as a bridged T, while the circuit at B is the com-

mon pi type. Both are useful as very broadband devices. It is interesting to note that the useful upper frequency of these attenuators often depends on the bias circuit isolation rather than the PIN diode characteristics.

### Light-Emitting Diodes (LEDs)

The primary component in optoelectronics is the LED. This diode contains a PN junction of crystal material that produces luminescence around the junction when forward bias current is applied. LED junctions are made from gallium arsenide (GaAs), gallium phosphide (GaP), or a combination of both materials (GaAsP). The latter depends on the color and light intensity desired. Today, the available LED colors are red, green and yellow.

Some LEDs are housed in plastic affixed to the base header of a transistor package. Other LEDs are contained entirely in plastic packages that have a dome-shaped head at the light-emitting end. Two wires protrude from the opposite end (positive and negative leads) for applying forward bias to the device.

There are countless advantages to the use of LEDs. Notable among them are the low current drain, long life (sometimes 50 years, as predicted) and small size. They are useful as visual indicators in place of incandescent panel lamps. One of their most common applications is in digital display units, where arrays of tiny LEDs are arranged to provide illuminated segments in numeric-display assemblies.

The forward bias current for a typical LED ranges between 10 and 20 mA for maximum brilliance. An applied voltage of  $1\frac{1}{2}$  to 2 is also typical. A 1000-ohm resistor in series with a 12-volt source will permit the LED to operate with a forward current of approximately 10 mA (IR drop = 10 V). A maximum current of 10 mA is suggested in the interest of longevity for the device.

LEDs are also useful as reference diodes, however unique the applications may seem. They will regulate dc at approximately 1.5 V.

The following are definitions and terms used in optics to characterize the properties of an LED.

**Incident flux density** is defined as the amount of radiation per unit area (expressed as lumens/cm<sup>2</sup> in photometry; watts/cm<sup>2</sup> in radiometry). This is a measure of the amount of flux received by a detector measuring the LED output.

**Emitted flux density** is also defined as radiation per unit area and is used to describe light reflected from a surface. This measure of reflectance determines the total radiant luminous emittance.

**Source intensity** defines the flux density that will appear at a distant surface and is expressed as lumens/steradian (photometry) or watts/steradian (radiometry).

**Luminance** is a measure of photometric brightness and is obtained by dividing the luminous intensity at a given point by the

projected area of the source at the same point. Luminance is a very important rating in the evaluation of visible LEDs.

While luminance is equated with photometric brightness, it is inaccurate to equate luminance as a figure of merit for brightness. The only case in which this rating is acceptable is when comparing physically identical LEDs. Different LEDs are subject to more stringent examination. Manufacturers do not use a set of consistent ratings for LEDs (such as optical flux, brightness and intensity). This is because of the dramatic differences in optical measurements between point- and area-source diodes. Point-source diodes are packaged in a clear epoxy or set within a transparent glass lens. Area-source diodes must employ a diffusing lens to spread the flux over a wider viewing area and hence have much less point intensity (luminance) than the point-source diodes.

### Solar-Electric Diodes

Sunlight can be converted directly into electricity by a process known as photovoltaic conversion. A solar cell is used for this purpose. It relies on the photoelectric properties of a semiconductor. Practically, the solar cell is a large-area PN junction diode. The greater the area of the cell, the higher the output current will be. A dc voltage output of approximately 0.5 is obtained from a single cell. Numerous cells can be connected in series to provide 6, 9, 12, 24 or whatever low voltage is required. In a like manner, cells can be connected in parallel to provide higher output current, overall.

The solar diode cell is built so that light can penetrate into the region of the PN junction, Fig. 31. Most modern solar cells use silicon material. Impurities (doping) are introduced into the silicon material to establish excess positive or negative charges which carry electric currents. Phosphorous is used to produce N-type silicon. Boron is used as the dopant to produce P-type material.

Light is absorbed into the silicon to generate excess holes and electrons (one hole/electron pair for each photon absorbed). When this occurs near the PN junction, the electric fields in that region will separate the holes from the electrons. This causes the holes to increase in the P-type material. At the same time the electrons will build up in the N-type material. By making direct connection to the P and N regions by means of wires, these excess charges generated by light (and separated by the junction) will flow into an external load to provide power.

Approximately 0.16 A can be obtained from each square inch of solar-cell material exposed to bright sunlight. A 3½-inch-diameter cell can provide 1.5 A of output current. The efficiency of a solar cell (maximum power delivered to a load versus total solar energy incident on the cell) is typically 11 to 12 percent.

Fig. 32 — Voltage/current/temperature curve for a Solar Power Corp. array that contains 36 solar-electric cells in series. The curves are for a model E12-01369-1.5 solar panel.

Fig. 33 — Schematic symbol and current-vs.-voltage characteristic for a tunnel diode.

Fig. 34 — Typical characteristics of a Zener diode (30 V).

Arrays of solar cells are manufactured for all manner of practical applications. A storage battery is used as a buffer between the solar panel and the load. A PN junction diode should be used between the solar-array output and the storage battery to prevent the battery from discharging back into the panel during dark periods. An article on the subject of solar cells and their amateur applications (DeMaw "Solar Power for the Radio Amateur," August 1977 *QST*) should be of interest to those who wish to utilize solar power. *Solar Electric Generator Systems*, an application pamphlet by Solar Power Corp. of N. Billerica, MA 01862, contains valuable information on this subject.

Fig. 32 shows the voltage/current curves to a Model E12-01369-1.5 solar array manufactured by Solar Power Corp. It can be seen that temperature has an effect on the array performance.

#### Tunnel Diodes

One type of semiconductor diode having no rectifying properties is called a tunnel diode. The bidirectional conduction of the device is a result of heavily doped P and N regions with a very narrow junction. The Fermi level lies within the conduction band for the N side and within the valence band for the P side. A typical current-vs.-voltage curve for a tunnel diode is sketched in Fig. 33. When the forward bias potential exceeds about 30 mV, increasing the voltage causes the current to decrease, resulting in a negative resistance characteristic. This effect makes the tunnel diode capable of amplification and oscillation.

At one time tunnel diodes were expected to dominate in microwave applications, but other devices soon surpassed tunnel diodes in performance. The two-terminal oscillator concept had great fad appeal, and some amateurs built low-power transmitters based on tunnel diodes. In the 1960s the Heath Company marketed a dip meter that used a tunnel diode oscillator. Tunnel diodes are not widely used in new designs;

Fig. 35 — Example of how a shunt type of Zener diode regulator is used. The equations show how to calculate the value of the series resistor and the diode power dissipation. In this example a 400-mW Zener diode will suffice (D1).

this material is included only for completeness.

### Zener Diodes

Zener diodes have, for the most part, replaced the gaseous regulator tube. They have been proved more reliable than tube types of voltage regulators, are less expensive and far smaller in size.

These diodes fall into two primary classifications: voltage regulators and voltage-reference diodes. When they are used in power supplies as regulators, they provide a nearly constant dc output voltage even though there may be large changes in load resistance or input voltage. As a reference element the Zener diode utilizes the voltage drop across its junction when a specified current passes through it in the reverse-breakdown direction (sometimes called the Zener direction). This "Zener voltage" is the value established as a reference. Therefore, if a 6.8-volt Zener diode was set up in this manner, the resultant reference voltage would be 6.8.

At the present time it is possible to purchase Zener diodes rated for various voltages between 2.4 and 200. The power ratings range from  $\frac{1}{4}$  to 50 watts. Fig. 34 shows the characteristics of a Zener diode designed for 30-volt operation.

Fig. 35 shows how to calculate the series

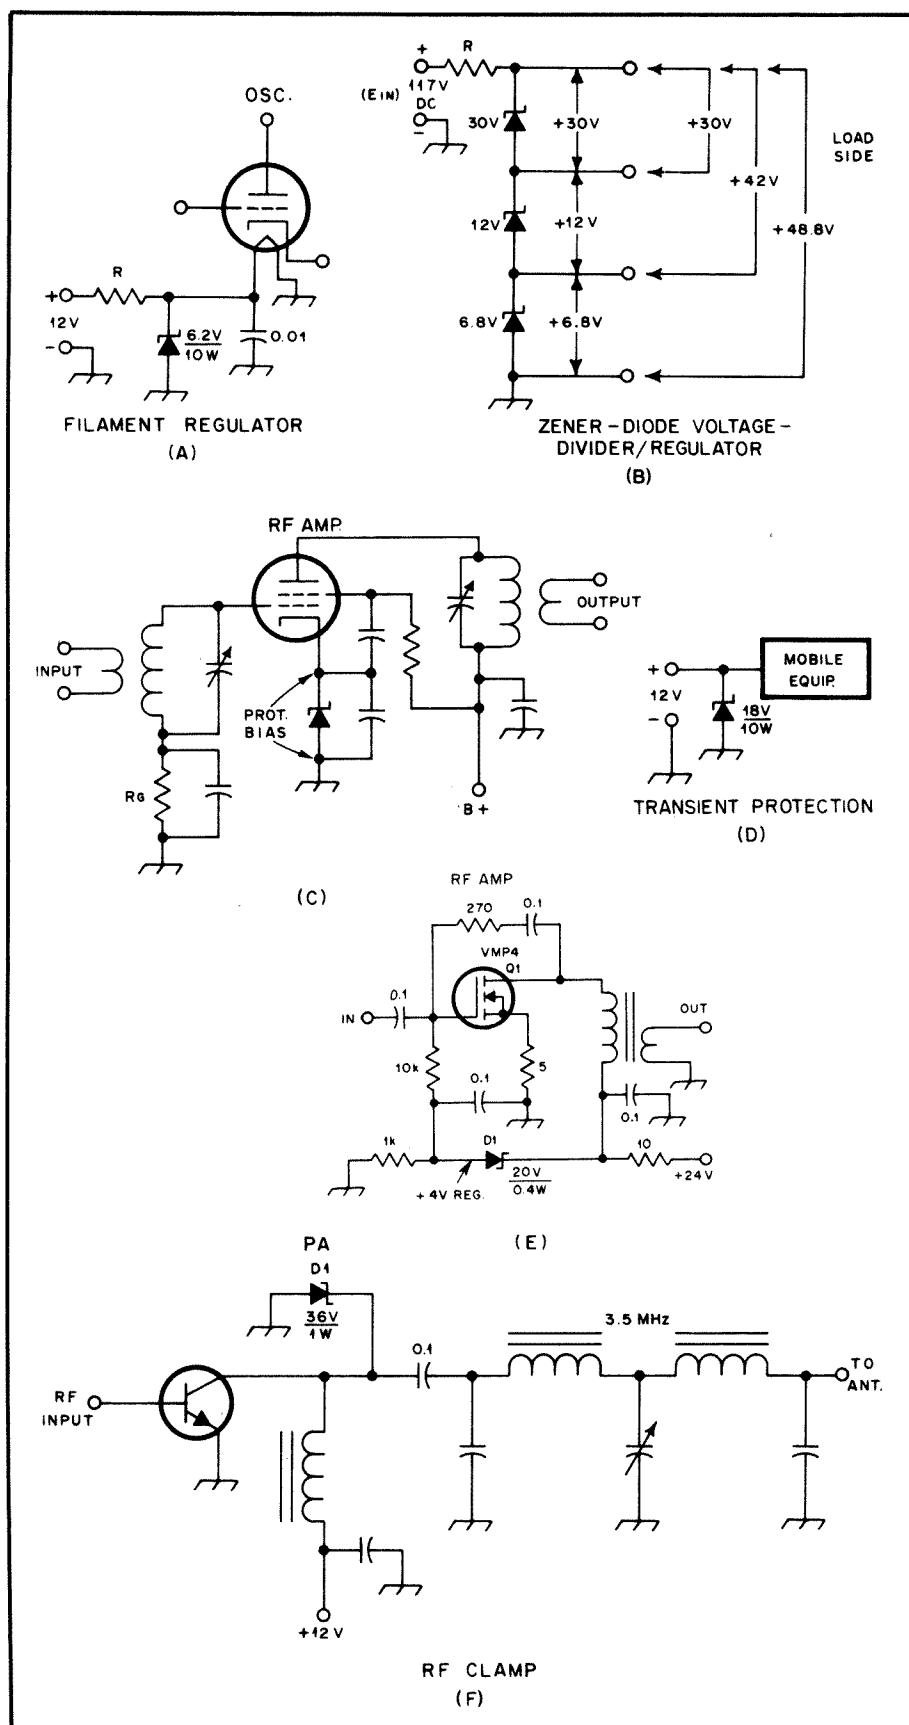

Fig. 36 — Practical examples of Zener diode applications. The circuit at A is useful for stabilizing the filament voltage of oscillators. Zener diodes can be used in series to obtain various levels of regulated voltage (B). Fixed-value bias for transmitter stages can be obtained by inserting a Zener diode in the cathode return (C). At D an 18-volt Zener diode prevents voltage spikes from harming a mobile transceiver. A Zener-diode series regulator (20-V drop) is shown at E and an RF clamp is shown at F. D1 in the latter circuit will clamp at 36 volts to protect the PA transistor from dc voltage spikes and extreme sine-wave excursions at RF. This circuit is useful in protecting output stages during no-load or short-circuit conditions.

resistance needed in a simple shunt regulator which employs a Zener diode. An equation is included for determining the wattage rating of the series resistor. Additional data on this subject is given in Chapter 7 of *Solid State Design for the Radio Amateur*.

Some practical applications for Zener diodes are illustrated in Fig. 36. In addition to the shunt applications given in the diagram, Zener diodes can be used as series elements when it is desired to provide a gate that conducts at a given voltage. These diodes can be used in ac as well as dc circuits. When they are used in an ac type of application they will conduct at the peak voltage value or below, depending on the voltage swing and the voltage rating of the Zener diode. For this reason they are useful as audio and RF clippers. In RF work the reactance of the diode may be the controlling factor above approximately 10 MHz with respect to the performance of the RF circuit and the diode.

Most Zener diodes which are rated higher than 1 watt in dissipation are contained in stud-mount packages. They should be affixed to a suitable heat sink to

prevent damage from excessive junction temperatures. The mounting techniques are the same as for power rectifiers and high-wattage transistors.

### Reference Diodes

While ordinary Zener diodes are useful as voltage regulators, they don't exhibit the thermal stability required in precision reference applications. A reverse-biased semiconductor junction has a positive temperature coefficient of barrier potential. A forward-biased junction has a negative coefficient. The way to temperature-compensate a Zener diode is to connect one or more common silicon diodes in series with it. When this is done as part of the manufacturing process, the resulting component is termed a reference diode. A 1N3499 6.2-volt reference diode will maintain a temperature coefficient of 0.0005 percent per degree over the range of 0 to 75° C. Reference diodes work best when operated at a few milliamperes of current from a high-impedance or constant-current bias source.

As the name implies, these diodes aren't suited for circuits where power is taken directly from the device. Reference diodes can't be tested with an ohmmeter because two junctions are back-to-back — the instrument can't supply enough voltage to overcome the Zener barrier potential.

### Step-Recovery Diodes

One device characterized by extremely low capacitance and short storage time is the step-recovery diode (SRD), sometimes called a "snap" diode. These diodes are used as frequency multipliers well into the microwave spectrum. Switching the device in and out of forward conduction is the multiplication mechanism, and the power efficiency is inversely proportional to the frequency multiple. Very high orders of multiplication are possible with step-recovery diodes. One use for this feature is in a comb generator, an instrument used to calibrate the frequency axis of a spectrum analyzer.

A single harmonic of the excitation frequency can be selected by an interdigital

filter or cavity resonator. A 1-watt, 220-MHz FM transmitter could drive a snap diode multiplier ( $\times 46$ ) and filter combination to an output of about 10 mW in the 10-GHz band — a typical and effective power level at that frequency. A representative system of this variety is suggested in Fig. 37. The exciter should be well isolated from the SRD and its matching network to prevent parasitic oscillations.

### Current-Regulator Diodes

A JFET with its gate shorted to its source or connected below a source resistor will draw a certain current whose value is almost entirely independent of the applied potential. The current ( $I_{DSS}$  in FET terminology) is also quite stable with temperature. Semiconductor manufacturers take advantage of those properties and package the JFET circuit of Fig. 38A in a two-terminal package and call it a constant-current diode. A special symbol, given in Fig. 38B, is assigned to this type of diode. The 1N5305 diode approaches an ideal current generator, in that it draws 2 mA over the range of 1.8 to 100 volts. Constant-current diodes find application in ohmmeters, ramp generators and precision voltage references.

### BIPOLAR TRANSISTORS

The word "transistor" was chosen to describe the function of a three-terminal PN junction device that is able to amplify signal energy (current). The inherent characteristic is one of "transferring current across a resistor." The transistor was invented by Shockley, Bardeen and Brattain at Bell Labs in 1947 and has become the standard amplifying device in electronic equipment. In RF and audio applications it is practical to obtain output power in excess of 1000 watts by using several amplifier blocks and hybrid power combiners. The primary limitation at the higher power levels is essentially a practical or economic one: Low voltage, high-current power supplies are required, and the cost can exceed that of a high-voltage moderate-current supply of the variety that would be employed with a vacuum-tube amplifier of comparable power. The primary advantages of solid-state power amplifiers are compactness and reliability.

In small-signal applications the transistor outweighs the vacuum-tube in performance. There remains in some quarters a belief that transistors are hard to tame, are noisier than tubes and are subject to damage at the flick of a switch. None of this is true. A transistorized circuit designed and operated correctly is almost always capable of outperforming an equivalent vacuum-tube circuit in all respects. An understanding of how transistors function will help to prevent poor circuit performance. The fundamentals outlined in this chapter are provided for the amateur designer so the common pitfalls can be avoided.

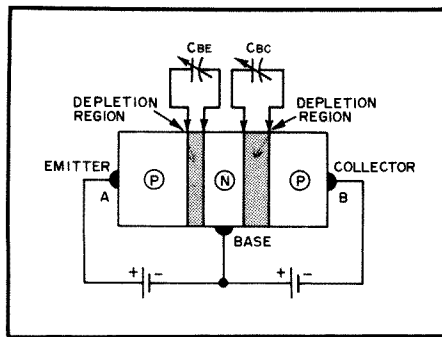

Fig. 39 — Illustration of a junction PNP transistor. Capacitances  $C_{be}$  and  $C_{bc}$  vary with changes in operating and signal voltage (see text).

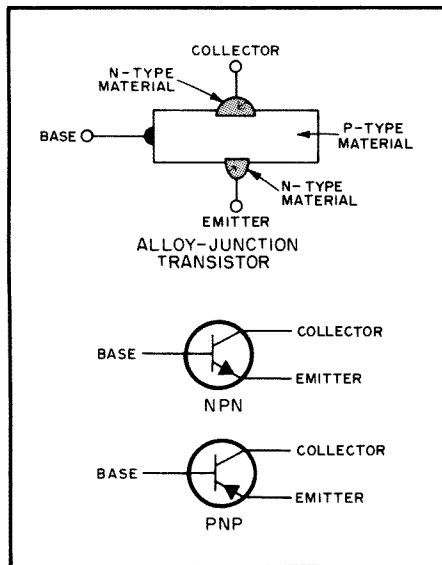

Fig. 40 — Pictorial and schematic representations of junction transistors. The base, collector and emitter can be compared to the grid, plate and cathode of a triode tube, respectively.

Fig. 39 shows a "sandwich" made from two layers of P-type semiconductor material with a thin layer of N-type between. There are in effect two PN junction diodes back-to-back. If a positive bias is applied to the P-type material at the left, current will flow through the left-hand junction, the holes moving to the right and the electrons from the N-type material moving to the left. Some of the holes moving into the N-type material will combine with the electrons there and be neutralized, but some of them also will travel to the region of the right-hand junction.

If the PN combination at the right is biased negatively, as shown, there would normally be no current flow in this circuit. However, there are now additional holes available at the junction to travel to point B and electrons can travel toward point A, so a current can flow even though this sec-

tion of the sandwich is biased to prevent conduction. Most of the current is between A and B and does not flow out through the common connection to the N-type material in the sandwich.

A semiconductor combination of this type is called a transistor, and the three sections are known as the emitter, base and collector. The amplitude of the collector current depends principally on the amplitude of the emitter current; that is, the collector current is controlled by the emitter current.

Between each PN junction exists an area known as the depletion, or transition, region. It is similar in characteristics to a dielectric layer, and its width varies in accordance with the operating voltage. The semiconductor materials either side of the depletion region constitute the plates of a capacitor. The capacitance from base to emitter is shown as  $C_{be}$  (Fig. 39), and the base-collector capacitance is represented as  $C_{bc}$ . Changes in signal and operating voltages cause a nonlinear change in these junction capacitances, which must be taken into account when designing some circuits. A base-emitter resistance,  $r_b'$ , also exists. The junction capacitance, in combination with  $r_b'$ , determines the useful upper frequency limit ( $f_T$  or  $f_a$ ) of a transistor by establishing an RC time constant.

### Power Amplification

Because the collector is biased in the back direction the collector-to-base resistance is high. On the other hand, the emitter and collector currents are substantially equal, so the power in the collector circuit is larger than the power in the emitter circuit ( $P = I^2R$ , so the powers are proportional to the respective resistances, if the currents are the same). In practical transistors emitter resistance is on the order of a few ohms while the collector resistance is hundreds or thousands of times higher, so power gains of 20 to 40 dB or even more are possible.

### Transistor Types

The transistor may be one of the types shown in Fig. 40. The assembly of P- and N-type materials may be reversed, so that PNP and NPN transistors are both possible.

The first two letters of the NPN and PNP designations indicate the respective polarities of the voltages applied to the emitter and collector in normal operation. In a PNP transistor, for example, the emitter is made positive with respect to both the collector and the base, and the collector is made negative with respect to both the emitter and the base.

Manufacturers are constantly working to improve the performance of their transistors — greater reliability, higher power and higher frequency ratings, and improved uniformity of characteristics for any given type number. One such development provided the overlay transistor, whose

emitter structure is made up of several emitters that are joined together at a common case terminal. This process lowers the base-emitter resistance,  $r_b'$ , and improves the transistor input time constant. The time constant is determined by  $r_b'$  and the junction capacitance of the device.

The overlay transistor is extremely useful in VHF and UHF applications. It is capable of high-power operation well above 1000 MHz. These transistors are useful as frequency doublers and triplers, and are able to provide an actual power gain in the process.

Another multi-emitter transistor that has been developed for use from HF through UHF should be of interest to the radio amateur. It is called a balanced-emitter transistor (BET), or "ballasted" transistor. The transistor chip contains several triode semiconductors whose bases and collectors are connected in parallel. The various emitters, however, have built-in emitter resistors (typically about 1 ohm) that provide a current-limiting safety factor during overload periods, or under conditions of significant mismatch. Since the emitters are brought out to a single case terminal the resistances are effectively in parallel, thus reducing the combined emitter resistances to a fraction of an ohm. (If a significant amount of resistance were allowed to exist it would cause degeneration in the stage and would lower the gain of the circuit.)

Most modern transistors are of the junction variety. Various names have been given to the several types, some of which are junction alloy, mesa and planar. Though their characteristics may differ slightly, they are basically of the same family and simply represent different physical properties and manufacturing techniques.

### Transistor Characteristics

An important characteristic of a transistor is its beta ( $\beta$ ), or current-amplification factor, which is sometimes expressed as  $H_{FE}$  (static forward-current transfer ratio) or  $h_{fe}$  (small-signal forward-current transfer ratio). Both symbols relate to the grounded-emitter configuration. Beta is the ratio of the collector current to the base current

$$\beta = \frac{I_c}{I_b}$$

Thus, if a base current of 1 mA causes the collector current to rise to 100 mA the beta is 100. Typical betas for junction transistors range from as low as 10 to as high as several hundred.

A transistor's alpha ( $\alpha$ ) is the ratio of the collector to the emitter current. Symbols  $h_{FB}$  (static forward-current transfer ratio) and  $h_{fb}$  (small-signal forward-current transfer ratio), common-base hookup, are frequently used in connection with gain. The smaller the base current, the closer the collector current comes to being equal to that of the emitter, and the closer alpha

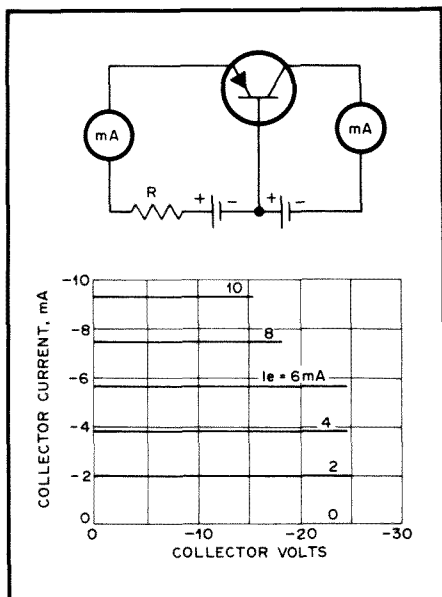

Fig. 41 — Typical collector-current versus collector-voltage characteristics of a junction transistor for various emitter-current values. Because the emitter resistance is low, a current-limiting resistor ( $R$ ) is placed in series with the source current. The emitter current can be set at a desired value by adjustment of this resistance.

Fig. 42 — Collector current versus collector voltage for various values of base current in a junction transistor. The illustration at A shows how the measurements are made. At B is a family of curves.

Fig. 43 — Curve-tracer display of a small-signal transistor characteristics.

is frequently used to express the useful upper-frequency limit of a transistor, and this relates to the common-base hookup. Alpha cutoff is the point at which the gain is 0.707 its value at 1000 Hz.

Another factor that limits the upper-frequency capability of a transistor is its transit time. This is the period of time required for the current to flow from emitter to collector, through the semiconductor base material, the greater the transit time. Hence, the thicker the base material the more likelihood there will be of phase shift of the signal passing through it. At frequencies near and above  $f_T$  or alpha cutoff, partial or complete phase shift can occur. This will give rise to positive feedback because the internal capacitance,  $C_{be}$ , feeds part of the in-phase collector signal back to the base. The positive feedback can cause instability and oscillation, and in most cases will interlock the input and output tuned circuits of an RF amplifier so it is almost impossible to tune them properly. This form of feedback can be corrected by using what is termed "unilateralization." Conventional positive feedback can be nullified by using neutralization, as is done with vacuum-tube amplifiers.

#### Characteristic Curves

The operating principles of transistors can be shown by a series of characteristic curves. One such set of curves is shown in Fig. 41. It shows the collector current vs. collector voltage for a number of fixed values of emitter current. Practically, the collector current depends almost entirely on the emitter current and is independent of the collector voltage. The separation between curves is quite uniform, indicating that almost distortionless output can be obtained over the useful operating range of the transistor.

Another type of curve is shown in Fig. 42, together with the circuit used for obtaining it. This also shows collector current vs. collector voltage, but for a number of

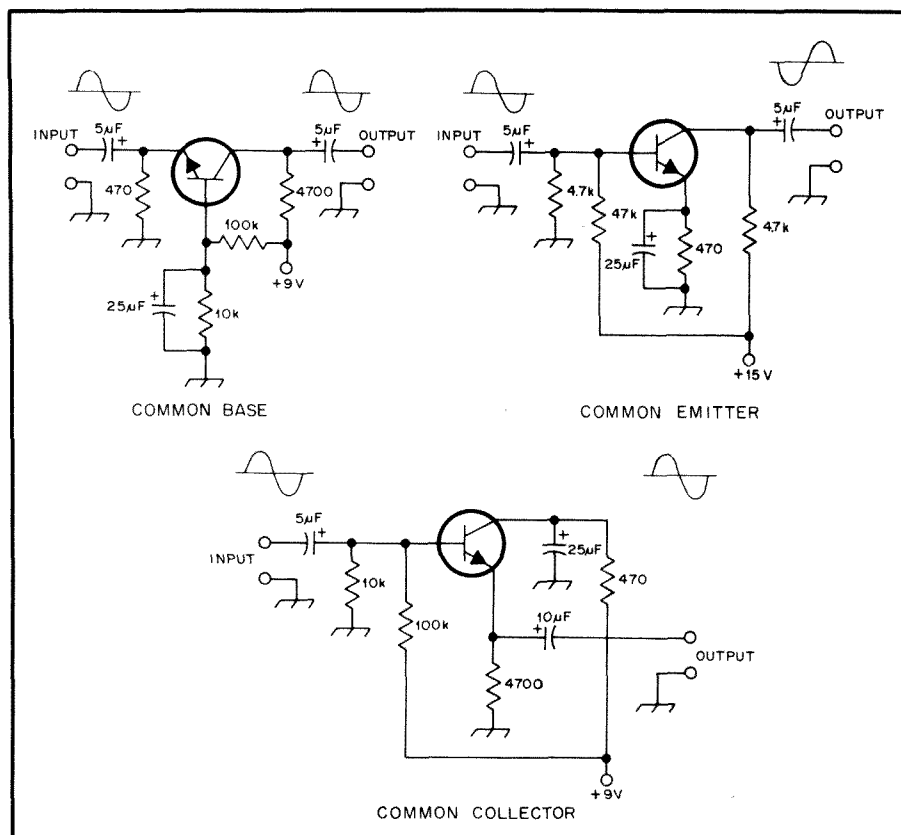

Fig. 44 — Basic transistor amplifiers. Observe the input and output phase relationships for the various configurations.

comes to being 1. Alpha for a junction transistor is usually between 0.92 and 0.98.

Transistors have frequency characteristics that are important to circuit designers.

Symbol  $f_T$  is the gain bandwidth product (common-emitter) of the transistor. This is the frequency at which the gain becomes unity, or 1. The expression "alpha cutoff"

different values of base current. In this case the emitter element is used as the common point in the circuit. The collector current is not independent of collector voltage with this type of connection, indicating that the output resistance of the device is fairly low. The base current also is quite low, which means the resistance of the base-emitter circuit is moderately high with this method of connection. This may be contrasted with the high values of emitter current shown in Fig. 41. An actual oscillograph of a characteristic family of curves for a small-signal transistor is shown in Fig. 43. It was obtained by means of a curve tracer.

### Transistor Amplifiers

Amplifier circuits used with transistors fall into one of three types, known as the common-base, common-emitter and common-collector circuits. These are shown in Fig. 44 in elementary form. The three circuits correspond approximately to the grounded-grid, grounded-cathode and cathode-follower circuits, respectively, used with vacuum tubes.

The important transistor parameters in these circuits are the short-circuit current transfer ratio, the cutoff frequency, and the input and output impedances. The short-circuit current transfer ratio is the ratio of a small change in output current to the change in input current that causes it, the output circuit being short-circuited. The cutoff frequency was discussed earlier in this chapter. The input impedance is that which a signal source working into the transistor would see, and the output impedance is the internal output impedance of the transistor (corresponding to the plate resistance of a vacuum tube, for example).

#### Common-Base Circuit

The input circuit of a common-base amplifier must be designed for low impedance, since the emitter-to-base resistance is of the order of  $26/I_e$  ohms, where  $I_e$  is the emitter current in milliamperes. The optimum output load impedance,  $R_L$ , may range from a few thousand ohms to 100,000, depending on the requirements.

In this circuit the phase of the output (collector) current is the same as that of the input (emitter) current. The parts of these currents that flow through the base resistance are likewise in phase, so the circuit tends to be regenerative and will oscillate if the current amplification factor is greater than one.

#### Common-Emitter Circuit

The common-emitter circuit shown in Fig. 44 corresponds to the ordinary grounded-cathode vacuum-tube amplifier. As indicated by the curves of Fig. 42, the base current is small and the input impedance is therefore fairly high — several thousand ohms in the average case. The collector resistance is some tens of thousands of ohms, depending on the

signal source impedance. The common-emitter circuit has a lower cutoff frequency than does the common-base circuit, but it gives the highest power gain of the three configurations.

In this circuit the phase of the output (collector) current is opposite to that of the input (base) current so such feedback as occurs through the small emitter resistance is negative and the amplifier is stable.

Because the common-emitter amplifier circuit illustrated in Fig. 44 is one of the most often seen applications for a bipolar transistor, a brief analysis and discussion of the design network biasing the base supplies an open-circuit potential of 1.36 V. Connecting the base has little loading effect if the transistor beta is high (a fair assumption). A beta of 100, for example, causes the 470-ohm emitter resistor to present a dc base resistance of 47 k $\Omega$ , which is a negligible shunt. The base-emitter junction drops 0.6 V, so the potential across the emitter resistor is  $1.36 - 0.6 = 0.76$  V. This voltage causes 1.6 mA to flow in the emitter and the 470-ohm resistor. Since the transistor alpha is nearly unity, the collector current is also 1.6 mA, which drops 7.52 volts across the collector load resistor. The quiescent (no signal) collector voltage is therefore  $15 - 7.52 = 7.48$  V. This value allows the maximum undistorted output voltage swing between cutoff and saturation.

Assuming the emitter bypass capacitor has negligible reactance at the operating frequency, the emitter is at ac ground. Because of the high alpha mentioned earlier, any emitter current variation caused by an input signal will also appear in the collector circuit. Since the current variation is the same, the voltage gain is the ratio of the collector load resistance to the (internal) emitter resistance. For small signals, this emitter resistance can be approximated by  $R_e = 26/I_e$ , where  $R_e$  is the emitter-to-base junction resistance, and  $I_e$  is the emitter current in milliamperes. In our example,  $I_e = 1.6$ , so  $R_e = 16.25 \Omega$ . The voltage gain, then, is 289, which is 49 dB. The ac base impedance is given by  $R_e$ . Using the previous values for beta and emitter resistance results in a base impedance of 1625  $\Omega$ . The circuit input impedance is found by shunting the base impedance with the bias resistors. The result in this case is about 1189  $\Omega$ .

If the emitter bypass capacitor is omitted, the external resistor dominates the gain equation, which becomes:  $A_v = R_L/R_E$ , where  $A_v$  is the voltage gain,  $R_L$  is the collector load resistance as before, and  $R_E$  is the unbypassed emitter resistance. Without the bypass capacitor, the common-emitter circuit in Fig. 44 exhibits a numerical voltage gain of 10 (20 dB). The base impedance becomes  $\beta R_E$ , or 47 k $\Omega$ . This value is swamped by the bias network for a circuit input impedance of 3.91 k $\Omega$ . The emitter resistor has introduced 29 dB of degenerative feedback to the circuit,

Fig. 45 — Differential amplifier. This arrangement can be analyzed as a composite of the common-collector and common-base circuits.

stabilizing the gain and impedance values over a wide frequency range. A dc beta of 100 was assumed in this example, and for convenience this value was also assigned at the operating frequency. In reality, however, beta decreases with increasing frequency, as noted in the section on transistor characteristics. Degenerative feedback overcomes this effect to a large extent.

#### Common-Collector Circuit (Emitter-Follower)

Like the vacuum-tube cathode follower, the common-collector transistor amplifier has high input impedance and low output impedance. The latter is approximately equal to the impedance of the signal input source multiplied by  $(1 - \alpha)$ . The input resistance depends on the load resistance, being approximately equal to the load resistance divided by  $(1 - \alpha)$ . The fact that input resistance is directly related to the load resistance is a disadvantage of this type of amplifier if the load is one whose resistance or impedance varies with frequency.

The current transfer ratio with this circuit is

$$\frac{1}{1 - \alpha}$$

and the cutoff frequency is the same as in the grounded-emitter circuit. The output and input currents are in phase.

#### Differential Amplifier Circuit

An important variation of the fundamental amplifier types is the differential amplifier, drawn in Fig. 45. The output voltage is proportional to the difference (with respect to ground) between the

Fig. 46 — Typical characteristic for the collector of an NPN transistor that shows the three primary regions involved during switching.

Fig. 47 — Illustration of the minority-carrier concentrations in an NPN transistor. No. 1 shows the cutoff region. No. 2 is the active region at the threshold of the saturation region. No. 3 is in the saturation region.

Fig. 48 — Circuit for a transistor switching circuit (saturated).

voltages applied to the input terminals. With the proper choice of operating conditions, several differential amplifier stages of the type shown can be cascaded directly. Fig. 45 shows the circuit in its classic balanced form, but many circuits use differential amplifiers in a single-ended configuration. When only a single input and output terminal is required, R1 could be a short circuit and the Q2 base could be grounded. Under these circumstances the differential amplifier can be understood as an emitter-follower driving a common-base stage. The output is taken between the Q2 collector and ground. R3 establishes the current in Q1 and Q2, which should be equal under static conditions.

Differential amplifiers work best when R3 is replaced by some type of constant-current source. One type of current regulator has been discussed in the diode section, and current sources made from bipolar transistors are covered later.

With a current source biasing Q1 and Q2 the input signal cannot modulate the total collector current; only the ratio of the currents varies. One beneficial result of the constant-current bias is that a higher impedance is presented to the driving signal.

### Bipolar Transistor Dissipation

Apart from the characteristics mentioned earlier, it is necessary to consider the matters of collector dissipation, collector voltage and current, and emitter current. Variations in these specifications are denoted by specific parameter symbols which appear later in the chapter. The maximum dissipation ratings of transistors, as provided on the manufacturer's data sheets, tend to confuse some amateurs. An acceptable rule of thumb is to select a transistor that has a maximum dissipation rating of approximately twice the dc input power of the circuit stage. That is, if a 5-watt dc input is contemplated, choose a transistor with a 10-watt or greater rating.

When power levels in excess of a few hundred milliwatts are necessary there is a need for heat sinking. A sink is a metal device that helps keep the transistor cool by virtue of heat transfer from the transistor case to the sink. At power levels below 5 watts it is common practice to employ clip-on heat sinks of the crown variety. For powers greater than 5 watts it is necessary to use large-area heat sinks fashioned from extruded aluminum. These sinks have cooling fins on one or more of their surfaces to hasten the cooling process. Some high-power, solid-state amplifiers employ cooling fans from which the air stream is directed on the metallic heat sink. Regardless of the power level or type of heat sink used, silicone heat-transfer compound should always be used between the mating surfaces of the transistor and the heat sink. Another rule of thumb is offered: If the heat-sink-equipped transistor is too warm to touch with comfort, the heat sink is not large enough in area.

Excessive junction heat will destroy a transistor. Prior to destruction the device may go into thermal runaway. During this condition the transistor becomes hotter and its internal resistance lowers. This causes an increase in emitter/collector and emitter/base current. This increased current elevates the dissipation and further lowers the internal resistance. These effects are cumulative: Eventually the transistor will be destroyed. A heat sink of proper size will prevent this type of problem. Excessive junction temperature will eventually cause the transistor to become open. Checks with an ohmmeter will indicate this condition after a failure.

Excess collector voltage will also cause immediate device failure. The indication of this type of failure, as noted by means of an ohmmeter, is a shorted junction.

### Bipolar Transistor Applications

Silicon transistors are the most common types in use today, although a few ger-

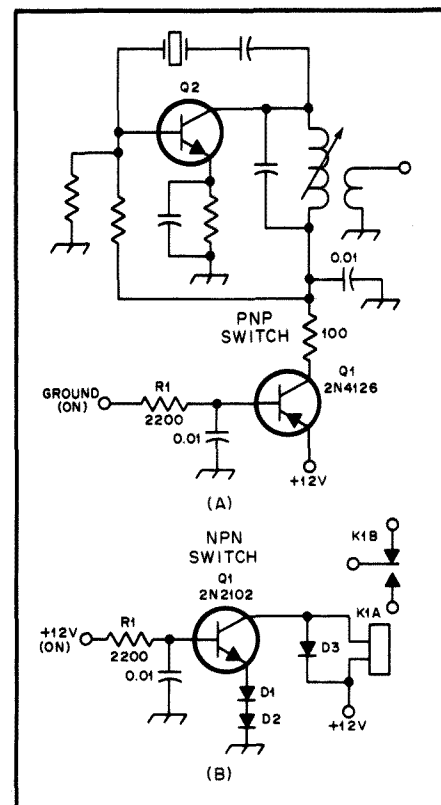

Fig. 49 — Examples of practical switching circuits. A PNP switch is used to key an oscillator at A. When R1 is grounded the switching transistor is forward biased to saturation, permitting current to flow from the dc supply line to Q2. The circuit at B shows Q1 as a relay-driver NPN switch. When +12 volts is applied to the base of Q1 it is forward biased to saturation, permitting current to flow through the field coil of K1A. D1 and D2 are included to reduce the static collector current of Q1, which in some instances could cause K1A to remain closed after forward bias was removed from Q1. D3 serves as a spike suppressor when the field of K1A collapses.

manium varieties are built for specific applications. Collector voltages as great as 1500 can be accommodated by some of the high-power silicon transistors available now. Most small-signal transistors will safely handle collector voltages of 25 or greater. Generally speaking, transistors in the small-signal class carry dissipation ratings of 500 mW or less. Power transistors are normally classed as 500-mW and higher devices.

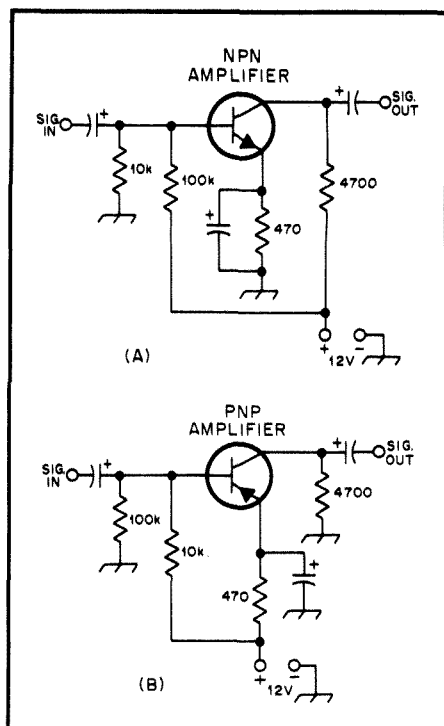

Fig 50 — Examples of PNP and NPN amplifiers operating from a power supply with a negative ground.

The practical applications for all of these semiconductors range from dc to the microwave spectrum.

### Bipolar Transistor Switches

Our present-day technology includes the use of solid-state switches as practical alternatives to mechanical switches. When a bipolar transistor is used in a switching application it is either in an "on" or "off" state. In the "on" state a forward bias is applied to the transistor, sufficient in level to saturate the device. The common-emitter format is used for nearly all transistor switches. Switching action is characterized by large-signal nonlinear operation of the device. Fig. 46 shows typical output characteristics for an NPN switching transistor in the common-emitter mode.

There are three regions of operation — cutoff, active and saturation. In the cutoff region the emitter-base and collector-base junctions are reverse biased. At this period the collector current is quite small and is comparable to the leakage current,  $I_{ce0}$ ,  $I_{cev}$  or  $I_{cbo}$ .

Fig. 47 illustrates the minority-carrier concentration relative to an NPN transistor. During cutoff the concentration is zero at both junctions because they are reverse biased (curve 1).

The emitter-base junction is forward biased in the active region. At this time the collector-base junction is reversed biased. Fig. 46 shows a load line along which switching from the cutoff to the active region is done. The transit time (speed)

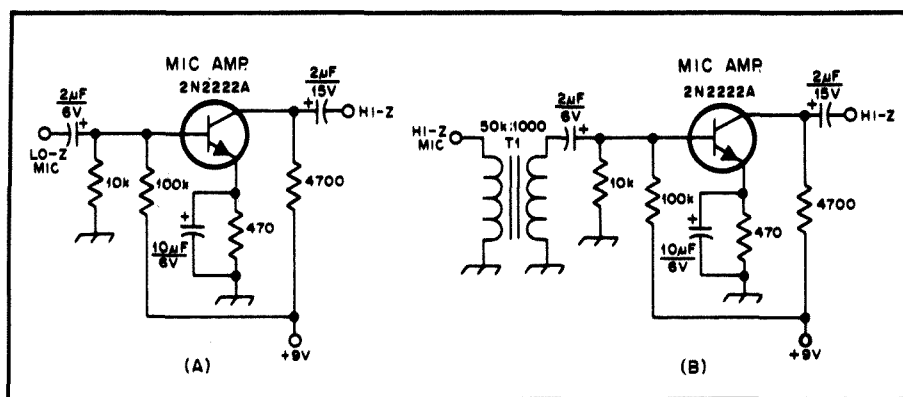

Fig. 51 — RC and transformer-coupled audio amplifiers suitable for high- and low-impedance microphones.

through the active region depends on the transistor frequency-response characteristics. Thus, the higher the frequency rating of the device, the faster the switching time. Curve 2 in Fig. 47 depicts the minority-carrier concentration of the active region.

In the saturation region the emitter-base and collector-base junctions are forward biased. During this period the forward voltage drop across the emitter-base junction  $V_{BE(sat)}$  is larger than it is across the collector-base junction. This results in a collector-emitter voltage termed  $V_{CE(sat)}$ . Series resistances present in the emitter and collector legs of the circuit contribute to the determination of  $V_{CE(sat)}$ . Since the collector in this state is forward biased, additional carriers are injected into the base. Some also reach the collector. Curve 3 in Fig. 47 shows this minority-carrier concentration. Fig. 48 contains the circuit for a basic saturated-transistor switch.

It is extremely important to make certain that none of the transistor voltage ratings is exceeded during the "off" period. The minimum emitter-base breakdown voltage,  $V_{(BR)EBO}$ , must not exceed  $V_{BE(off)}$ . Also, the minimum collector-base breakdown voltage,  $V_{(BR)CBO}$ , should be no greater than  $V_{cc} + V_{BE(off)}$ . Finally, the minimum collector-to-emitter breakdown voltage,  $V_{(BR)CERL}$ , must be greater than  $V_{cc}$ . As is true in any transistor application, the junction temperature must be maintained at a safe value by whatever means necessary.

A transistor switch can be turned on by means of a pulse (Fig. 48) or by application of a dc forward bias. Typical circuits for the latter are given in Fig. 49. The circuit at A illustrates how a PNP transistor can be used as a low-power switch to turn oscillator Q2 on and off. In the "on" state R1 is grounded. This places the bipolar switch, Q1, in a saturated mode, thereby permitting current to flow to Q2. A transistor switch of the type shown at A of Fig. 49 can be used to control more than one circuit stage simultaneously. The primary criterion is that the switching transistor be

capable of passing the combined currents of the various stages under control. The method shown at A is often used in keying a transmitter.

An NPN transistor switch is shown in Fig. 49B. If desired, it can be "slaved" to the circuit of Fig. 49A by attaching R1 of circuit B to the collector of Q1 in circuit A. Because an NPN device is used at B, a positive forward bias must be applied to the base via R1 to make the transistor saturate. When in that state, current flows through the relay (K1A) field coil to actuate the contacts at K1B. D3 is connected across the relay coil to damp inductive spikes that occur when the relay-coil field collapses.

D1 and D2 may not be necessary. This will depend on the sensitivity of the relay and the leakage current of Q1 in the off state. If there is considerable leakage, K1 may not release when forward bias is removed from Q1. D1 and D2 will elevate the emitter to approximately 1.4 volts, thereby providing sufficient reverse bias to cut off Q1 in the off state. It can be seen from the illustrations in Fig. 49 that either NPN or PNP transistors can be used as electronic switches.

### Transistor Audio Amplifiers

Bipolar transistors are suitable for numerous audio-amplifier applications from low-level to high power. It is common practice to use all NPN or all PNP devices, regardless of the polarity of the power supply. In other circuits a mixture of the two types may be found, especially when direct-coupled or complimentary-symmetry stages are included. Fig. 50 shows how PNP or NPN stages can be used with power supplies that have positive or negative grounds. The essential difference in the circuits concerns returning various elements to the negative or positive sides of the power supply. The illustrations show that all one needs to do to use either type of device with the same power supply is to interchange the resistor connections. The same principle applies when using NPN or PNP transistors with a power supply that

has a positive ground. Knowledge of how this is done enables the designer to mix NPN and PNP devices in a single circuit. This basic technique is applicable to any type of transistor circuit — RF, audio or dc.

Some basic low-level audio amplifiers are shown in Fig. 51. These stages operate in the Class A mode. The input impedance of these circuits is low — typically between 500 and 1500 ohms. For the most part the output impedance is established by the value to the collector load resistor. A matching transformer can be used at the input of these stages (Fig. 51B) when it is necessary to use, for example, a high-impedance microphone with one of them. T1 serves as a step-down transformer.

Some direct-coupled audio amplifiers are shown in Fig. 52. The circuit at A combines PNP and NPN devices to provide a compatible interface between them. Three NPN stages are in cascade at B to provide high gain. This circuit is excellent for use in direct-conversion receivers, owing to the need for very high gain after the detector. At C is a Darlington pair, named after the person who developed the configuration. The principal advantages of this circuit are high gain, high input impedance and low output impedance.

#### Transistor RF Amplifiers

In most respects small-signal RF amplifiers are similar in performance to those used in audio applications. However, to effect maximum stable amplification some important design measures are necessary. Furthermore, the matter of proper impedance matching becomes more important than it is in simple audio amplifiers. Other considerations are noise figure, purity of the amplified signal and dynamic range.

Although bipolar transistors can be used as RF amplifiers for receiver front ends, they are not found there in most of the high-performance receivers: Field-effect transistors are more often the designer's choice because of their high input impedance and good dynamic-range traits. A correctly designed bipolar RF input stage can exhibit good dynamic range, however. It is necessary to operate a fairly husky low-noise transistor in Class A, using a relatively high standing collector current — 50 to 100 mA, typically.

Some RF and IF amplifier circuits that use bipolar transistors are shown in the examples of Fig. 53. When used with the appropriate L and C networks they are suitable for either application. At A in Fig. 53 the transistor base is tapped near the cold end of the input tuned circuit to provide an impedance match. The collector is tapped down on the output tuned circuit to provide a proper match. If it is desired, the base and collector taps can be moved even farther down on the tuned circuits. This will result in a deliberate mismatch. The technique is sometimes used to aid

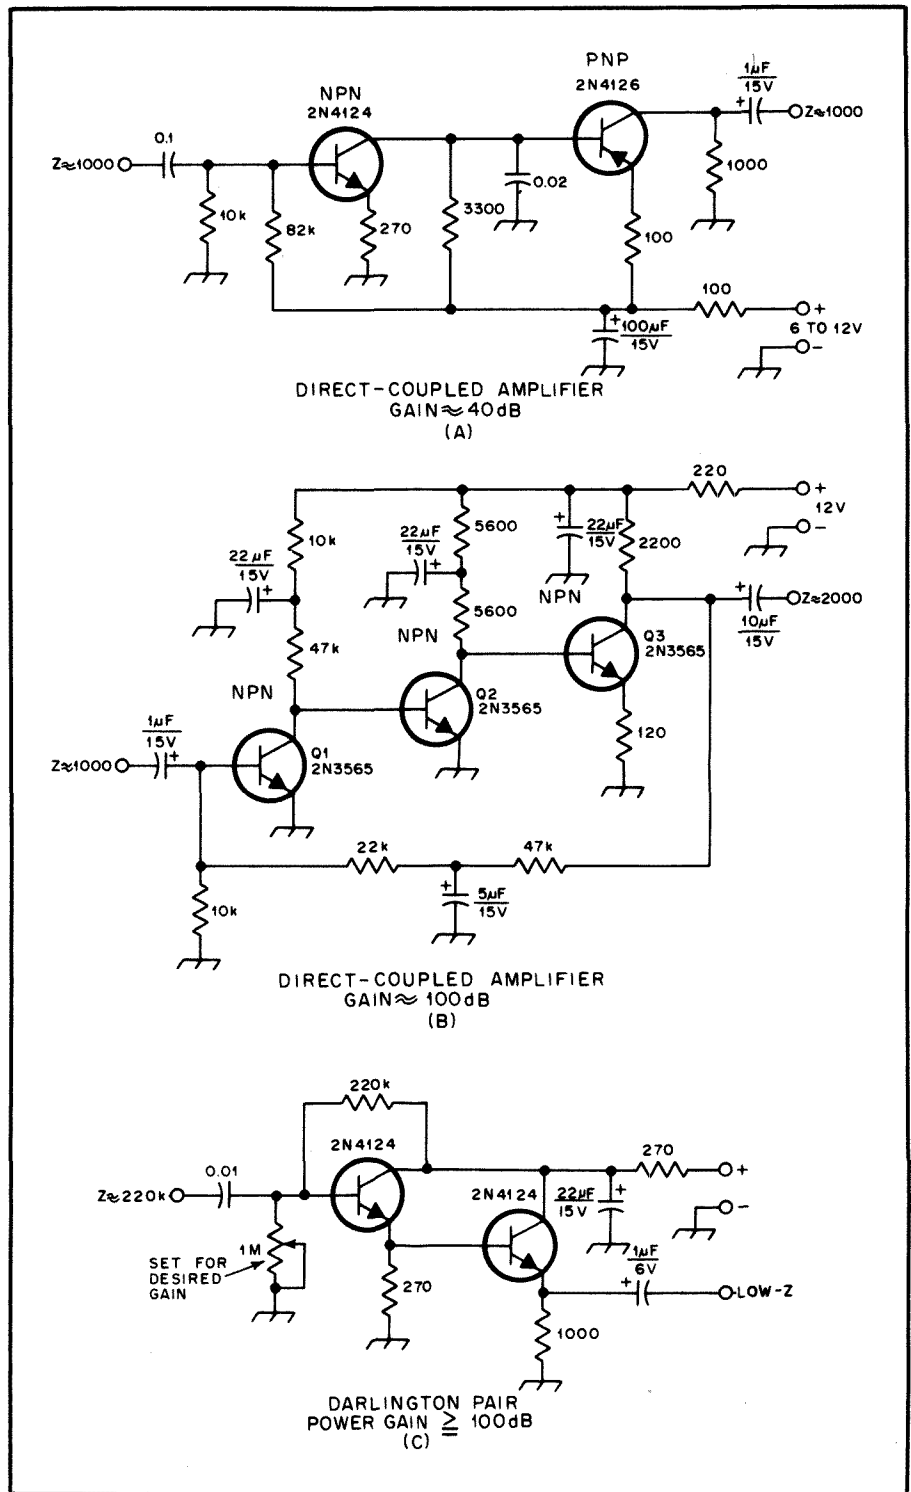

Fig. 52 — Practical examples of direct-coupled audio amplifiers.

stability and/or lower the stage gain. The circuit at B is operated in the common-base mode. Taps are shown on the input and output coils for impedance-matching purposes.

Broadband amplifiers with heavy negative feedback are useful as small-signal RF and IF amplifiers. An example is shown at C in Fig. 53. Not only is negative feedback applied (collector to base), but

degenerative feedback is obtained by virtue of the unbypassed 10-ohm emitter resistor. The use of feedback ensures an unconditionally stable stage. As the operating frequency is decreased the negative feedback increases because the feedback-network reactance becomes lower. This is important if reasonably constant gain is desired over a wide range of frequencies, say from 1.8 to 30 MHz.

This form of gain compensation is necessary because as the operating frequency of a given transistor is decreased, the gain increases. Typically, the gain will increase on the order of 6 dB per octave. Therefore, the probability of instability (self-oscillations) becomes a major consideration at low frequencies in an uncompensated RF amplifier.

The circuit of Fig. 53C operates stably and has a characteristic input and output impedance of approximately 50 ohms. The broadband 4:1 transformer in the collector circuit is required to step down the collector impedance to 50 ohms. Design information on this type of circuit is provided in the ARRL book, *Solid State Design for the Radio Amateur*. A band-pass filter is needed at the amplifier input. Another can be used at the output of the 4:1 transformer if desired. The transistor used in any of the amplifiers of Fig. 53 should have an  $f_T$  that is 5 to 10 times greater than the highest operating frequency of the stage. The 2N5179 has an  $f_T$  in excess of 1000 MHz, making it a good device up to 148 MHz for this application.

### Transistor RF Power Amplifiers

RF power amplifiers that use bipolar transistors fall into two general categories — Class C and linear. The latter is used for AM and SSB signal amplification and the class of operation is A or AB. These amplifiers are designed for narrow or wide-band applications, depending on the purpose for which the stage or stages will be used. Class C bipolar-transistor amplifiers are used for FM and CW work.

Most wideband amplifiers contain ferrite-loaded broadband transformers at the input and output ports. The output transformer is followed by a multipole low-pass filter for each band of operation. This is necessary to attenuate harmonic currents so they will not be radiated by the antenna system. Although this type of filtering is not always needed with a narrow-band amplifier (the networks provide reasonable selectivity), filters should be used in the interest of spectral purity. Two-section filters of the half-wave or two-pass T variety are entirely suitable for harmonic reduction at the 50-ohm output ports of amplifiers.

One of the principal difficulties encountered by amateurs who design and build their own high-power, solid-state amplifiers is instability at some point in the power range. That is, an amplifier driven to its maximum rated output may be stable when terminated properly, but when the drive level is reduced it is apt to break into self-oscillation at the operating frequency, at VHF or perhaps at very low frequencies. Part of the problem is caused by an increase in beta as the collector current is decreased. This elevates the amplifier gain to encourage instability. Also, solid-state amplifiers are designed for a specific network impedance at a specified power-output level. When the drive is reduced the

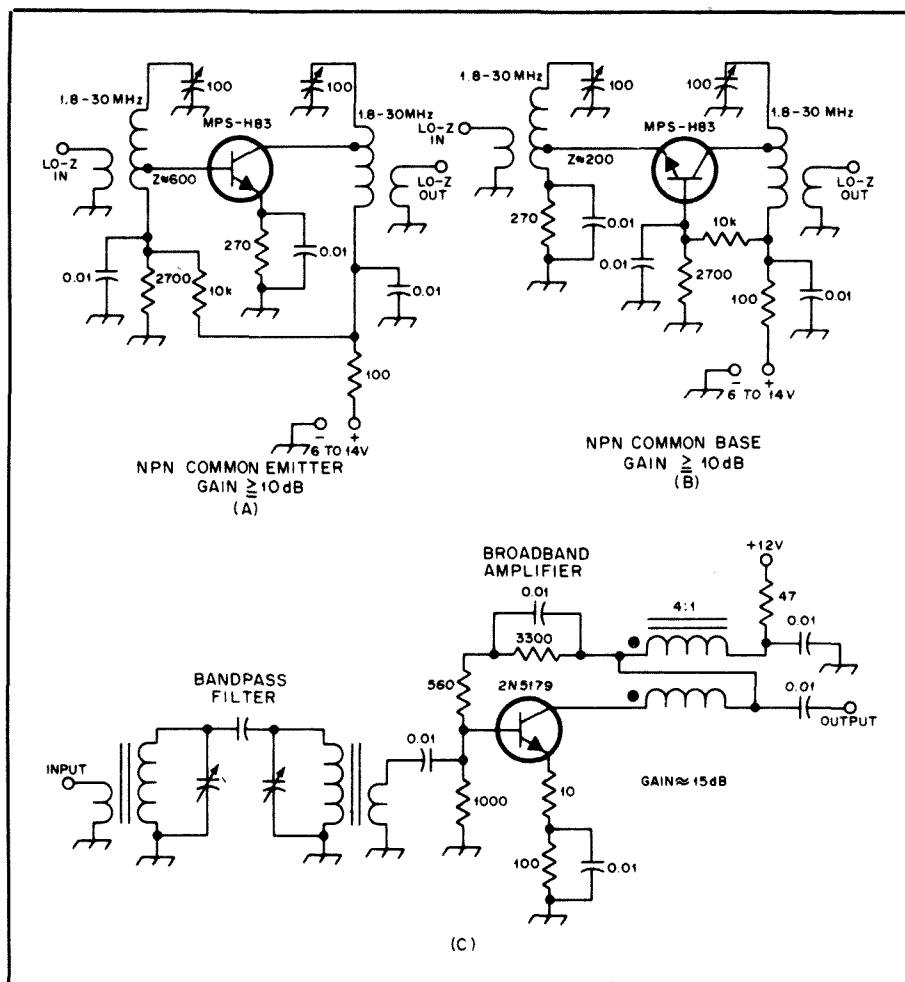

Fig. 53 — Illustrations of common-emitter and common-base RF amplifiers for narrow-band use. The circuit at C is that of a fed-back broadband amplifier that has a band-pass filter at the input.

collector and base impedances increase. This causes a mismatch. An increase in the loaded Q of the networks may also result — a situation that encourages instability. Therefore, it is best to design for a specified power output and adhere closely to that level during operation.

Solid-state power amplifiers should be operated just below their saturation points for best efficiency and stability. That is the point which occurs when no additional RF output can be obtained with increased driving power. Some designers recommend that, for example, a 28-volt transistor be used for 12-volt operation. Saturation will take place at a level where the transistors are relatively safe from damage if a significant output mismatch is present. Stability is usually better under these same conditions, although the gain of the transistors will be considerably lower than would be the case if equivalent types of 12-volt devices were used.

Fig. 54 shows two single-ended amplifiers of typical design. At A a broadband input transformer steps down the 50-ohm source to the lower base impedance of Q1. (Most power stages have a base im-

pedance of 5 ohms or less.) Although a number of suitable tuned networks can be used to effect the desired impedance match, the use of T1 eliminates components and the sometimes complex calculations required for the design of a proper network. When the actual base impedance of Q1 is unknown (it varies with respect to drive level and operating frequency), empirical adjustment of the T1 turns ratio will permit close matching. An SWR indicator can be used between T1 and the signal source to indicate a matched condition. This test should be made with the maximum intended drive applied.

To continue the discussion relating to Fig. 54A, a 10-ohm resistor (R1) is bridged across the secondary of T1 to aid stability. This measure is not always necessary. It will depend on the gain of the transistor, the layout and the loaded Q of T1. Other values of resistance can be used. A good rule of thumb is to employ only that value of resistance which cures instability. It must be remembered that R1 is in parallel with the transistor input impedance. This will have an effect on the turns ratio of T1. When excessive driving power is available,

a deliberate mismatch can be introduced at the input to Q1 by reducing the number of secondary turns. If that is done, R1 can often be eliminated.

The shortcoming resulting from this technique is that the driving source will not be looking into a 50-ohm termination. T1 is normally a ferrite-loaded transformer — toroidal or solenoidal. The core material for operation from 1.8 to 30 MHz is typically the 950- $\mu_i$  (initial permeability) type. The primary winding of T1 (and other broadband transformers) should be approximately four times the terminal impedance with respect to reactance. Therefore, for a 50-ohm load characteristic the primary-winding reactance of T1 should be roughly 200 ohms.

Two RF chokes are shown in Fig. 54A. These are necessary to assure ample dc-lead decoupling along with the related bypass capacitors. The upper RF choke serves also as a collector load impedance. The reactance should be four or five times the collector impedance. Three values of bypass capacitors are used to ensure effective decoupling at VHF, HF and LF. If the decoupling is inadequate, RF from the amplifier can flow along the 12-volt bus to other parts of the transmitter, thereby causing instability of one or more of the stages. A simple low-pass T network is used for matching the collector to the 50-ohm load. It also suppresses harmonic energy. The loaded Q of this general type of matching network should be kept below 4 in the interest of amplifier stability. Information on this and other types of tuned matching networks is given in the *ARRL Electronics Data Book*. Data are also given in that volume concerning broadband transformer design.

Fig. 54B shows the same general amplifier. The difference is in the biasing. The circuit at A is set up for Class C. It is driven into the cutoff region during

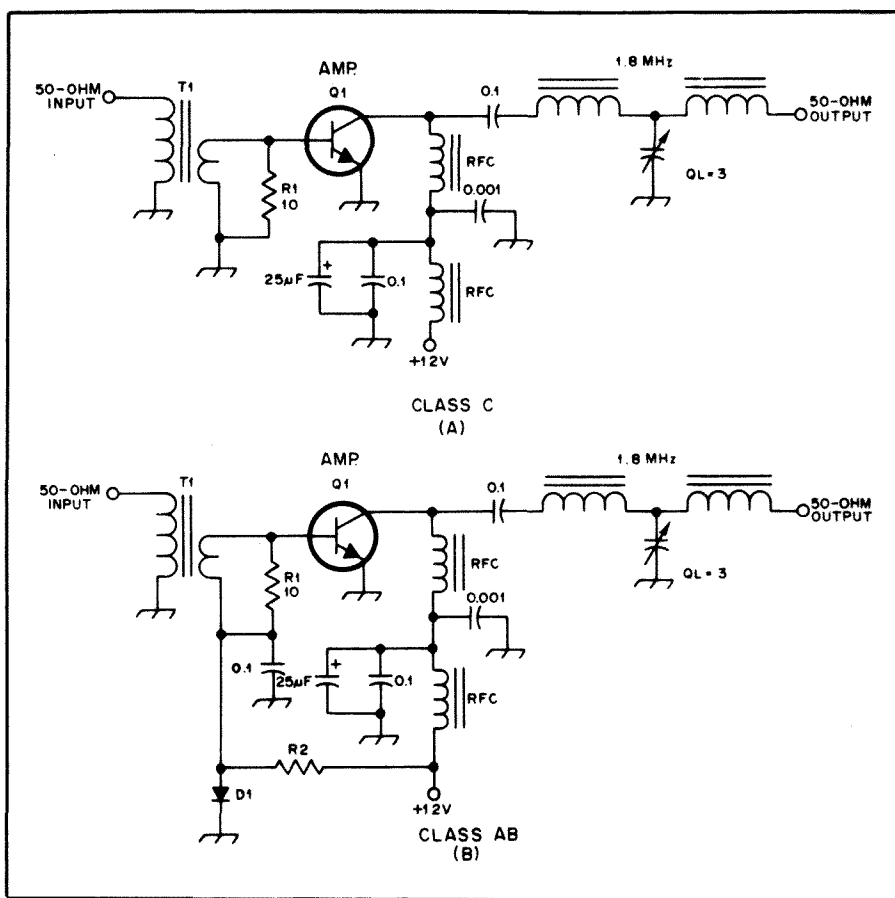

Fig. 54 — Circuits for RF power amplifiers. At A is a Class C type. The circuit at B is biased for linear amplification.

operation. At B there is a small amount of forward bias applied to Q1 (approximately 0.7 volt) by means of the barrier voltage set by D1, a silicon power diode. D1 also functions as a simple bias regulator. R2 should be selected to provide fairly substantial diode current. The forward bias establishes linearity for the amplifier so

SSB and AM driving energy can be amplified by Q1 with minimum distortion.

Although some transistors are designed especially for linear amplification, any power transistor can be used for the purpose. Once the proper biasing point is found for linear amplification with a Class C type of transistor, an investigation of

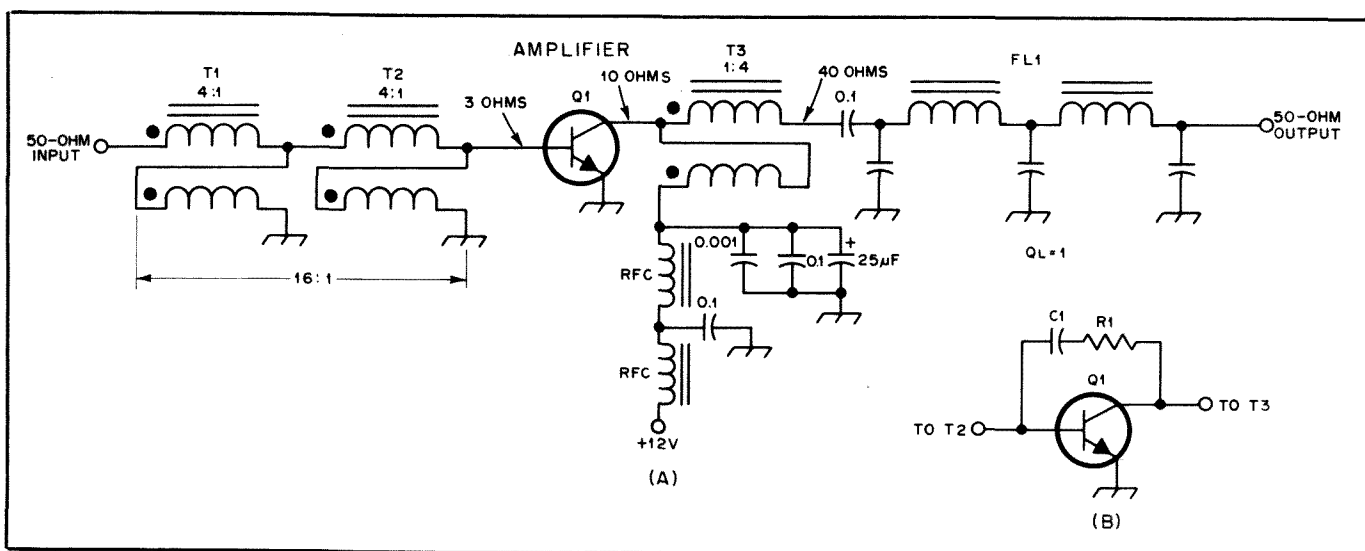

Fig. 55 — Broadband transformers are employed at A for impedance matching. FL1 suppresses harmonic currents at the amplifier output. In the examples at B are feedback components C1 and R1 (see text).

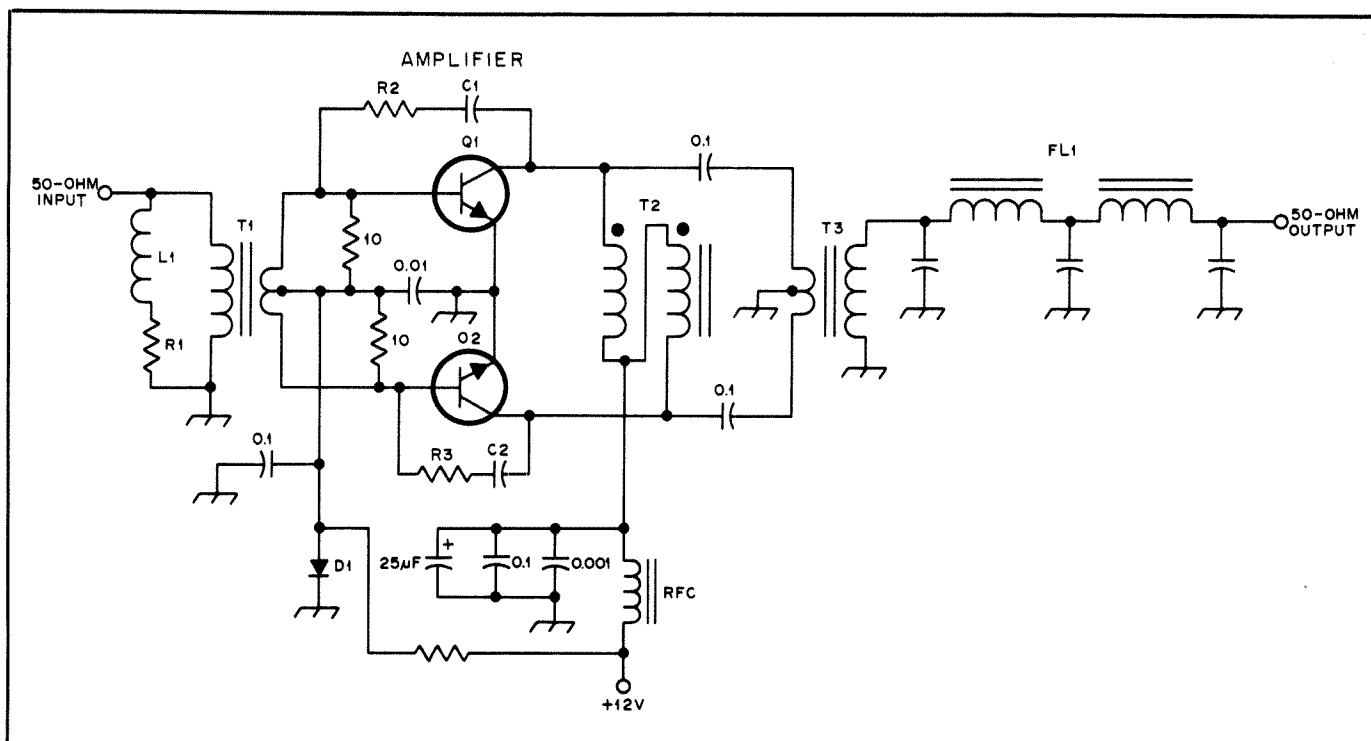

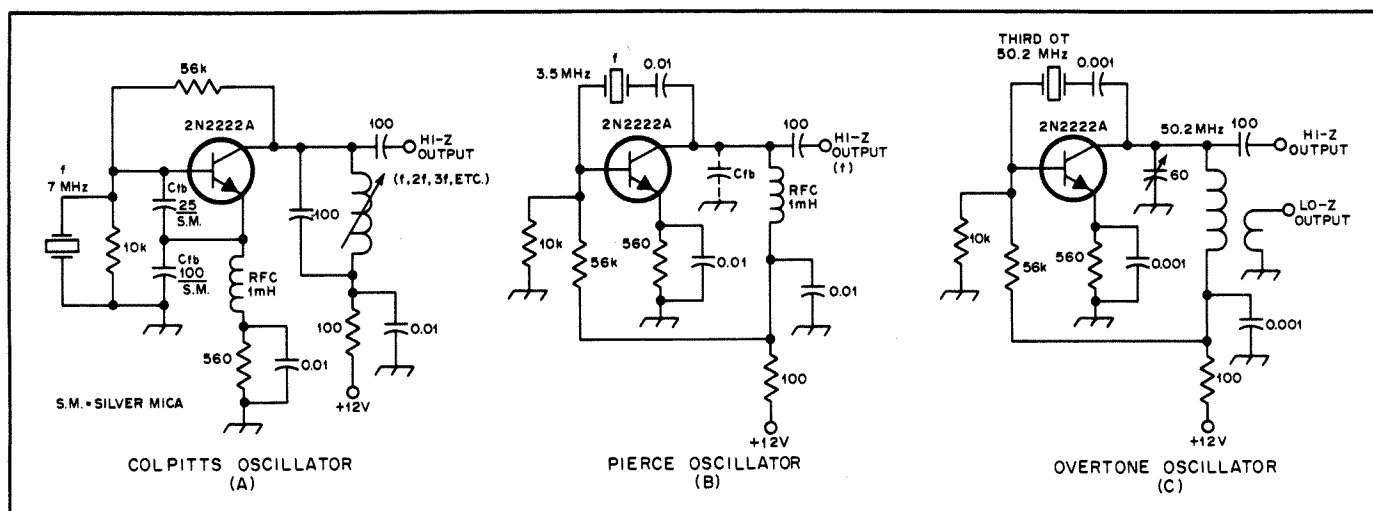

Fig. 56 — Example of a fed-back, push-pull, RF power amplifier set up for broadband service from 1.8 to 30 MHz. The circuit is biased for linear amplification.

**Fig. 57 — Examples of transistor oscillators that use crystal control.**

linearity versus output power should be undertaken. Some Class C transistors are incapable of delivering as much power (undistorted) in Class AB as they can under Class C conditions. Most power transistors intended for linear amplification have built-in, degenerative-feedback resistors at the emitter sites. This technique aids linearity. Depending on the package style of a Class C type of transistor, an emitter-feedback resistor can be added externally. Such resistors are usually on the order of 1 ohm.

A broadband Class C amplifier is shown in Fig. 55A. T1 and T2 are 4:1 broadband transformers connected in series to provide an impedance step down of 16:1. For most

applications this arrangement will provide an acceptable match between 50 ohms and the base impedance of Q1. In the example we have assumed a base impedance of approximately 3 ohms.

T3 serves as a collector load and a step-up transformer. It is useful to use a step-up transformer when the collector impedance is low (25 ohms or less). This enables the designer to work with filter-component values (FL1) that are more practical than would be the case if an attempt were made to match 10 ohms to 50 ohms with the filter network. FL1 in this example is a double pi-section low-pass type (half-wave filter). It is designed to

match 40 ohms to 50 ohms and has a loaded  $Q$  of 1.

Feedback can be applied to stabilize the amplifier. This is seen in Fig. 55B. C1 and R1 are chosen to reduce the amplifier gain by whatever amount is necessary to provide stability and the broadband characteristics desired. C1 serves as a dc blocking capacitor.

A push-pull broadband linear amplifier is illustrated at Fig. 56. When additional frequency compensation is desired (beyond that available from a negative-feedback network) L1 and R1 can be added across the amplifier input. They are selected to roll off the driving power toward the low end

of the amplifier operating range. As the frequency is reduced, L1 represents a lower reactance, thereby permitting some of the drive power to be dissipated in R1.

T1 is a conventional broadband transformer (not a transmission-line type) with a turns ratio set for matching 50 ohms to the base load presented by Q1 and Q2. T2, another broadband transformer, is used to provide balanced dc feed to the collectors. T3 is another broadband transformer which is wound for lowering the collector-to-collector impedance to 50 ohms. FL1 is designed for a bilateral impedance of 50 ohms in this example.

### Bipolar-Transistor Oscillators

Transistors function well as crystal-controlled or LC oscillators. RC oscillators are also practical when a bipolar transistor is used as the active element. The same circuits used for tube-type oscillators apply when using transistors. The essential difference is that transistor oscillators have lower input and output impedances, operate at low voltages and deliver low output power — usually in the milliwatt range. The greater the oscillator power, the greater the heating of the transistor junction and other circuit elements. Therefore, in the interest of oscillator stability it is wise to keep

the dc input power as low as practical. The power level can always be increased by means of subsequent amplifier stages at minor cost.

Some representative examples of crystal-controlled oscillators are provided in Fig. 57. At A is an oscillator that can be used to obtain output at  $f$  (the crystal frequency), or at multiples of  $f$ . The circuit at B illustrates a Pierce type of oscillator for fundamental output at 3.5 MHz.  $C_{fb}$  may be necessary with some crystals to provide ample feedback to cause oscillation. The value of  $C_{fb}$  will depend on the operating frequency and the gain of the transistor. Typically for 1.8 to 20-MHz crystals (fundamental mode) the capacitance value ranges from 25 to 100 pF. The higher values are typical at the lower end of the frequency range. In Fig. 57C is an overtone oscillator. The collector tuned circuit must be able to resonate slightly above the crystal overtone frequency in order to ensure oscillation. Low-impedance output can be had by means of the link shown. Alternatively, a capacitive divider can be placed across the inductor to provide a low-Z tap-off point. The trimmer should be retained in parallel with the inductor to permit resonating the circuit.

Some typical RF and audio oscillators

are shown in Fig. 58. The circuit at A obtains feedback by means of the emitter tap on the tuned circuit. Approximately 25 percent of the oscillator RF power is used as feedback. The tap point on this type of oscillator is between 10 and 25 percent of the total coil turns. The designer should use the smallest amount of feedback that will provide reliable oscillator performance with the load connected.

Fig. 58B illustrates a series-tuned Colpitts oscillator, although this general circuit is often referred to as a "series-tuned Clapp" oscillator. It is very stable when polystyrene capacitors are used in the feedback and tuned circuits. Silver-mica capacitors can be used as substitutes at a slight sacrifice in drift stability (long term).

A twin-T audio oscillator is shown at C in Fig. 58. It is a very stable type of circuit that delivers a clean sine-wave output. Mylar or polystyrene capacitors should be used for best stability.

A simple feedback circuit is effected by means of T1 in Fig. 58D. T1 is a small transistor output transformer with a center-tapped primary and an 8-ohm secondary. This circuit is excellent for use as a code-practice or side-tone oscillator. All of the RF oscillators described in these examples should be followed by one or more buffer

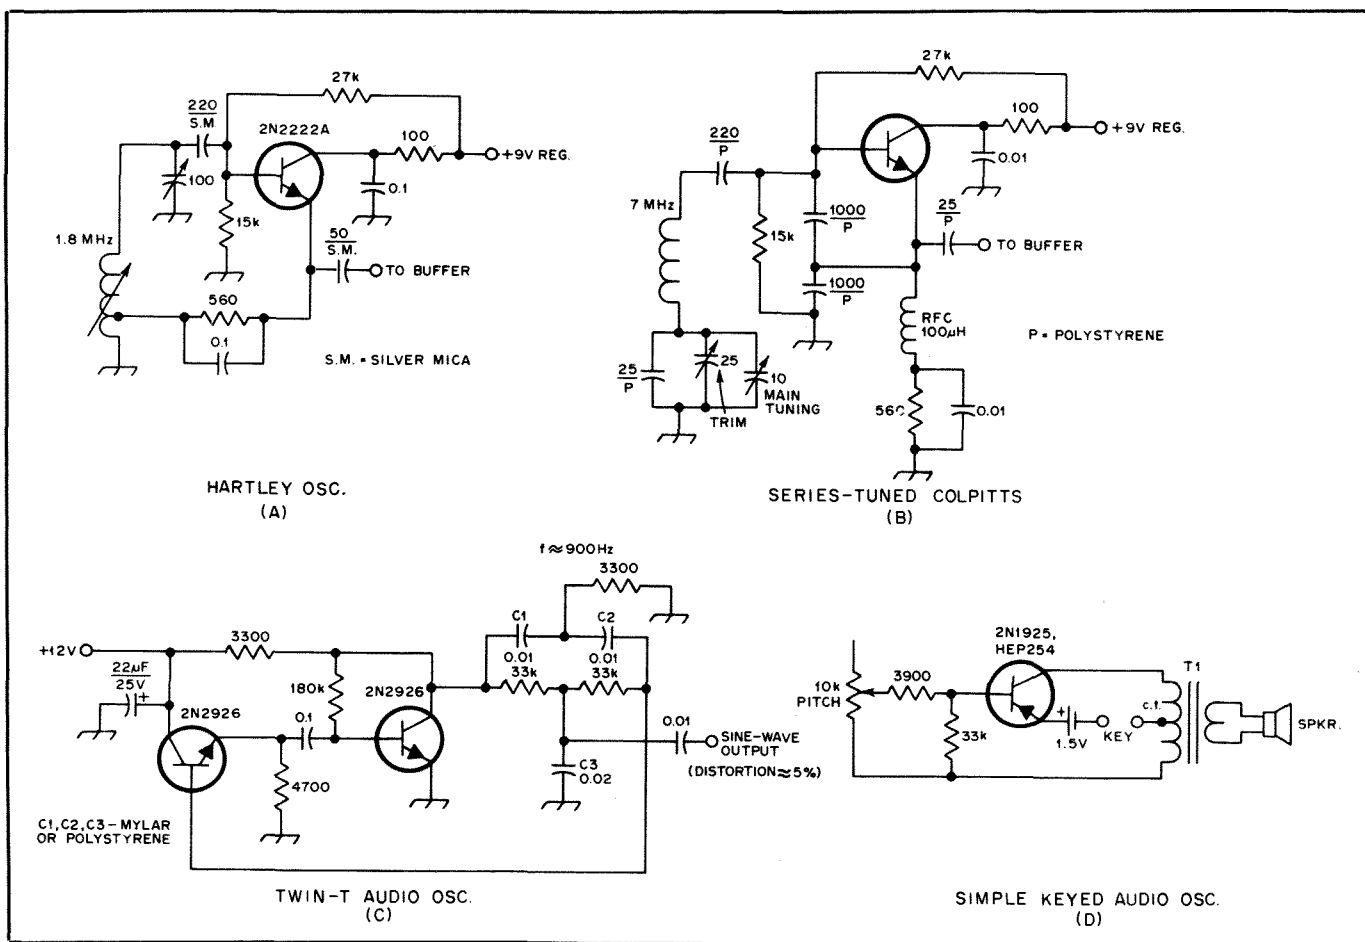

Fig. 58 — The circuits at A and B are VFOs for use in transmitters or receivers. Audio oscillators are shown at C and D.

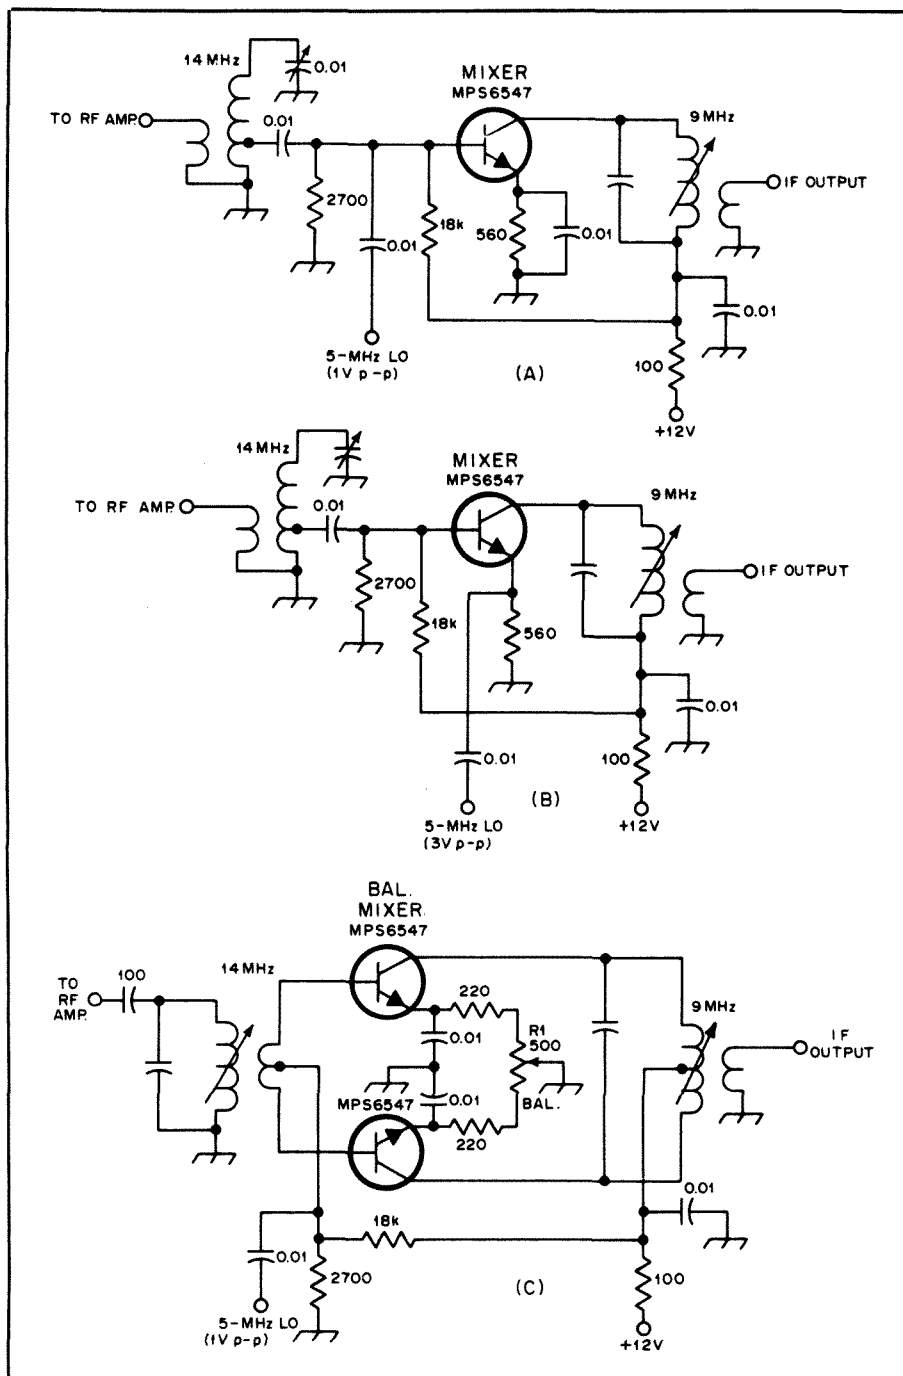

Fig. 59 — Some typical bipolar-transistor mixers. Their characteristics are discussed in the text.

stages to prevent frequency changes resulting from load variations occurring after the oscillator chain.

### Transistor Mixers

Much of the modern equipment used by amateurs contains mixers that use FETs or diode rings, both of which offer good dynamic range. However, there is no reason why a bipolar mixer can't be used to obtain satisfactory results if care is taken with the operating parameters and the gain distribution in the receiver and transmitter where they are used. The bipolar transistors used in receiver mixers should be selected

according to noise figure (low) and dynamic range (high). The signal applied to it should be kept as low as possible, consistent with low-noise operation. Most semiconductor manufacturers specify certain transistors for mixer service. Although this does not mean other types of bipolar transistors can't be used for mixing, it is wise to select a device designed for that class of service.

Fig. 59 contains examples of three basic types of transistor mixers. At A is the most common one. It is found in simple circuits such as transistor AM broadcast-band receivers. As an aid to dynamic range, the

mixers of Fig. 59 can be used without RF amplifier stages ahead of them for frequencies up to and including 7 MHz. The noise in that range (ambient from the antenna) will exceed that of the mixer.

The primary limitation in the performance of the mixer of Fig. 59A is that the local-oscillator voltage is injected at the base. This does not afford good LO/input-signal isolation. The unfavorable result can be oscillator "pulling" with input load changes, and/or radiation of the LO energy via the antenna if the front-end selectivity is marginal or poor. The advantage of the circuit is that it requires less injection voltage than the one at B, where emitter injection is used.

At Fig. 59B is the same basic mixer, but with LO voltage applied to the emitter. This technique requires slightly higher levels of LO energy, but affords greater isolation from the mixer input port.

A singly balanced bipolar-transistor mixer is illustrated in Fig. 59C. R1 is adjusted to effect balance. This circuit could be modified for emitter injection by changing R1 to 1000 ohms, replacing the 220-ohm resistors with 1-mH RF chokes, and injecting the LO output at the junction of the two 0.01- $\mu$ F capacitors. The center tap of the input transformer (base winding) would then be bypassed by means of a 0.01- $\mu$ F capacitor.

### Other Uses for Bipolar Transistors

It is possible to take advantage of the junction characteristics of small-signal transistors for applications that usually employ diodes. One useful technique is using transistors as voltage-variable capacitors (varactors). This method is depicted in Fig. 60. The collector-base junction of Q1 and Q2 serve as diodes for tuning the VFO. In this example the emitters are left floating. A single transistor could be used, but by connecting the pair in a back-to-back arrangement they never conduct during any part of the RF cycle. This minimizes loading of the oscillator. The junction capacitance is varied by adjusting the tuning control, R1. In this circuit the tuning range is approximately 70 kHz.

A bipolar-transistor junction can be used as a Zener diode in the manner shown in Fig. 61. Advantage is taken of the reverse-breakdown characteristic of Q1 to establish a fixed reference level. Most transistors provide Zener-diode action between 6 and 9 volts. The exact value can be determined experimentally.

When the base and collector of a bipolar transistor are connected and a forward bias applied to the base-emitter junction, a superdiode results. If the collector were left open, the base-emitter junction would behave like an ordinary diode. With the collector tied to the base, the diode current rises much more rapidly with applied voltage because of the amplification provided by the transistor action. Two cross-

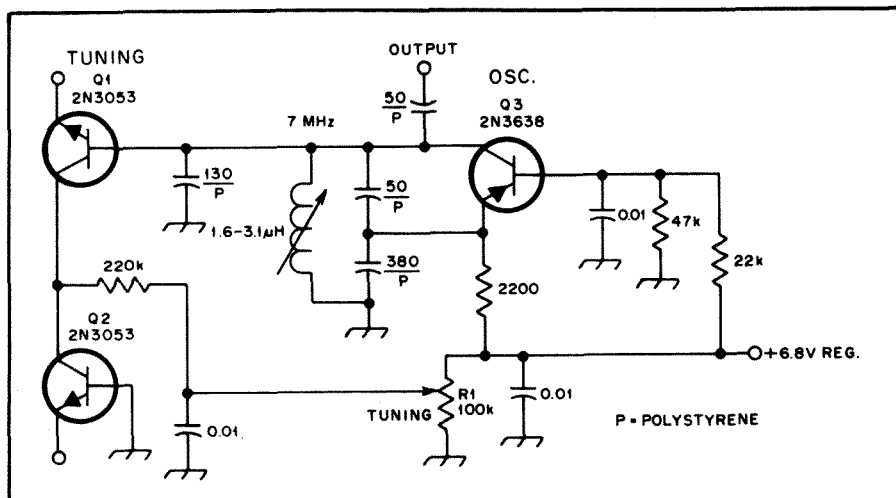

Fig. 60 — Bipolar transistors serve as varactor tuning diodes in this circuit (Q1 and Q2).

Fig. 61 — A bipolar transistor will function as a Zener diode when connected as shown here.

Fig. 62 — A peak clipper circuit using bipolar transistors connected in the superdiode configuration.

connected super-diodes form the basis for a highly effective peak clipper or hard limiter. Fig. 62 illustrates the application. NPN transistors are shown, but PNP units

will yield identical performance.

#### Constant-Current Generators

The curves in Figs. 41 to 43 show that

Fig. 64 — An SCR and its discrete functional near-equivalent.

the collector current of a bipolar transistor is essentially independent of the collector-to-emitter potential when the device is biased in its active region. Fig. 63A illustrates a constant-current source (or sink, if actual electron flow is considered) using a PNP transistor. A fairly constant 1.2-volt potential drop is maintained across the diode string. The base-emitter junction introduces a diode drop, so the EMF applied to the 62-Ω resistor is a constant 0.6 volt. A constant voltage across a resistor forces a constant current. This current flows in the emitter, and the high alpha causes the collector current to be nearly the same.

The circuit of Fig. 63B works in a similar manner. R1 biases Q1 into conduction. When the EMF developed by R2 reaches 0.6 volt, Q2 begins to conduct, shunting base drive away from Q1 and limiting its collector current.

A device that passes an arbitrary current independent of the applied voltage presents an infinite dynamic impedance to the driving signal. This feature makes the constant-current generator valuable in several applications. One use for the circuits of Fig. 63 is in the bias control circuit of a differential amplifier. Either configuration can be used to establish the proper amplifier current while providing the tightest possible coupling between the emitters of the differential pair.

Another way to employ a constant-current circuit is to use it as an active load for the collector of a transistor amplifier stage. The infinite dynamic impedance of the current source causes the amplifier to exhibit very high voltage gain. When the amplifier is an NPN transistor, the current source must be a PNP device, and vice-versa.

#### Thyristors

Two complementary bipolar transistors connected as in Fig. 64 form the solid-state analog of the latching relay; a trigger pulse applied to the base of Q2 will initiate current flow in both devices. This current is limited only by the external circuit resistance and continues independent of the trigger signal until the main source is interrupted. Four-layer semiconductors

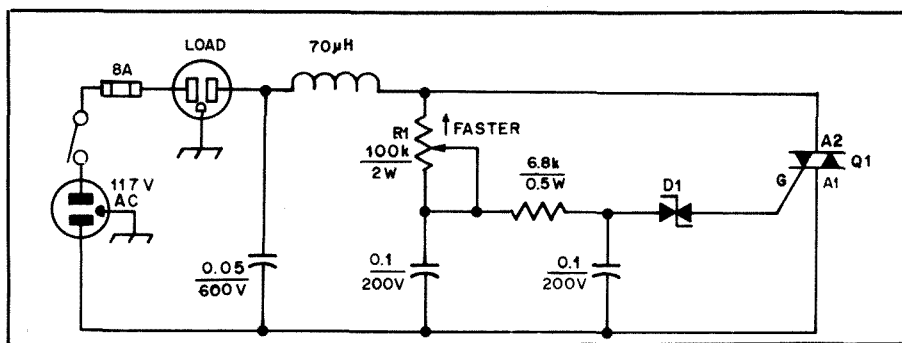

Fig. 65 — Schematic diagram of motor-speed control.

Q1 — Triac (silicon bidirectional thyristor), 8A, 200 V (Motorola MAC2-4 or HEP340 or equiv.). D1 — Diac (silicon bilateral trigger), 2 A, 300 mW.

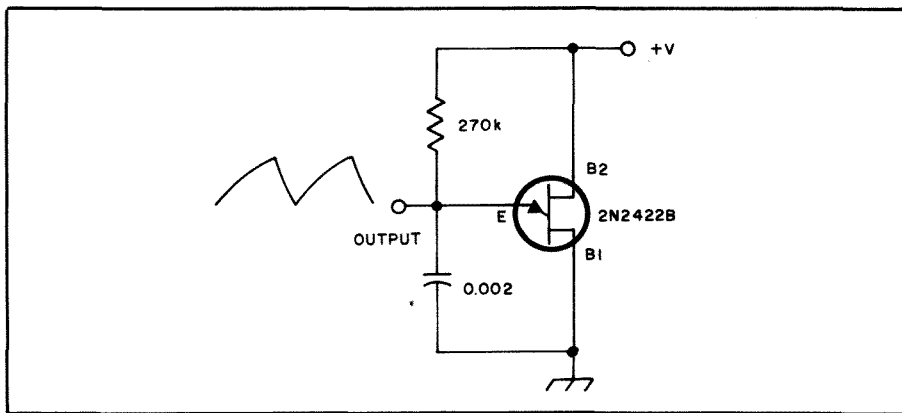

Fig. 66 — A relaxation oscillator based on a unijunction transistor. The frequency of oscillation is approximately 1500 Hz.

(PNPN or NPNP) having this property are known as thyristors or silicon controlled rectifiers (SCRs). SCRs find use in power supply overvoltage protection circuits (crowbars), electronic ignition systems, alarms, solid-state commutating systems for dc motors and a host of other applications.

Two complementary SCRs fabricated in parallel, with a common gate terminal, form a triac. These are used to switch alternating currents. The most common application of the triac is in incandescent light dimmers. Triacs have sensitive gates, and prolonging the trigger signal or injecting excessive gate current can cause excessive heating. In circuits operating on 117-volt ac, a diac is used to trigger a triac. A diac is a bidirectional current-limiting diode. Structurally, it can be compared to a triac without a gate. A motor speed control illustrating the use of triacs and diacs are drawn in Fig. 65.

### Unijunction Transistors

An unusual three-terminal semiconductor device is the unijunction transistor (UJT), sometimes called a double-base diode. The elements of a UJT are base 1, base 2 and emitter. The single rectifying junction is between the emitter and the silicon substrate. The base terminals are ohmic contacts, meaning the current is a

linear function of the applied voltage. Current flowing between the bases sets up a voltage gradient along the substrate. In operation, the direction of flow causes the emitter junction to be reverse biased.

The relaxation oscillator circuit (the most common UJT application) of Fig. 66 illustrates the function of the UJT. When the circuit is energized, the capacitor charges through the resistor until the emitter voltage overcomes the reverse bias. As soon as current flows in the emitter, the resistance of the base 1 region decreases dramatically, discharging the capacitor. The decreased base 1 resistance alters the voltage distribution along the substrate, establishing a new bias point for the emitter junction. As more and more emitter current flows, the majority carrier injection builds a space charge in the base 1 region, which causes the emitter current to cease. Current is again available to charge the capacitor and the cycle repeats.

If the resistor were replaced by a constant-current source, the output waveform would be a linear ramp instead of a sawtooth. The UJT schematic symbol resembles that of an N-channel JFET — the angled emitter distinguishes the unijunction transistor.

### Field-Effect Transistors

Field-effect transistors are assigned that

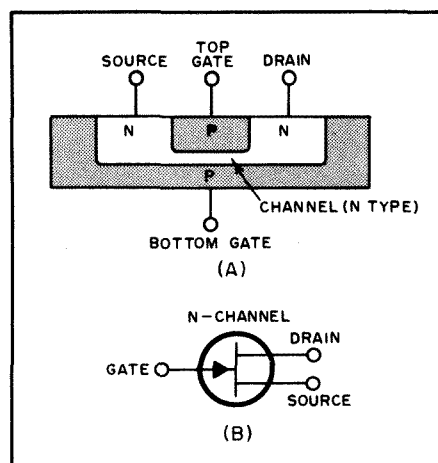

Fig. 67 — Profile and symbol for an N-channel junction field-effect transistor. In a P-channel device, all polarities are reversed and the gate arrow points away from the substrate.

name because the current flow in them is controlled by varying electric field that is brought about through the application of a voltage that controls the electrode known as the gate. By contrast, in a bipolar transistor, output current flow is controlled by the current applied to the base electrode.

There are two types of field-effect transistors (FETs) in use today — the junction FET (JFET) and the MOSFET. The JFET has no insulation between its elements, as is the case with a bipolar transistor. The MOSFET has a thin layer of oxide between the gate or gates and the drain-source junction. The term MOSFET is derived from metal-oxide silicon field-effect transistor. The basic characteristic of the two types are similar — high input impedance and good dynamic range. These characteristics apply to small-signal FETs. Power FETs, which will be treated later, have different characteristics.

Although some MOSFETs have but one gate, others have two gates. Single-gate FETs can be equated to a triode vacuum tube. The gate represents the grid, the anode is similar to the drain and the cathode is like the source. The input impedance of FETs is a megohm or greater. Their noise figure is quite low, making them ideal as preamplifiers for audio and RF well into the UHF region. Nearly all of the MOSFETs manufactured today have built-in gate-protective Zener diodes. Without this provision the gate insulation can be perforated easily by small static charges on the user's hands or by the application of excessive voltages. The protective diodes are connected between the gate (or gates) and the source of FET.

### The Junction FET

As was stated earlier, field-effect transistors are divided into two main groups: Junction FETs and MOSFETs. The basic JFET is shown in Fig. 67.

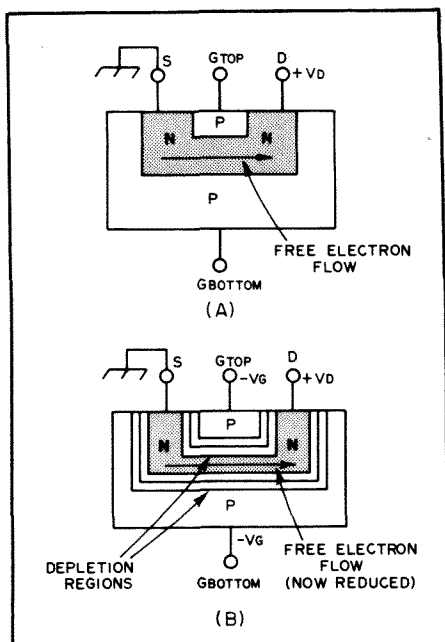

Fig. 68 — Operation of a JFET under applied bias. A depletion region (light shading) is formed, compressing the channel and increasing the resistance to current flow.

Fig. 69 — Profile and symbol for a MOSFET.

The reason for the terminal names will become clear later. A dc operating condition is set up by starting a current flow between source and drain. This current flow is made up of free electrons since the semiconductor is N-type in the channel, so a positive voltage is applied at the drain. This positive voltage attracts the negatively charged free electrons and the current flows (Fig. 68). The next step is to apply a gate voltage of the polarity shown in Fig. 68. Note that this reverse-biases the gates

Fig. 70 — At A are typical JFET characteristic curves. The picture at B shows an actual oscillograph of the family of curves produced by a curve tracer.

Fig. 71 — Typical characteristic curves for a MOSFET.

with respect to the source, channel and drain. This reverse-bias gate voltage causes a depletion layer to be formed, which takes up part of the channel. Since the electrons now have less volume in which to move, the resistance is greater and the current between source and drain is reduced. If a large gate voltage is applied, the depletion regions meet, causing pinch-off; consequently, the source-drain current is reduced nearly to zero. Since the large source-drain current changes with a relatively small gate

voltage, the device acts as an amplifier. In the operation of that JFET, the gate terminal is never forward biased, because if it were the source-drain current would all be diverted through the forward-biased gate junction diode.

The resistance between the gate terminal and the rest of the device is very high, since the gate terminal is always reverse biased, so the JFET has a very high input resistance. The source terminal is the source of current carriers, and they are drained out of the circuit at the drain. The gate opens and closes the amount of channel current that flows in the pinch-off region. The operation of an FET thus closely resembles the operation of the vacuum tube with its high grid-input impedance.

### MOSFETs (Metal-Oxide Semiconductors)

The other large family that makes up field-effect transistors is the insulated-gate FET, or MOSFET, which is pictured schematically in Fig. 69. In order to set up a dc operating condition, a positive polarity is applied to the drain terminal. The substrate is connected to the source, and both are at ground potential, so the channel electrons are attracted to the positive drain. In order to regulate this source-drain current, voltage is applied to the gate contact. The gate is insulated from the rest of the device by a layer of very thin dielectric material, so this is not a PN junction between the gate and the device — thus the name insulated gate. When a negative gate polarity is applied, positive-charged holes from the P-type substrate are attracted toward the gate and the conducting channel is made more narrow; thus, the source-drain current is reduced.

When a positive gate voltage is connected, the holes in the substrate are repelled, the conducting channel is made larger and the source-drain current is increased. The MOSFET is more flexible since either a positive or negative voltage can be applied to the gate. The resistance between the gate and the rest of the device is extremely high because they are separated by a layer of thin dielectric. Thus, the MOSFET has an extremely high input impedance. In fact, since the leakage through the insulating material is generally much smaller than through the reverse-biased PN gate junction in the JFET, the MOSFET has a much higher input impedance. Typical values of  $R_{in}$  for the MOSFET are over a million megohms.

Both single-gate and dual-gate MOSFETs are available. The latter has a signal gate, gate 1, and a control gate, gate 2. The gates are effectively in series, making it an easy matter to control the dynamic range of the device by varying the bias on gate 2. Dual-gate MOSFETs are widely used as AGC-controlled RF and IF amplifiers, as mixers and product detectors and as variable attenuators. The isolation between the gates is relatively high in mixer service. This reduces oscillator "pulling"

Fig. 72 — Profile and symbol for a power FET (VMOS enhancement-mode type).

and reduces oscillator radiation. The forward transadmittance (transconductance, or  $G_m$ ) of dual-gate MOSFETs is as high as 40,000 microsiemens.

### FET Characteristics

The characteristic curves for the FETs described above are shown in Figs. 70 and 71. The drain-source current is plotted against drain-source voltage for given gate voltages.

The dynamic characteristics of an FET are most heavily influenced by dynamic mutual conductance or transconductance. This parameter is defined as the ratio of drain current change to the small gate-to-source voltage change that caused it. Mathematically, the relationship is expressed  $G_m = \Delta I_D / \Delta E_{GS}$ , where  $\Delta$  represents a small change or increment. Typical general-purpose JFETs for small-signal RF and audio work have  $G_m$  values in the neighborhood of 5000 microsiemens, while some units designed for CATV service feature transconductance over 13,000  $\mu S$ . As mentioned earlier, 40,000  $\mu S$  (40 mS) is the transconductance figure for the "hottest" dual-gate MOSFETs. Some JFETs intended for analog switching also have 40 mS or more of transconductance to achieve low ON resistance. The newer power FETs boast transconductance figures on the order of 1 siemen.

Transconductance is of great importance in calculating the gain and impedance values of FET circuits. In common-source and common-gate amplifiers with no degeneration, the numerical voltage gain is given by  $A_v = G_m R_L$ , where  $A_v$  is the gain,  $G_m$  is the transconductance in siemens and  $R_L$  is the drain load resistance

Fig. 73 — Curve showing relationship between gate-source voltage and drain current of a power FET.

in ohms. Also, the source impedance of a common-gate or common-drain (source follower) amplifier is approximately  $1/G_m$ .

### Classifications

Field-effect transistors are classified into two main groupings for application in circuits — enhancement mode and depletion mode. The enhancement-mode devices are those specifically constructed so they have no channel. They become useful only when a gate voltage is applied that causes a channel to be formed. IGFETs (insulated-gate FET) can be used as enhancement-mode devices since both polarities can be applied to the gate without the gate becoming forward biased and conducting.

A depletion-mode unit corresponds to Figs. 66 and 67, shown earlier, where a channel exists with no gate voltage applied. For the JFET we can apply a gate voltage and deplete the channel, causing the current to decrease. With the MOSFET we can apply a gate voltage of either polarity so the device can be depleted (current decreased) or enhanced (current increased).

To sum up, a depletion-mode FET is one that has a channel constructed; thus, it has a current flow for zero gate voltage. Enhancement-mode FETs are those that have no channel, so no current flows with zero gate voltage.

### Power FETs

FETs capable of handling substantial amounts of power are available for use from dc through the VHF spectrum. They are known under more than one name — vertical FETs, MOSPOWER FETs and VMOS FETs. The power FET was introduced in 1976 by Siliconix, Inc. The device enabled designers to switch a current of 1 ampere in less than 4 nanoseconds. The transfer characteristic of the power FET is a linear one. It can be employed as a linear power amplifier or a low-noise, small-signal amplifier with high dynamic range. With

Fig. 74 — Curves for 24- and 36-volt operation of a power FET.

this kind of FET there is no thermal runaway, as is the case with power types of bipolar transistors. Furthermore, there is no secondary breakdown or minority-carrier storage time. This makes them excellent for use in switching amplifiers (Class D service). Of particular interest to amateurs is the immunity of power FETs to damage from a high SWR (open or short condition). These devices can be operated in Class A, AB, B or C. Zero bias results in Class C operation.

Fig. 72 illustrates the manner in which a power FET is formed. These devices operate in the enhancement mode. The current travels vertically. The source is on top of the chip but the drain is on the bottom of the chip. In this vertical structure there are four layers of material (N+, P, N- and N+). This device offers high current density, high source/drain breakdown capability and low gate/drain feedback capacitance. These features make the transistor ideal for HF and VHF use.

Fig. 73 depicts the drain current as being linearly proportional to the gate-to-source voltage. The more conventional JFET exhibits a square-law response (drain current being proportional to the square of the gate-to-source voltage).

As an example, the M/A COM PHI VMP-4 power FET can provide a power just short of 20 watts (saturated) at 160 MHz. Fig. 74 shows curves for this device respective to saturated output power versus frequency. In this case both the input and output impedances of the transistor are matched conjugately. An advantage to this device over the power bipolar transistor is that these impedances are barely affected by the drive levels applied. In wideband amplifier service the power FET can be operated with complete stability. In-depth data on these devices is given in M/A COM application note AN80-2.

### GaAsFETs

For low-noise amplification at UHF and

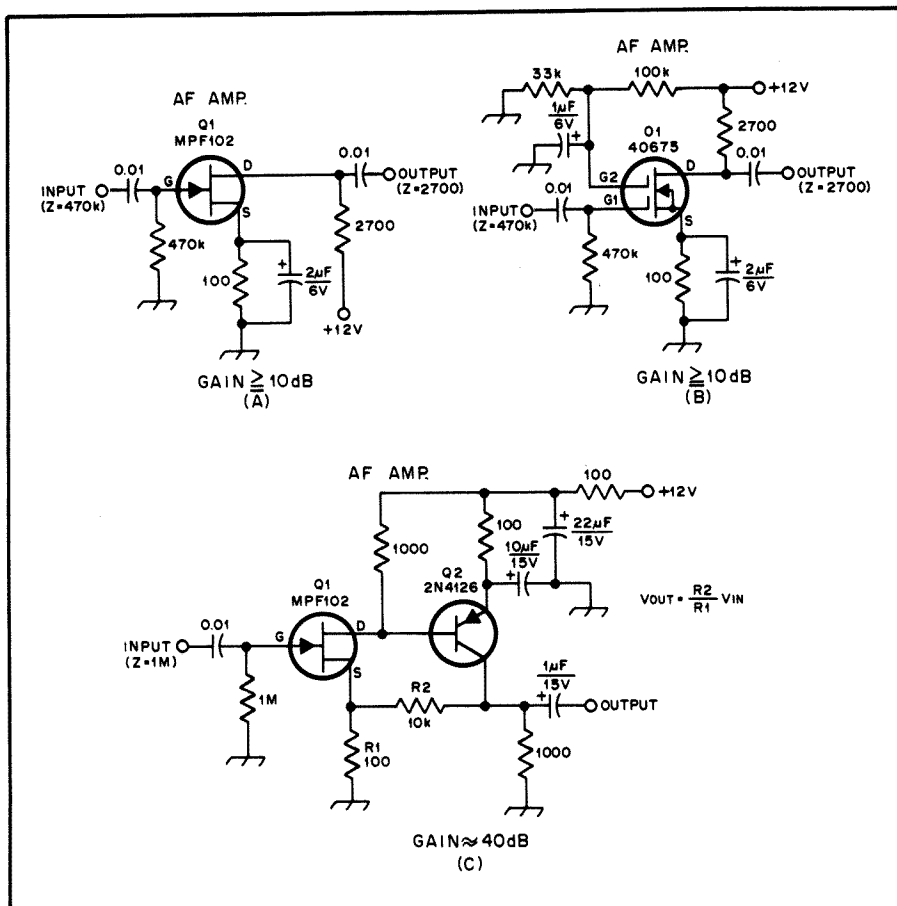

Fig. 75 — Some typical audio amplifiers that employ FETs.

microwaves, the state of the art is defined by field-effect transistors fabricated from gallium arsenide. Also used in LEDs and microwave diodes, gallium arsenide is semiconductor compound, as opposed to silicon and germanium, which are elements. This compound exhibits greater carrier mobility (the electrons can move more freely) than silicon or germanium; hence, the transit time is reduced and high-frequency performance improved in GaAsFETs. GaAsFETs are classified as depletion-mode junction devices. The gate is made of gold or aluminum, (which is susceptible to damage from static charges).

GaAsFETs are available for both small-signal and power applications. The power devices have noise figures almost as low as those specified for the small-signal types, and naturally exhibit greater dynamic range and ruggedness. Several semiconductor manufacturers offer gallium-arsenide field-effect transistors in various noise figure, frequency and power ratings. In the U.S., Hewlett-Packard and Microwave Semiconductor Corp. feature units usable up through frequency of Ku-band. Representative type numbers are HFET-2201 and MSC H001, respectively. In Great Britain,

the Plessey GAT5 and GAT6 devices feature low-noise performance up to 14 GHz. The Nippon Electric Company of Japan is also competing strongly for leadership in the GaAsFET market. A practical GaAsFET preamplifier is featured in Chapter 32. For more background information on GaAsFETs, see Wade, "Introduction to GaAs Field-Effect Transistors," *Ham Radio*, January 1978, and Wade and Katz, "Low-Noise GaAsFET UHF preamplifiers," *QST*, June 1978.

#### Practical FET Circuits

Small-signal FETs can be used in the same general types of circuits given earlier for bipolar transistors. The primary obstacle in some types of amplifier circuits is instability. Certain precautions are necessary to prevent unwanted self-oscillations, but they do not differ markedly from those techniques applied when working with triode tubes.

In Fig. 75 are examples of FET audio amplifiers. The circuit at A shows a simple RC coupled stage with a gain of 10 dB or greater. The input and output impedances are set by the gate and drain resistors. The circuit at B in Fig. 75 is similar to that at

A, except that a dual-gate MOSFET is used as the active device (Q1). A positive bias is supplied to gate 2 by means of a resistive divider. In the circuit of Fig. 75C, a PNP transistor is combined with a JFET to provide a direct-coupled pair. This configuration provides high gain. The amount of gain is set by the ratio of R1 and R2. Again, the input and output impedances are largely determined by the values of the input and output resistors, 1 megohm and 1000 ohms, respectively.

#### RF and IF Amplifiers

Small-signal RF and IF amplifiers that use FETs are capable of good dynamic range and will exhibit a low noise figure. It is for these reasons that many designers prefer them to bipolar transistors. Fig. 76 contains examples of FET RF or IF amplifiers. In the example at A the gate and drain elements of Q1 are tapped down on L2 and L3 to provide stability. This represents an intentional mismatch, which causes a slight sacrifice in stage gain. The 10-ohm drain resistor (R1) is used only if VHF parasitic oscillations occur.

Fig. 76B depicts a common-gate FET amplifier. The source is tapped well down on the input tuned circuit to effect an impedance match. This circuit is characterized by its excellent stability, provided the gate lead is returned to ground by the shortest path possible. This type of circuit will have slightly less gain capability than the common-source example at A.

In Fig. 76C is an illustration of a dual-gate MOSFET amplifier. Provided the input and output tuned circuits are well isolated from one another, there is less chance for self-oscillation than with a JFET. A positive bias is applied to gate 2, but AGC voltage can be used in place of a fixed-value voltage if desired. This circuit can provide up to 25 dB of gain.

Fig. 76D shows the configuration of a cascode RF amplifier in which a dual JFET (Siliconix U257) is specified. The advantage in using the dual FET is that both transistors have nearly identical characteristics, because they are fabricated on a common substrate. Two separate JFETs can be used in this circuit if the one nearest to  $V_{DD}$  has an  $I_{DSS}$  higher than its mate. This ensures proper dc bias for cascode operation. Unmatched FETs require special forward-biasing techniques and ac-coupling measures that aren't seen in this circuit.

Cascode amplifiers are noted for their high gain, good stability and low noise figure. With the circuit shown the noise figure at 28 MHz is approximately 1.5 dB. Short leads are necessary, and shielding between the tuned circuits is recommended in the interest of stability. Careful layout will permit the use of toroidal inductors at L2 and L3. These components should be spaced apart and mounted at right angles to one another in order to reduce unwanted infringing magnetic fields. AGC can be ap-

plied to this amplifier by routing the control voltage to the gate of Q1B.

## FET Mixers

There are three types of FET mixers in common use today — single-ended, singly balanced and doubly balanced. In all cases there is an advantage to using active devices in place of passive ones (diodes). This ensures a conversion gain that helps minimize the number of gain stages required in a given circuit.

A single-ended JFET mixer requires 0 dBm of LO injection power. It can provide several decades of bandwidth and has a good IMD characteristic. The latter is far superior to most bipolar single-ended mixers. The major shortcoming is very poor isolation between the three mixer ports (RF, LO and IF). A typical single-ended mixer using a JFET is shown in Fig. 77A. Optimum trade-off between conversion gain and IMD occurs near the point where the self-bias is 0.8 V. LO injection voltage will be on the order of 1 (P-P) to provide good mixer performance. Conversion gain with this mixer will be approximately 10 dB.

Fig. 77B illustrates a singly balanced JFET mixer. A broadband transformer (T1) provides a low-impedance source for the LO and supplies injection voltage in push-pull to the gates of Q1 and Q2. The latter should be matched FETs or a dual FET such as the U430 by Siliconix. This mixer provides between 10 and 20 dB of isolation between the mixer ports. The signal is applied in parallel across the sources of Q1 and Q2 by means of broadband transformer T2. Output at the IF is taken from a balanced tuned circuit.

A doubly balanced FET mixer is shown at C in Fig. 77. Broadband transformers are used throughout, with FL1 and FL2 providing low-pass selectivity at the mixer output. The filters also provide an impedance stepdown between the drains of Q1 and T4 (1700 ohms to 100 ohms). LO injection is supplied to the gates and signal input is to the sources. Port-to-port isolation with this mixer is on the order of 30 dB or greater. Bandwidth is one octave. In-depth information on this type of circuit is given in Siliconix application note AN-73-4.

Fig. 78 contains the circuit of a typical

dual-gate MOSFET single-ended mixer. Its performance characteristics are similar to those of the mixer at Fig. 77A. The primary exception is that the port-to-port isolation is somewhat better by virtue of the gate 2 isolation from the remainder of the electrodes. This mixer and all other active FET mixers require a fairly low drain-load impedance in the interest of good IMD. If the drain tuned circuit is made high in terms of impedance (in an effort to improve conversion gain) the drain-source peak signal swing will be high. This will lead to a change in junction capacitance (varactor effect) and the generation of harmonic currents. The result is distortion.

Of primary significance is the condition called "drain-load distortion." This malady occurs when excessive signal levels overload the drain circuit. The result is degraded IMD and cross-modulation effects. R1 in Fig. 78 is used to decrease the drain-load impedance by means of swamping. A value of 10,000 ohms is suitable for a 40673 MOSFET mixer. Some JFETs require a lower drain load for optimum performance. Values as low as 5000 ohms are not unusual. This form of

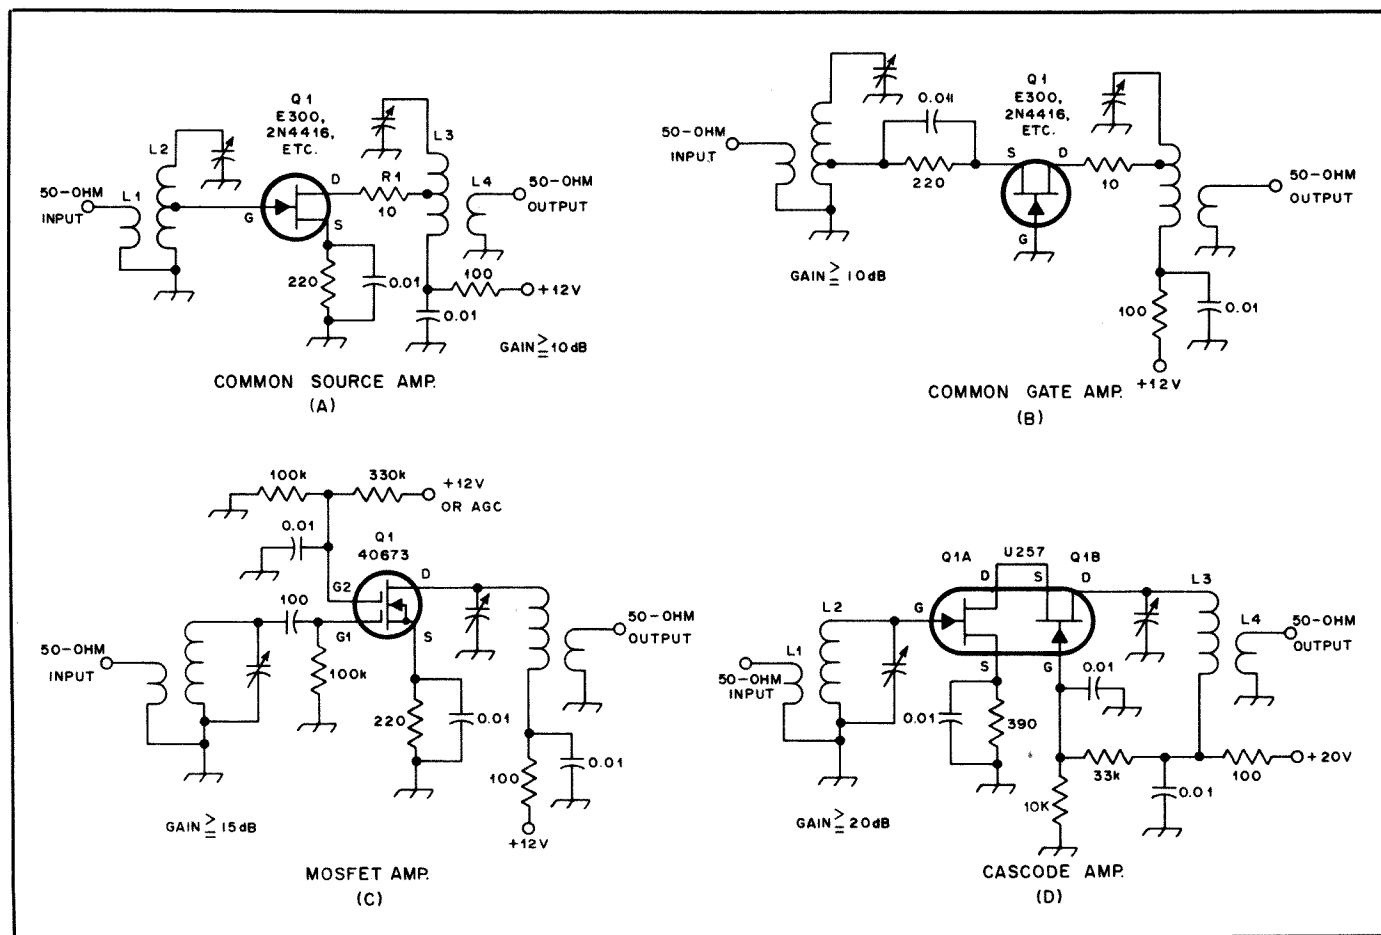

Fig. 76 — Examples of FET amplifiers suitable for RF or IF applications.

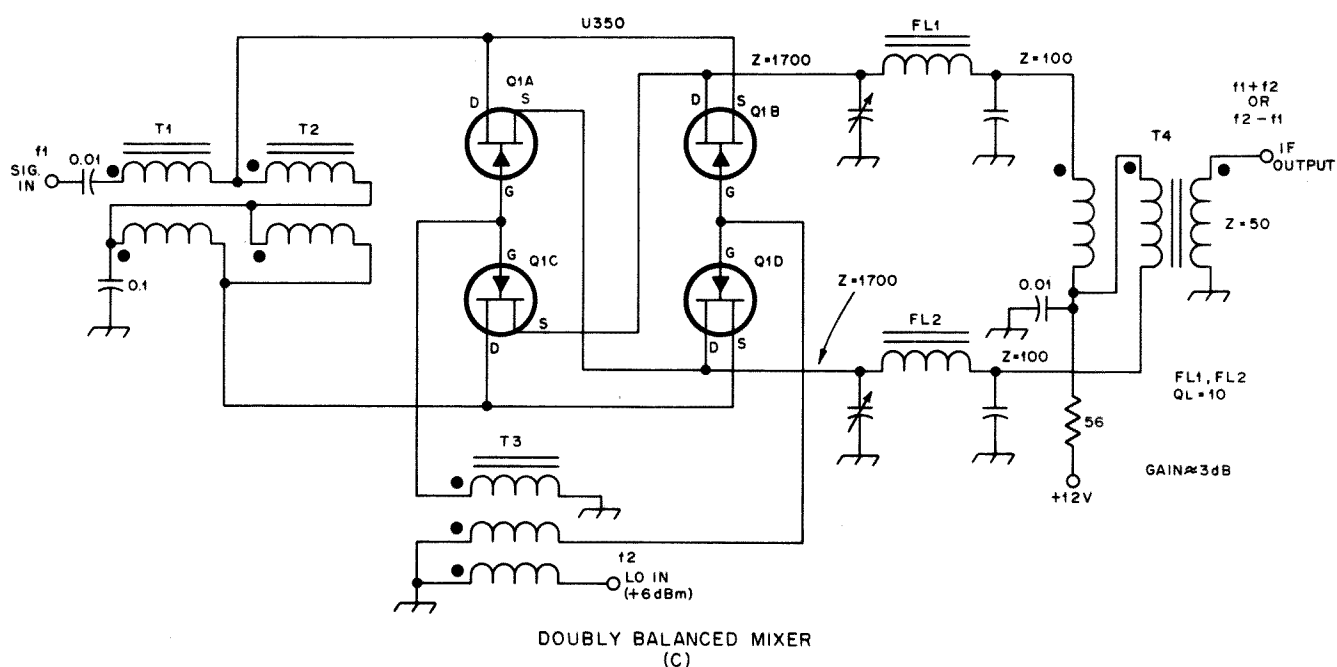

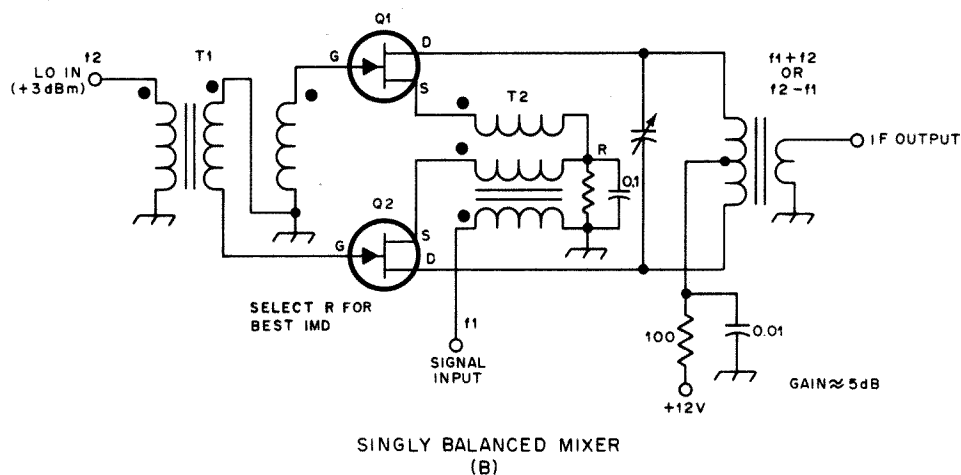

Fig. 77 — Various JFET mixers. See text for data.

overloading is more pronounced at low dc drain-voltage levels, such as 6 to 8.

#### FET Crystal Oscillators

A group of crystal-controlled FET oscillators is presented in Figs. 79 and 80.

At Fig. 79A is an overtone type. The tuned circuit in the drain is resonated slightly higher than the crystal frequency to ensure reliable oscillation. The circuit at B is a variation of the one at A, but performs the same function. A Pierce triode oscillator

is shown in Fig. 80 at A. It is suitable for use with fundamental types of crystals. A Colpitts oscillator appears at B in Fig. 80.  $C_{fb}$  in these circuits are feedback capacitors.  $C_{fb}$  in the circuit at C is chosen experimentally. Typically, it will be from

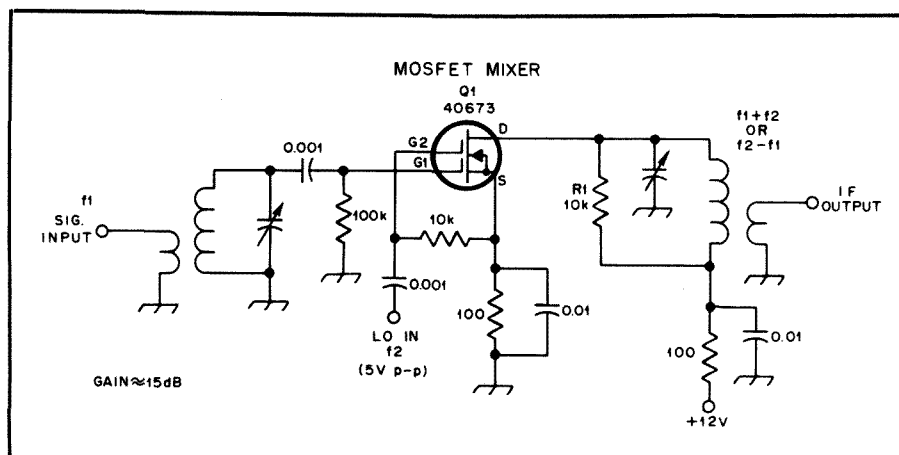

Fig. 78 — A dual-gate MOSFET single-ended mixer.

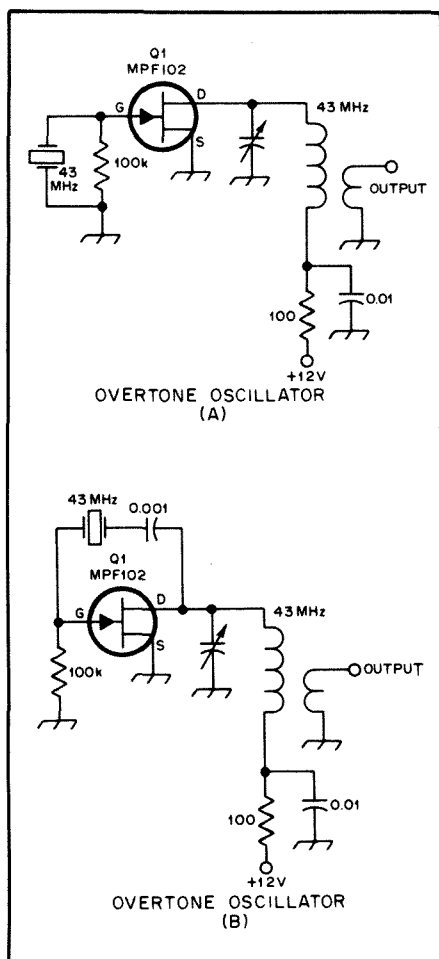

Fig. 79 — Overtone crystal oscillators using FETs.

100 to 500 pF, depending on the transistor characteristics and the crystal activity.

### FET VFOs

The principle of operation for FET VFOs is similar to that discussed in the section on bipolar transistor oscillators. The notable difference is the impedance level at the device input. The circuits of Fig. 81 all

have high-impedance gate terminals. Furthermore, fewer parts are needed than is true of bipolar transistor equivalent circuits: There is no resistive divider for applying forward bias.

The circuits of Fig. 81A and B are identical except for the biasing of gate 2 at B. Both circuits illustrate oscillators. The source tap on L1 should be selected to provide approximately 25 percent of the oscillator power as feedback. D1 in each example is used to stabilize the gate bias. It acts as a diode clamp on positive-going excursions of the signal. This aids oscillator stability and reduces the harmonic output of the stage. The latter is reduced as a result of the positive swing of the sine-wave being limited by D1, which in turn limits the device transconductance on peaks. This action reduces changes in junction capacitance, thereby greatly restricting the varactor action that generates harmonic currents. D1 is most effective when source-bias resistors are included in the circuit (R1).

Shown in Fig. 81 at C is a series-tuned Colpitts VFO that uses a JFET. This is an exceptionally stable VFO if careful design and component choice is applied. All of the fixed-value capacitors in the RF parts of the circuit should be temperature-stable. Polystyrene capacitors are recommended, but dipped silver-mica capacitors will serve adequately as a second choice. L1 should be a rigid air-wound inductor. A slug-tuned inductor can be used if the coil Q is high. In such cases the slug should occupy the least amount of coil space possible: Temperature changes have a marked effect on ferrite or powdered-iron slugs, which can change the coil inductance markedly. Capacitors  $C_{fb}$  of Fig. 81C are on the order of 1000 pF each for 3.5-MHz operation. They are proportionally lower in capacitance as the operating frequency is increased, such as 680 pF at 7 MHz, and so on.

### Power FET Examples

Fig. 82 contains examples of three

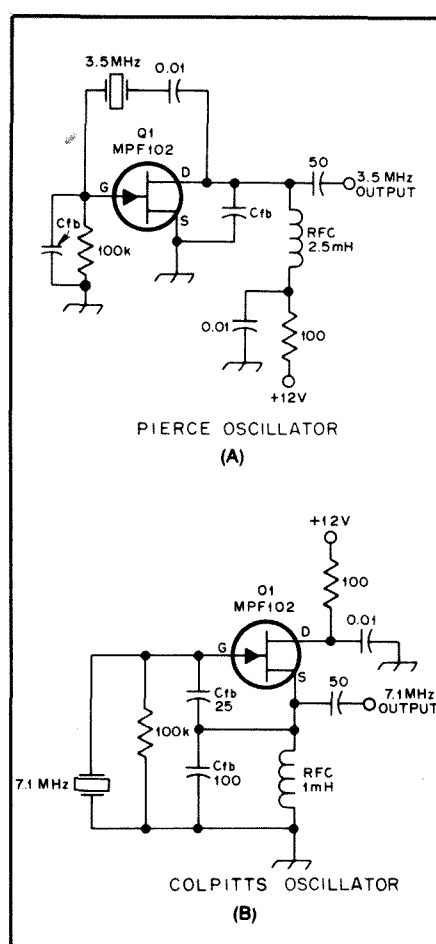

Fig. 80 — Fundamental-mode FET crystal oscillators.

amplifiers that use power FETs. The circuit at A is an audio amplifier that can deliver 4 watts of output. At 3 watts of output the distortion is approximately two percent. Feedback is employed to aid the reduction of distortion.

A Class C amplifier is shown at B in Fig. 82. The VN67AJ is capable of a saturated output near 15 watts at 30 MHz. In this circuit the power output is considerably less. A medium output power of 7 to 10 watts is suggested. The gain is approximately 8 dB over the frequency range specified (with the appropriate drain tank). If proper layout techniques are used, this amplifier is unconditionally stable.

A broadband HF linear amplifier is shown at C. A narrow-band linear VHF power amplifier is shown at D in Fig. 82. Power output is 5 watts PEP. IMD is -30 dB. It is interesting to realize that this same amplifier is suitable as a high-dynamic-range preamplifier for a VHF receiver. In this application the noise figure is on the order of 2.5 dB and the gain is 11 dB.

### Other FET Uses

Fig. 83 contains illustrations of additional practical uses for JFETs. The circuit

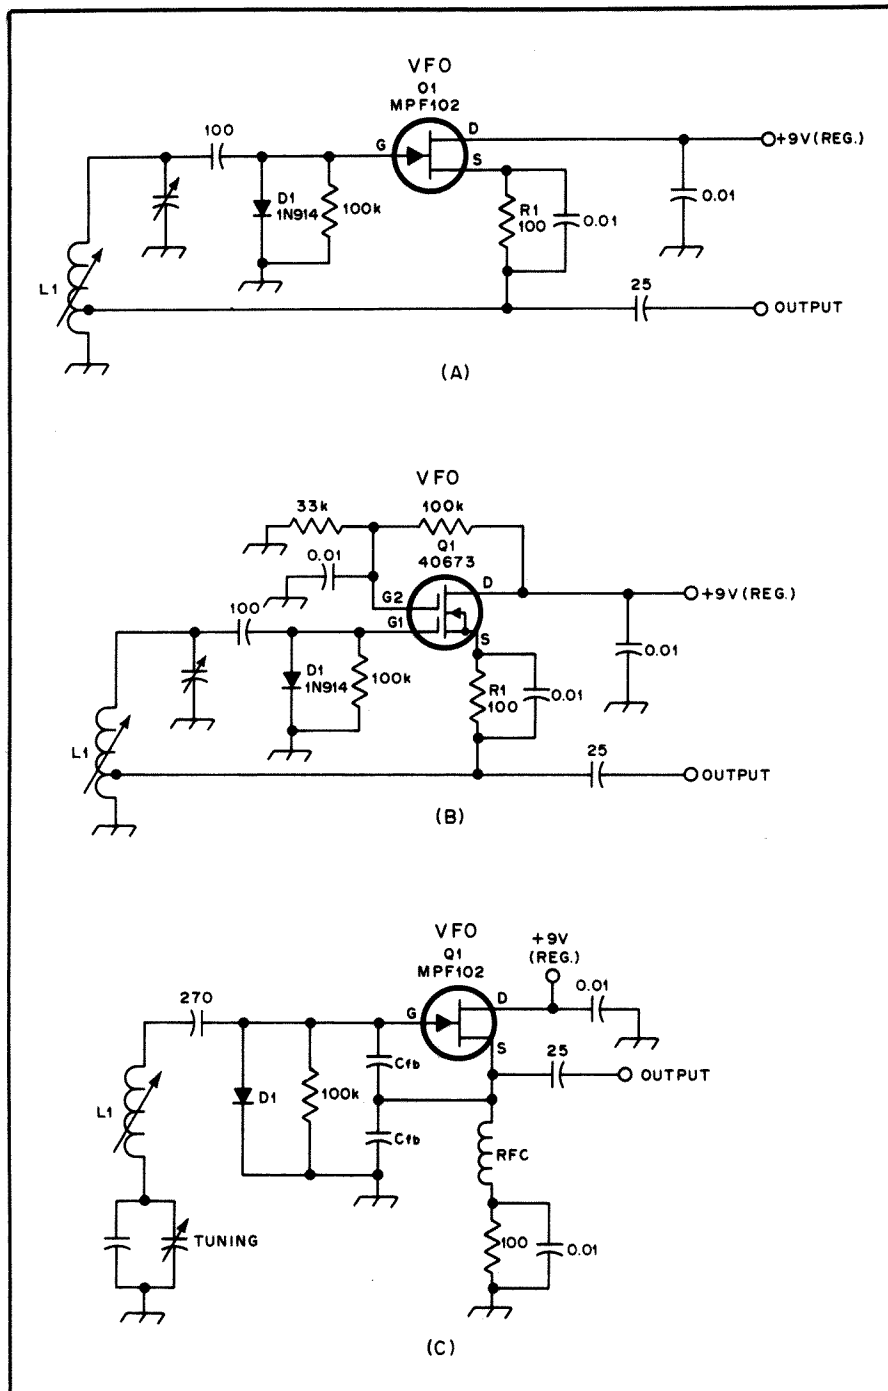

Fig. 81 — Three examples of VFOs in which FETs are used.

at A shows a Schmitt trigger. It is emitter-coupled and provides a comparator function. Q1 places very light loading on the measured input voltage. Q2 has high beta to enable the circuit to have a fast transition action and a distinct hysteresis loop. Additional applications of this type are found in *Linear Applications* by National Semiconductor Corp.

A simple FET dc voltmeter with high input impedance is shown in Fig. 83B. Multiplier resistances are given for a full-

scale range of 2 or 20 volts. Meter accuracy is quite good, with a linear reading provided by M1.

A push-push frequency doubler is shown at C in Fig. 83. The input frequency ( $f$ ) is applied to the gates of Q1 and Q2 in push-pull. Output from the doubler is taken with the connected drains in parallel. R1 is adjusted for best waveform purity at  $2f$ . The efficiency of this Class C doubler is on par with that of a straight-through Class C amplifier. Careful adjustment will nearly

eliminate frequency component  $f$  at the doubler output.

## LINEAR INTEGRATED CIRCUITS

There are two general types of ICs (integrated circuits). The first variety, which we are addressing at the moment, are called linear ICs. The other group are known generally as logic ICs. These devices will be discussed later in the chapter.

ICs are characterized by the term "microcircuit." In essence they are composed of numerous — sometimes hundreds — of bipolar and/or field-effect transistors on a single silicon chip (substrate). Along with the individual transistors formed on the substrate are diodes, capacitances and resistances. Some ICs contain only diodes. Others may contain only resistors.

The principal advantages of ICs are their compactness over an equivalent number of discrete transistors, and the fact that all of the devices on the substrate are evenly matched in characteristics. That is the result of the manufacturing process, whereby all of the IC transistors are formed from a single slice of semiconductor material under the same environmental conditions. This provides an inherent balance in their performance traits — a condition nearly impossible to realize with closely matched discrete transistors. Therefore, when changes in IC temperature take place, the parameters of the transistors on the chip change in unison — a distinct advantage when the IC is used in, say, a balanced modulator, mixer or push-push doubler.

Most of the theory given earlier for bipolar transistors applies to ICs, so it will not be repeated here. Rather, the text will provide data on practical applications of ICs. Linear ICs are so-called because in most applications where they are used the performance mode is a linear one. This does not mean, however, that they can't be used in a nonlinear mode, such as Class C. The biasing will determine the operating mode, Class A through Class C.

## IC Structures

The basic IC is formed on a uniform chip of N-type or P-type silicon. Impurities are introduced into the chip, their depth into it being determined by the diffusion temperature and time. The geometry of the plane surface of the chip is determined by masking off certain areas, applying photochemical techniques and providing a coating of insulating oxide. Certain areas of the oxide coating are then opened up to allow the formation of interconnecting leads between sections of the IC. When capacitors are formed on the chip, the oxide serves as the dielectric material.

Fig. 84 shows a representative three-component IC in both pictorial and schematic form. Most integrated circuits are housed in TO-5 type cases, or in flat-pack epoxy blocks. ICs may have as many as 12 or more leads that connect to the various elements on the chip.

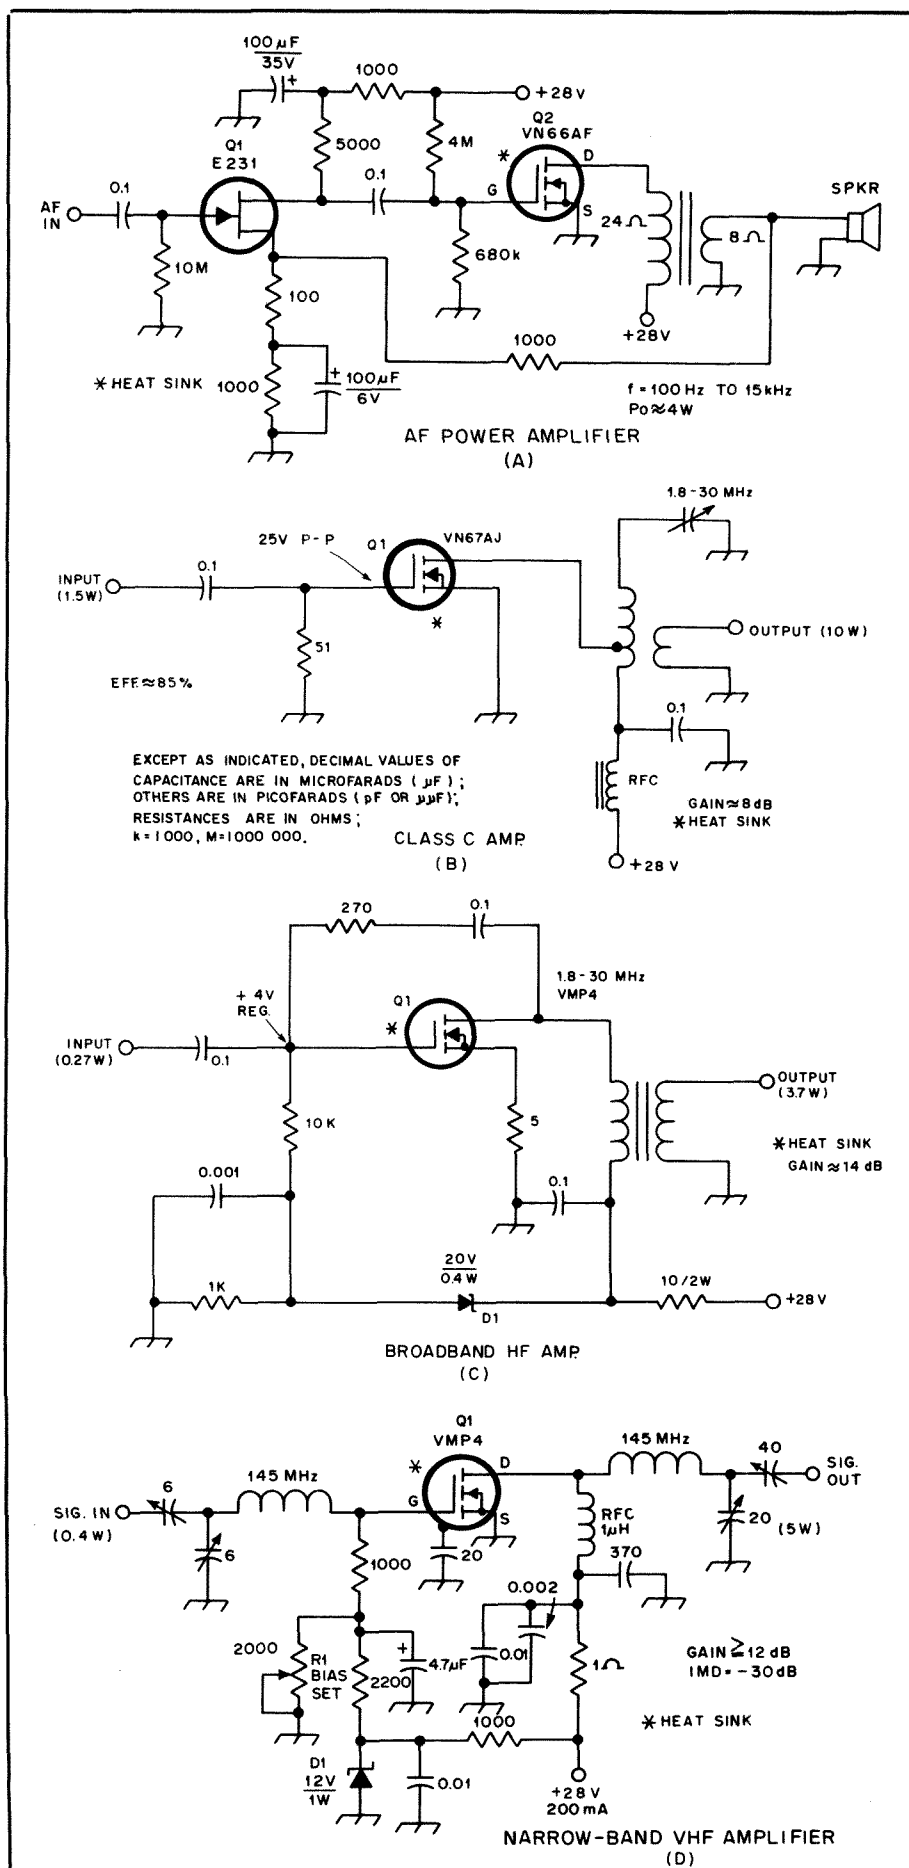

Fig. 82 — Examples of power FETs in three amplifier circuits.

Some present-day ICs are called LSI (large-scale integration) chips. Such devices may contain the equivalent of several conventional ICs, and can have dozens of dual-in-line package (DIP) connector pins. LSI ICs are used in electronic organs, digital clocks, electronic calculators and so on. Essentially, they are just super-size ICs.

### Some Practical Considerations

In circuits where slight extra lead lengths can be tolerated, it is prudent to install the ICs in sockets rather than solder them into the PC board directly. In amateur work there is an occasional need to replace an IC during circuit development for a typical one-shot design. This is particularly pertinent when bargain-house ICs are purchased: Many have defects, and the task of removing an IC that is not in a socket is a task no builder finds delightful.

When using ICs for RF work it is best to install them in a low-profile type of IC socket (minimum lead length type). The thicker sockets are suitable for dc and audio applications, where lead length is not likely to be a critical factor. Excessive lead length can cause instability. This is brought on by having numerous high-gain devices packaged physically close to one another on the common substrate: High gain and stray lead coupling set the stage for self-oscillation!

### CMOS ICs

The term CMOS means the IC is a complementary metal-oxide silicon type of integrated circuit. Essentially, the internal workings of the device are similar to the MOSFETs that were treated earlier in this chapter: MOSFETs are formed on the CMOS IC substrates.

CMOS devices consume very low power — especially advantageous in battery-operated equipment. The transit time (propagation delay) through the FET gates of a CMOS IC is very short — ideal in logic circuits. It ranges from 25 to 50 ns in most devices. This does not imply that CMOS ICs aren't useful in linear applications. Some are designed primarily for the linear amplification of audio and RF energy (CA3600E, for one).

Another salient feature of CMOS chips is low noise. Because FETs are used in these ICs the input impedance is high, making them more suitable than bipolar ICs for interfacing with comparable impedance levels outside the IC package. Fig. 85 shows the diagram of a CA3600E CMOS IC along with the block-symbol circuit for its use as a high-gain audio amplifier.

### Array ICs

One branch of the linear-IC family is known as the IC array group. A short course on these and other linear ICs was given by DeMaw in *QST* for January through March 1977. Basically, the IC array is a substrate which contains a number of individual diodes or NPN

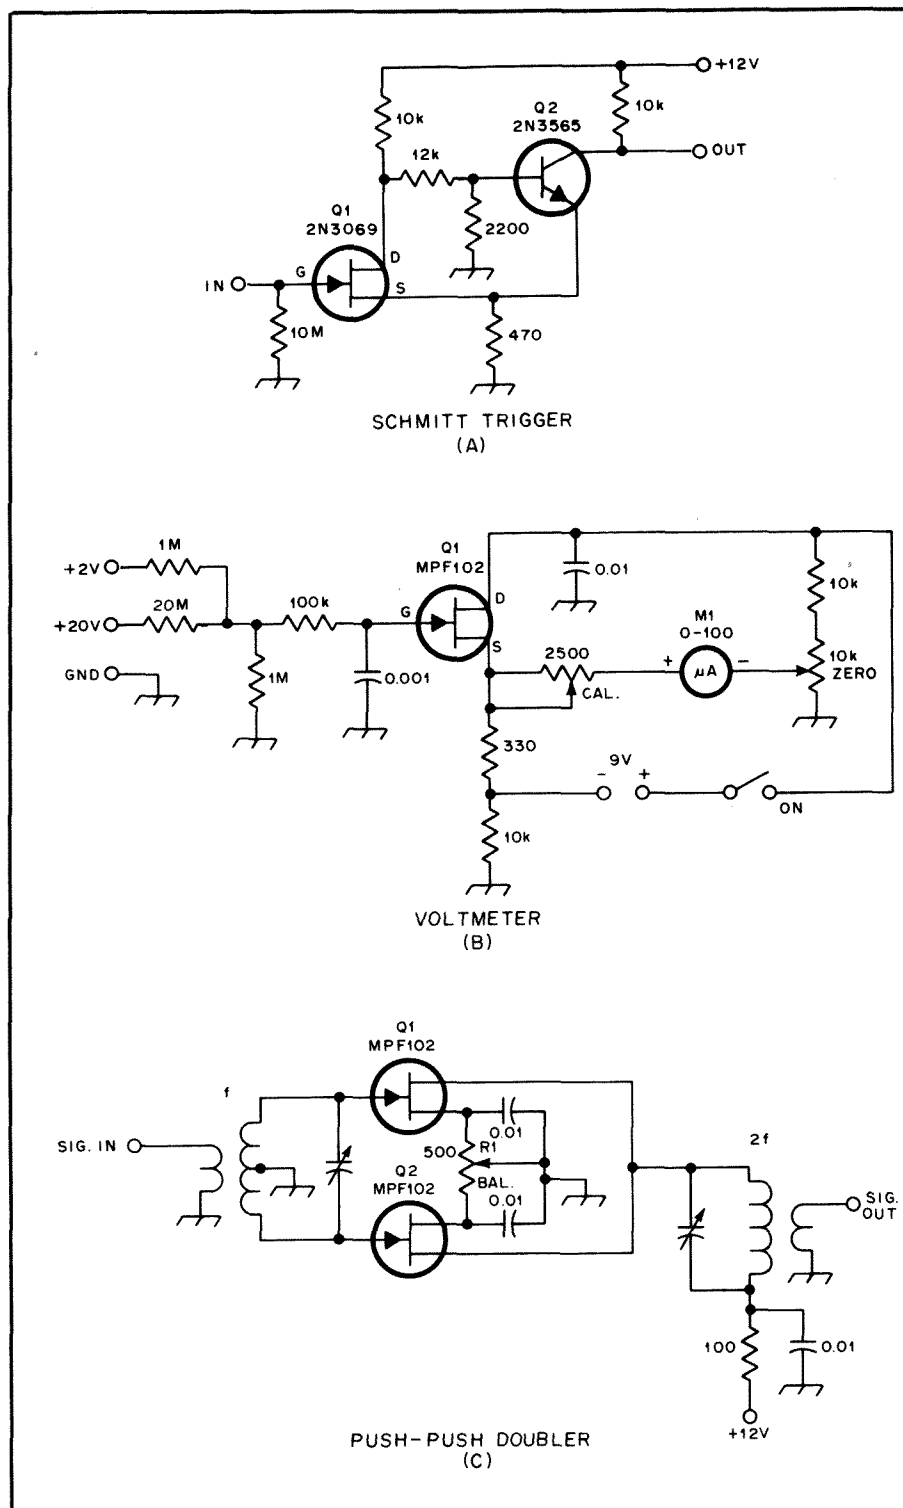

Fig. 83 — JFETs are useful in additional kinds of circuits. Here are three examples.

bipolar transistors. They differ from conventional ICs by virtue of having each of the transistors independent from one another. Each transistor base, emitter and collector is brought out of the IC package by means of its own single pin. This enables the designer to treat each transistor as a discrete device, with the advantage that each transistor has nearly identical electrical characteristics ( $f_T$ , beta, dissipation rating, etc.). Some array ICs have  $f_T$  ratings as

high as 1200 MHz, with maximum collector dissipation ratings as high as 1 watt. Schematic illustrations of some popular RCA array ICs are shown in Fig. 86.

#### Subsystem ICs

A branch of the linear-IC family tree is the subsystem IC. It is a conventional-package integrated circuit, but contains nearly as much circuitry as an LSI chip. Some of these devices represent the entire

Fig. 84 — Pictorial and schematic representation of a simple IC.

active-device circuitry for an FM or AM radio receiver. The designer need only add essential outboard components (front-end tuned circuits, IF transformers, tuning meter and audio power amplifier) to realize a composite piece of equipment. Other subsystem ICs may contain only the IF amplifiers, product detectors, AGC loops and audio amplifiers. This style of IC is sold by such manufacturers as RCA, National Semiconductor and Plessey.

Fig. 87 illustrates an example of this kind of device — the RCA CA3089E, designed expressly for use in wide- or narrow-band FM receivers. It features a quadrature detector, and contains amplifiers, limiters, squelch circuit, metering circuit and an AF amplifier. Those interested in compact portable amateur receivers should find these devices especially interesting.

#### Practical Examples

The main disadvantage in the use of IC symbols in circuit diagrams is that the internal workings are not shown. This makes the designer work with a collection of "magic boxes." Fortunately, IC manufacturers publish data books that show the block symbols, pin arrangements and the schematic diagrams of the active devices on the chips. This permits the amateur to understand what the circuit configuration is before the design work is started. It is impractical to include the schematic diagrams of the ICs used in this book, but we will show the circuit of the RCA CA3028A, because it is used frequently in the next section. Fig. 88 contains the block and schematic representation of this IC.

#### RF and IF Amplifiers

Nearly every manufacturer of ICs produces chips that are suitable for use as RF/IF amplifiers, mixers, detectors, oscillators and audio amplifiers. The circuits of Fig. 89 are examples of CA3028A RF or IF amplifiers to which AGC is applied. Maximum gain occurs when the

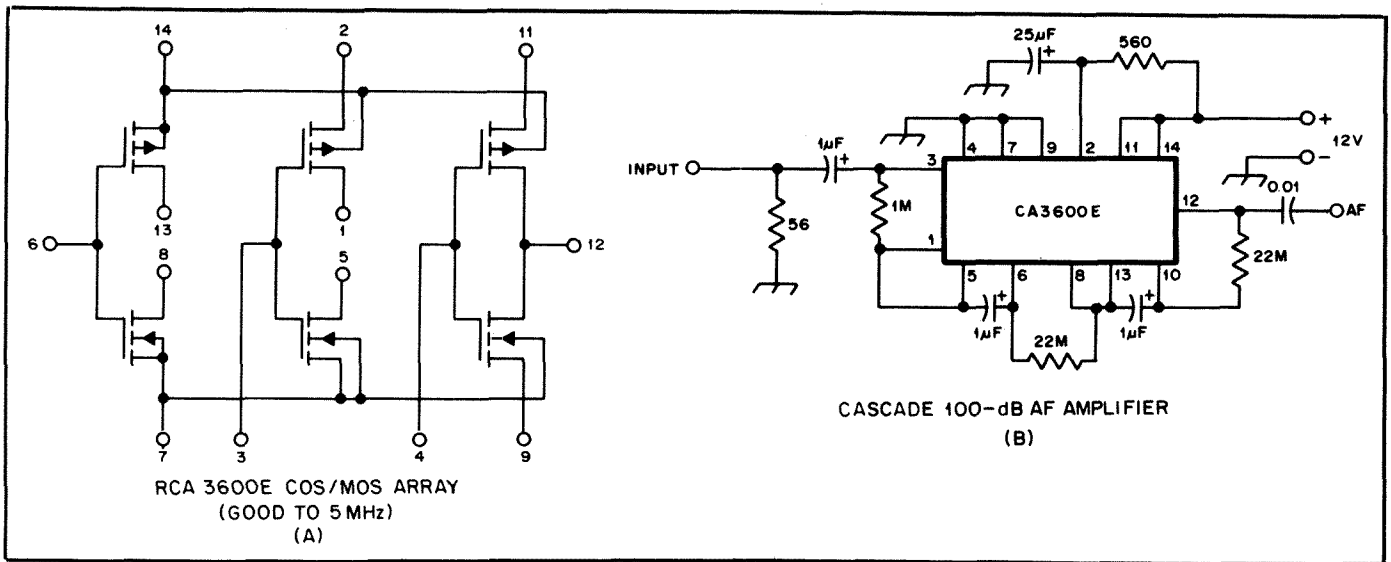

Fig. 85 — The diagram at A shows the internal workings of a CMOS IC. A 100-dB audio amplifier that employs the CA3600E is shown at B.

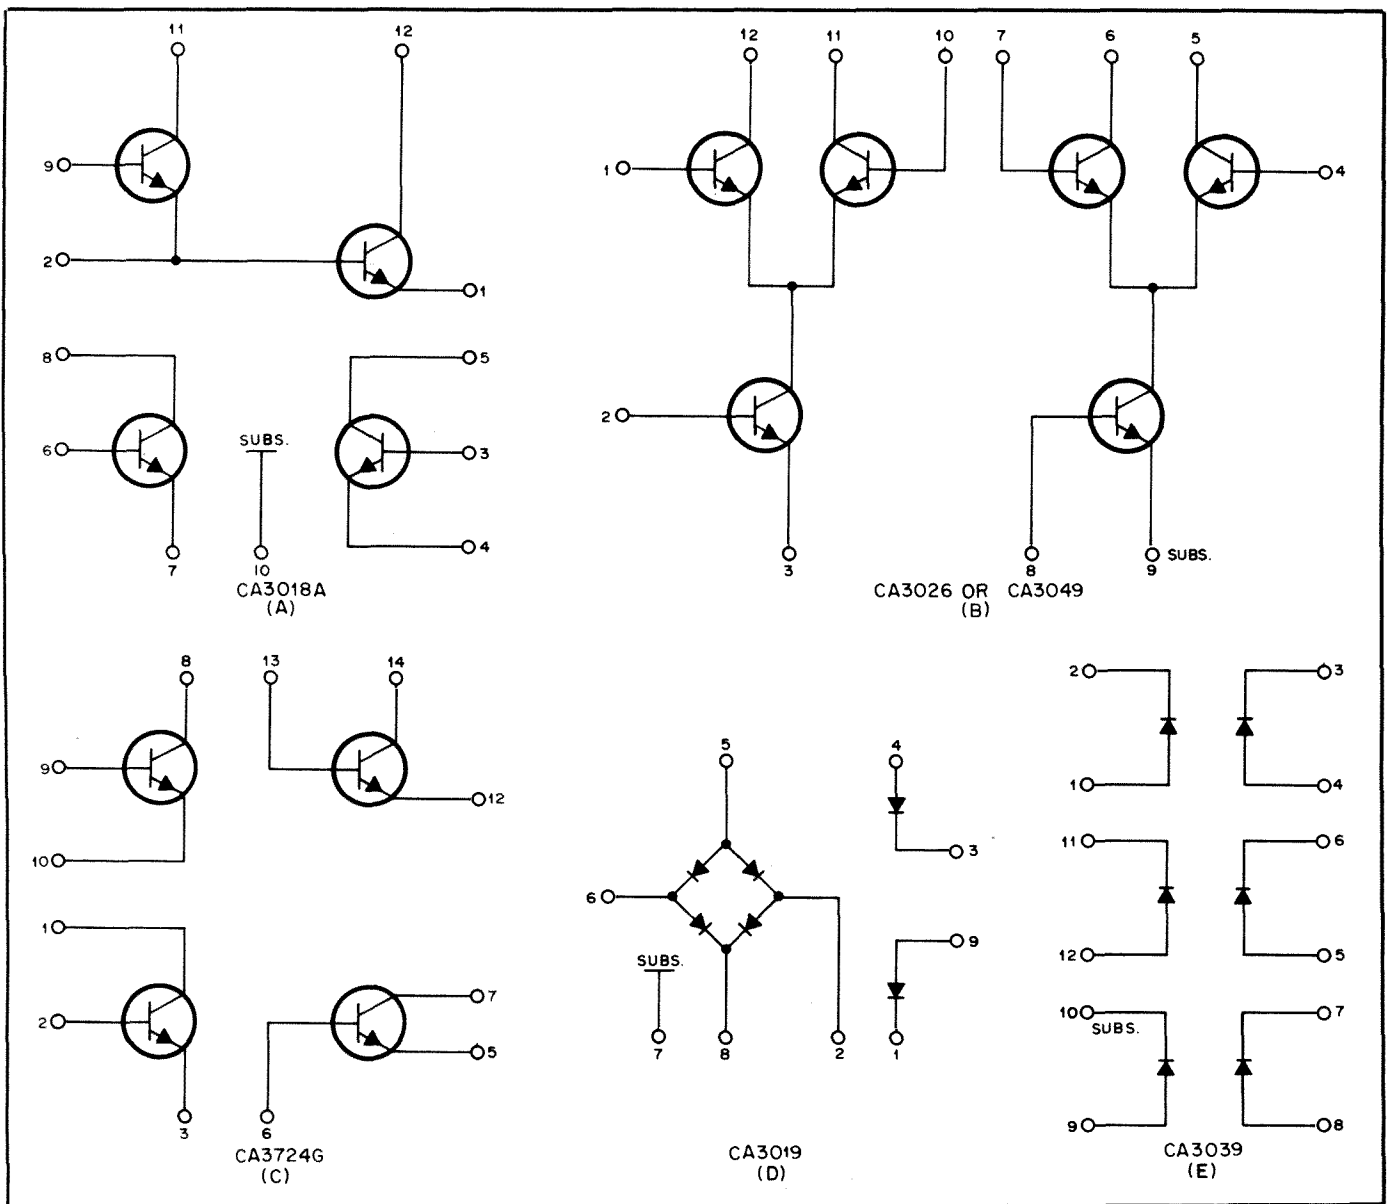

Fig. 86 — Various transistor and diode-array ICs. The configurations suggest a variety of amateur applications.

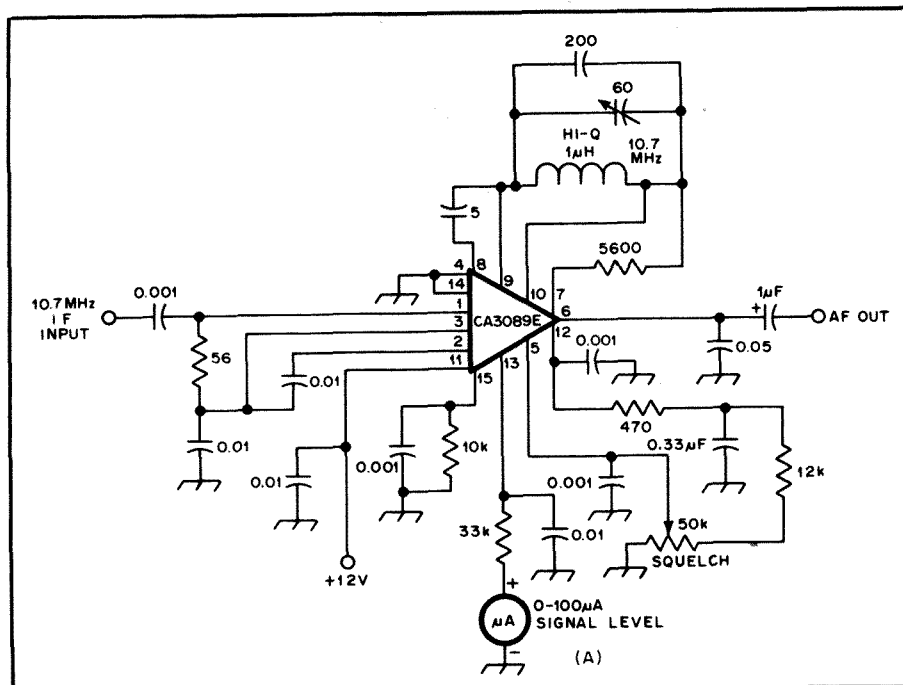

Fig. 87 — Example of a subsystem IC used as the heart of a narrow-band FM receiver.

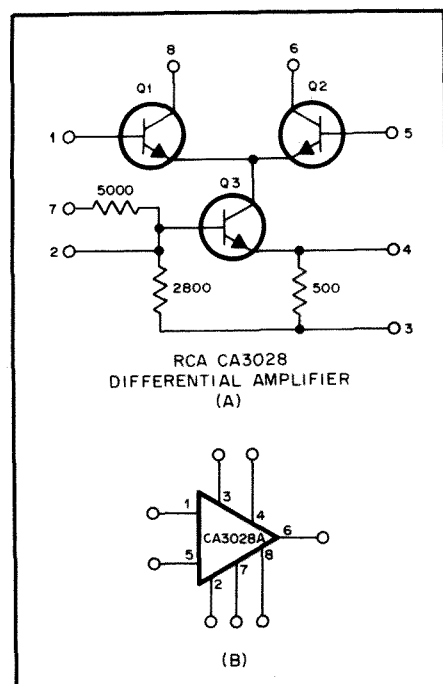

Fig. 88 — Schematic and block examples of an RCA CA3028A IC.

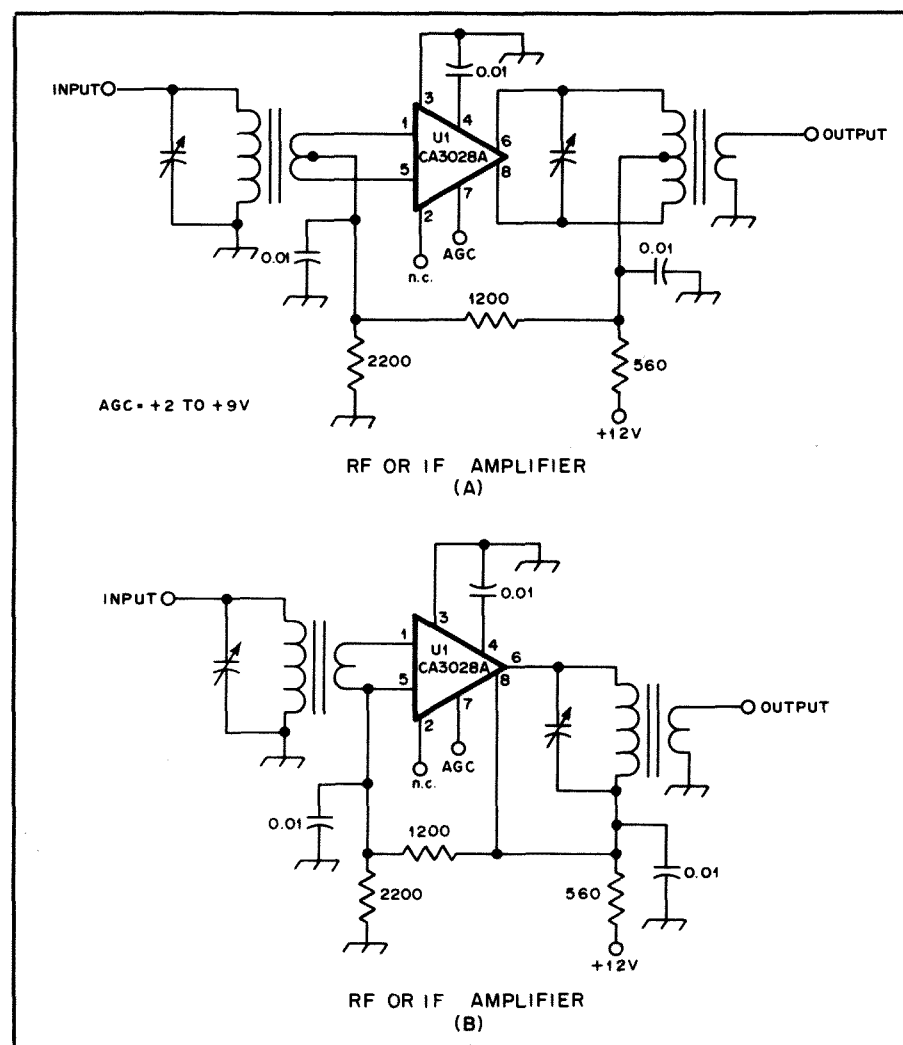

Fig. 89 — RF and IF amplifiers using the CA3028A IC. The example at A is balanced for ac and dc, whereas the circuit at B is balanced only for dc conditions.

AGC voltage (IC forward bias) is at its highest potential. The IC is nearly cut off when the AGC level drops below 2 volts. The circuit of Fig. 89A functions as a differential amplifier, as does the one at B. The basic difference is that dc and ac balance are featured at A, whereas only dc balance is effected at B. The gain of either stage is approximately 40 dB. Pin 2 of U1 is left floating, but is used for LO injection when the CA3028A is employed as a mixer or product detector. A Motorola MC1550G is similar to the IC shown in Fig. 89. A MC1590G is a more suitable IC for IF amplification when greater amounts of stage gain or AGC control are desired.

An example of an MC1590G amplifier is given in Fig. 90A. It is shown with AGC applied to pin 2. The lower the AGC voltage the higher the stage gain. This is the opposite condition from that of the CA3028A of Fig. 89, where the gain increases with elevated AGC voltage. The MC1350P of Fig. 90B is the low-cost version of the MC1590G. It is shown with manual control of the gain (R1), but AGC voltage can be applied instead.

#### IC Mixers

Examples of IC active mixers are given in Fig. 91. At A is a singly balanced mixer formed by the differential transistor pair in a CA3028A. A doubly balanced mixer is illustrated at B in Fig. 91. The MC1496G contains two differential transistor pairs to permit the doubly balanced configuration. This circuit does not exactly follow the suggested one by Motorola. It has been optimized for use as a transmitting mixer by W7ZOI and KL7IAK (*Solid State Design for the Radio Amateur*, 1st edition, page

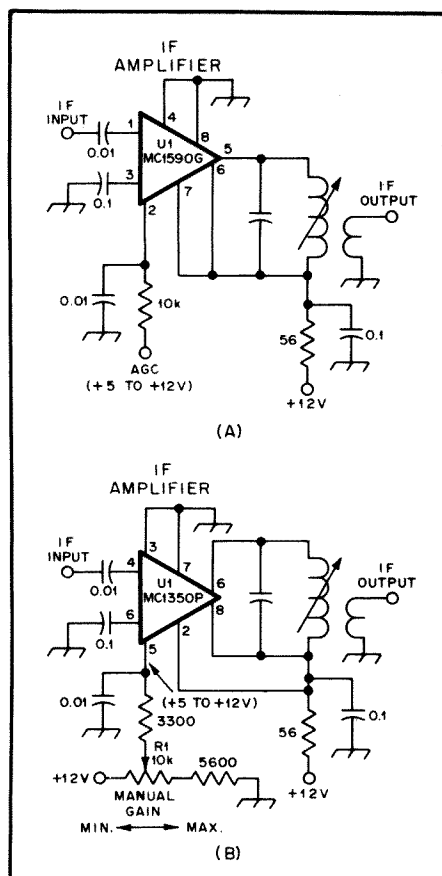

Fig. 90 — Circuit examples for Motorola IC IF amplifiers.

204). Numerous other ICs can be used as mixers. Examples of many practical circuits are given in the ARRL book just referenced.

The circuit arrangements for product detectors and balanced modulators are similar to those shown in Fig. 91. They will not be described in this text, because the primary difference between them and a regular mixer lies in the frequencies of the signals mixed (AF versus RF) and the frequency of the resulting output energy.

### IC Audio Amplifiers

Practically every IC manufacturer offers a line of audio ICs. Some are for use as low-noise preamplifiers and others are capable of delivering up to a few watts of output to a loudspeaker. Most of the audio-power ICs are designed for looking directly into an 8- or 16-ohm load without the need for a matching transformer. Because these circuits are relatively mundane they shall not be offered here as examples. Practical applications for audio ICs can be found in the construction projects elsewhere in this *Handbook*. Manufacturer's data sheets also provide definitive information on the use of these devices.

### Operational Amplifiers

An operational amplifier (op amp) is a high-gain, direct-coupled differential amplifier whose characteristics are chiefly

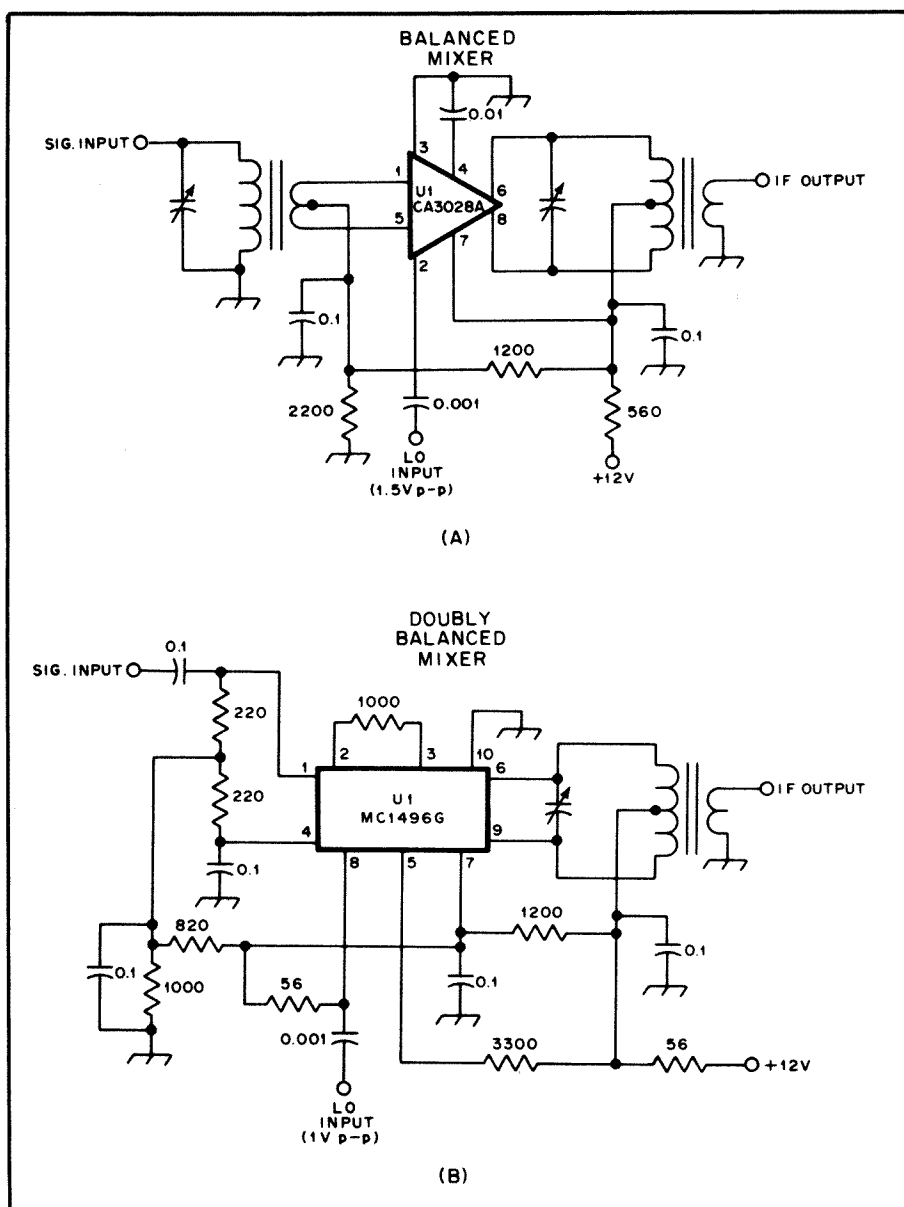

Fig. 91 — Two types of ICs are shown as mixers. The one at A is a singly balanced mixer.

Fig. 92 — An operational amplifier assembled from discrete components. IC op amps contain more transistors (for current limiting and other peripheral functions), but the circuit topology is similar to that shown here.

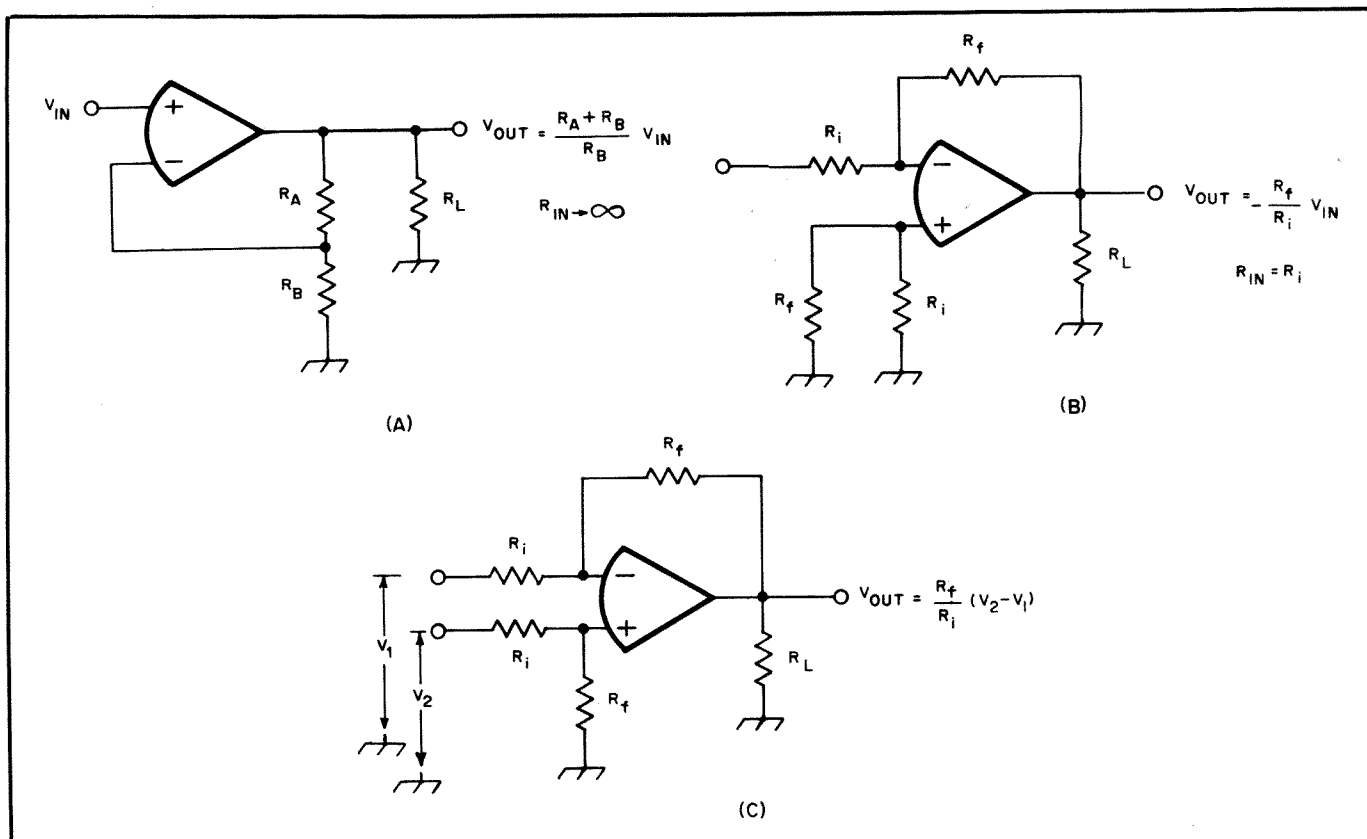

Fig. 93 — The standard negative-feedback op-amp circuits with their transfer equations. At A is a noninverting amplifier, at B an inverting amplifier, and at C is a differential amplifier.

determined by components external to the amplifier unit. Op amps can be assembled from discrete transistors, but better thermal stability results from fabricating the circuit on a single silicon chip. Integrated circuit op amps are manufactured with bipolar, JFET and MOSFET devices, either exclusively or in combination.

A design based on discrete components is shown in Fig. 92. Circuits of this variety

were in common use before the advent of inexpensive IC-fabrication technology. The input stage consists of a differential pair biased by a constant current source. The terminal marked “-” is the inverting input and the one marked “+” is the noninverting input. The next stage, the PNP transistor, provides most of the voltage gain. High gain is realized through the use of a constant current source for the

PNP collector load. The frequency response is determined by the collector-to-base capacitance of the PNP stage. This capacitance is fixed internally in some IC op amps and connected externally to others. A pair of emitter followers in a complementary symmetry arrangement forms the output buffer. A more comprehensive discussion of operational amplifiers is given by Woodward in “A

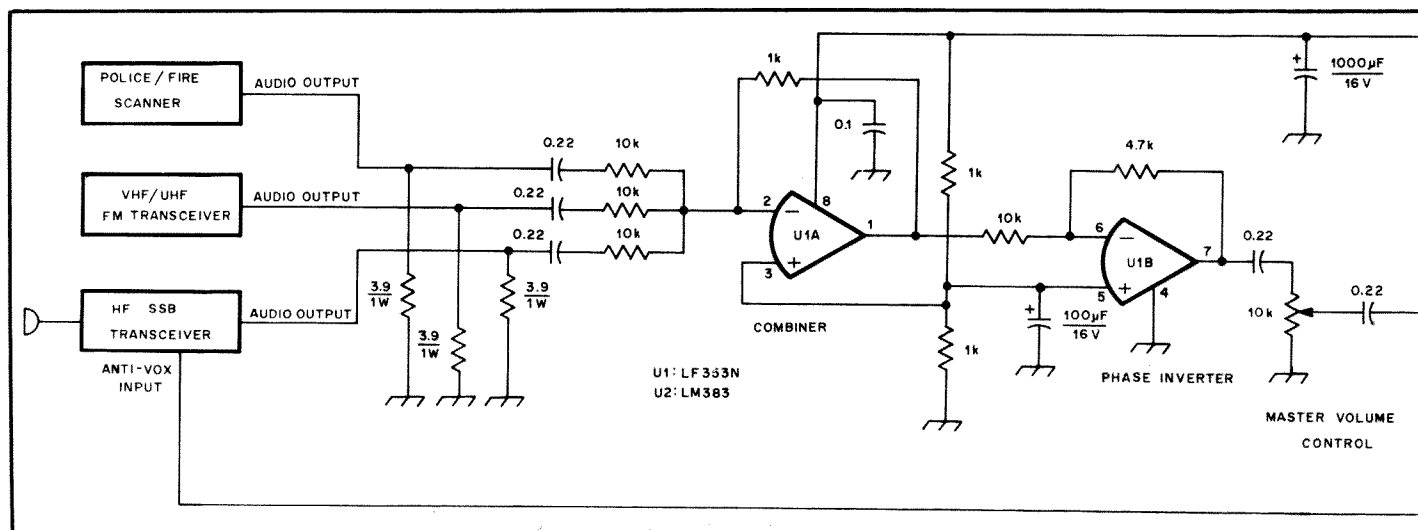

Fig. 94 — An amateur application for a summing amplifier — an audio combiner.

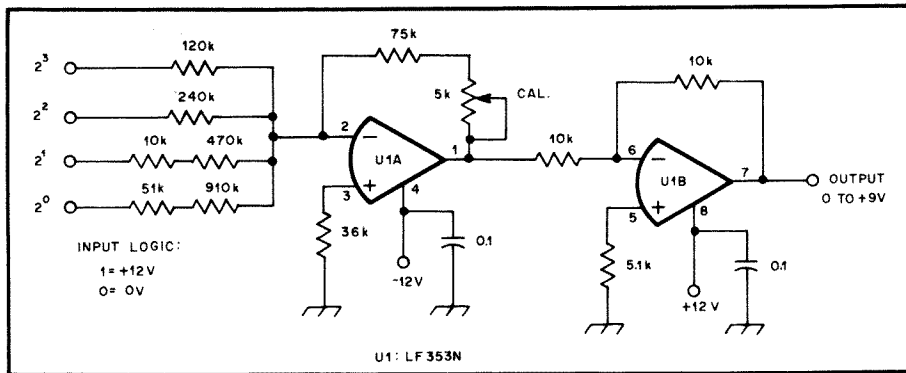

Fig. 95 — BCD D/A converter suitable for connection to a B-series CMOS driving source.

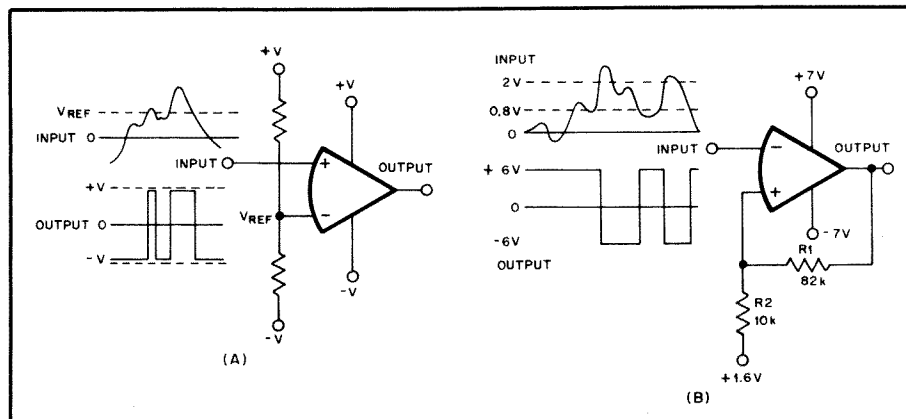

Fig. 96 — (A) Differential voltage comparator. Either inverting or noninverting circuits may be used. (B) Schmitt trigger. The constants shown here are suitable for connecting +5-V TTL to  $\pm 7$ -V CMOS logic.

## Beginner's Look at Op Amps," April and June 1980 QST.

The most common application for op amps is in negative feedback circuits operating from dc to perhaps a few hundred kilohertz. Provided the device has sufficient open-loop gain, the amplifier transfer function is determined almost solely by the external feedback network. The

differential inputs allow for both inverting and noninverting circuits. Fig. 93 shows these configurations and gives their transfer equations.  $R_L$  does not appear in the equations, implying that the output impedance is zero. This condition results from the application of heavy negative feedback. Most IC op amps have built-in current limiting. This feature protects the IC from damage caused by short circuits, but also limits the values of load resistance for which the output impedance is zero. Most op amps work best with load resistances of at least 2 k $\Omega$ .

Since the op amp magnifies the difference between the voltages applied to its inputs, applying negative feedback has the effect of equalizing the input voltages. In the inverting amplifier configuration the feedback action combined with Kirchhoff's current law establishes a zero impedance, or virtual ground at the junction of  $R_f$  and  $R_i$ . The circuit input impedance is just  $R_i$ . Negative feedback applied to the noninverting configuration causes the input impedance to approach infinity.

The virtual ground at the inverting input terminal of an inverting operational amplifier circuit allows several currents to be summed without interaction. This principle can be used to advantage by the amateur wishing to simplify his or her station control system. An example of a summing amplifier is given in Fig. 94. The cir-

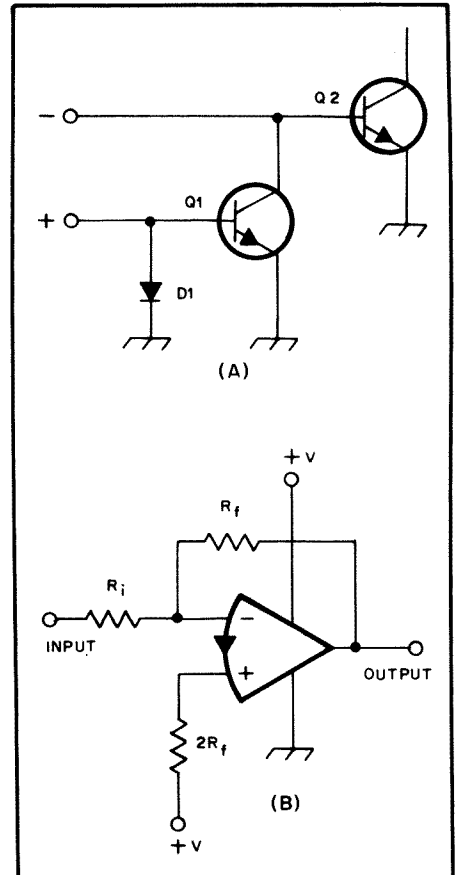

Fig. 97 — (A) Input circuit of a Norton operational amplifier. (B) Norton op amp connected as an inverting amplifier. Note the special symbol used to denote a Norton IC.

cuit shown allows the operator to monitor the outputs of several receivers with one loudspeaker. The 3.9- $\Omega$  resistors simulate the loudspeaker in each receiver. An inverter follows the summing amplifier to restore the antixox signal to the proper phase. Fig. 95 shows another application for a summing amplifier, a D/A converter. An FET-input operational amplifier can operate with the high-value resistors required by CMOS digital ICs while maintaining low offset and drift errors.

ICs intended for op-amp service can also be used in open-loop or positive feedback applications. Connecting one input to a fixed reference voltage as in Fig. 96A forms a comparator. The open-loop gain of the IC is so high that it acts more like a switch than an amplifier. When the voltage applied to the free input terminal is less than the reference voltage, the IC output stays near one of the power rails. If the input voltage exceeds the reference, the output swings to the opposite rail. A comparator with positive feedback, or hysteresis, is called a Schmitt trigger. A Schmitt trigger is illustrated in Fig. 96B. The potential on the noninverting input terminal depends on the output state as well as the reference voltage.

## The Norton Amplifier

An unusual type of op amp is the

Fig. 98 — Open-loop gain and closed-loop gain as a function of frequency. The vertical distance between the curves is the feedback or gain margin.

Norton, named for the network theorem on which its operation is based. Fig. 97 shows a simplified diagram of the input stage of a Norton amplifier. The noninverting input makes use of D1 and Q1 in a current mirror configuration. When input current is applied to Q1, it steals base drive from Q2, the inverting input. This amplifier must have input current to operate, hence it is not a high-impedance device. In the inverting-amplifier configuration the numerical voltage gain is  $R_f/R_i$ , but the noninverting input terminal must be returned to the positive supply through a resistance of  $2R_f$  to equalize the input currents. Any attempt to use this type of IC as a voltage follower is doomed to failure — the input stage will be destroyed by excessive current. The chief use of Norton amplifiers is for single-supply applications where the dc level of the signal is very near ground.

#### Important Op Amp Specifications

Construction projects in the amateur literature call for the 709 and 741 more than any other type of operational amplifier because until recently they were the only ones commonly available to the electronics hobbyist. A much wider selection of op amps is available today, and the amateur designer can choose the components best suited to the application. Also, the performance of some existing circuits can be upgraded by replacing 709s and 741s with improved devices. To this end, a brief survey of op amp specifications is in order.

Offset voltage is the potential between the amplifier input terminals in the closed-loop condition. Ideally, this voltage would be zero. Offset results from imbalance between the differential input transistors. Values range from millivolts in ordinary consumer-grade devices to only nanovolts in premium Milspec units. The temperature

coefficient of offset voltage is drift. Drift is usually considered in relation to time. Heat generated by the op-amp itself or by associated circuitry will cause the offset voltage to change over time. A few microvolts per degree Celsius (at the input) is a typical drift specification.

There are two types of noise associated with operational amplifiers. Burst or popcorn noise is a low-frequency pulsing, usually below 10 Hz. The amplitude of this noise is approximately an inverse function of temperature. The other noise is sometimes called flicker, and is a wideband signal whose amplitude varies inversely with frequency. For some analytical purposes, drift is considered as a very low fre-

Fig. 99 — Energy-level diagram of a single atom is shown at A. At B, the levels split when two atoms are in close proximity.

quency noise component. Op amps that have been optimized for offset, drift and noise are called instrumentation amplifiers. The latest instrumentation amplifier is the National Semiconductor LM10, designed by Robert Widlar, the acknowledged "father of the IC op amp." The architecture of the LM10 is different from any other device, but the practical applications are the same.

The small-signal bandwidth of an op amp is the frequency range over which the open-loop voltage gain is at least unity. This specification depends mostly on the frequency compensation scheme (for example, the capacitor in Fig. 92). Fig. 98 shows how the maximum closed-loop gain varies with the frequency. The power bandwidth of an operational amplifier is a function of slew rate, and is always less than the small-signal value. Slew rate is a measurement of output voltage swing per unit time. Values from 0.8 to 13 volts per microsecond are typical of modern devices.

The hobbyist should maintain a supply of inexpensive 741 and 301 op amps for breadboarding, but should also be prepared to use improved devices in the final design. In an active filter for example, a 741 will

Fig. 102 — Semiconductor energy-level representation.

demonstrate whether or not the circuit is working, but a low-noise, wide-bandwidth device will give higher performance, especially in receiving service. An abbreviated table of operational amplifier specifications is given in Chapter 35. Most of the devices listed are available from hobby electronics stores or the mail-order firms listed in Chapter 35.

## APPENDIX

### The Physics of Solid-State Devices

The electrical characteristics of solid-state devices such as diodes and transistors depend on phenomena that take place at the atomic level. While semiconductors can be employed without a complete knowledge of these effects, some understanding is helpful in various applications. Electrons, which are the principal charge carriers in both vacuum tubes and semiconductors, behave much differently in either of the two circumstances. In free space, an electron can be considered as a small charged solid particle. On the other hand, the presence of matter affects this picture greatly. For instance, an electron attached to an atom has many properties similar to those of RF energy in tuned circuits. It has a frequency and wavelength that depend on atomic parameters just as the frequency associated with electrical energy in a tuned circuit depends on the values of inductance and capacitance.

A relation between the energy of an electron in an atomic orbit and its associated frequency is given by

$$f(\text{Hz}) = \frac{E (\text{joules})}{6.625 \times 10^{-34}}$$

where the expression in the denominator is called Planck's constant. This equation is quite important when an electron is either raised or falls between two different energy states. For instance, when an electron drops from one level to a lower one, energy is emitted in the form of electromagnetic radiation. This is the effect that gives the characteristic glow to neon tubes, mercury-vapor rectifiers and light-emitting diodes. The frequency of the emitted radiation is given by the formula where  $E$  is the difference in energy. However, if an electron

receives enough energy such that it is torn from an atom, a process called ionization is said to occur (although the term is also loosely applied to transitions between any two levels). If the energy is divided by the charge of the electron ( $-1.6 \times 10^{-19}$  coulombs), the equivalent in voltage is obtained.

A common way of illustrating these energy transitions is by means of the energy-level diagram shown in Fig. 99A. It should be noted that unlike ordinary graphical data, there is no significance to the horizontal axis. In the case of a single atom, the permitted energy can only exist at discrete levels (this would be characteristic of a gas at low pressure where the atoms are far apart). However, if a single atom is brought within close proximity of another one of similar type, the single energy levels split into pairs of two that are very close together (Fig. 99B). The analogy between tuned circuits and electron energy levels can be carried even further in this case.

Consider the two identical circuits that are coupled magnetically as shown in Fig. 100A. Normally, energy initially stored in C1 would oscillate back and forth between L1 and C1 at a single frequency after the switch was closed. However, the presence of the second circuit consisting of L2 and C2 (assume L1 equals L2 and C1 equals C2) results in the waveform shown in Fig. 100B. Energy also oscillates back and forth between the two circuits and the current then consists of components at two slightly different frequencies. The effect is similar to the splitting of electron energy levels when two atoms are close enough to interact.

### Conductors, Insulators and Semiconductors

Solids are examples of large numbers of atoms in close proximity. As might be expected, the splitting of energy levels continues until a band structure is reached. Depending on the type of atom, and the physical arrangement of the component atoms in the solid, three basic conditions can exist. In Fig. 101A, the two discrete energy levels have split into two bands. All the states in the lower band are occupied by electrons while the ones in the higher energy band are only partially filled.

Fig. 103 — The effects on the energy level if impurity atoms are introduced.

In order to impart motion to an electron, the expenditure of energy is required. This means an electron must then be raised from one energy state to a higher one. Since there are many permitted states in the upper level of Fig. 101A that are both unoccupied and close together, electrons in this level are relatively free to move about. Consequently, the material is a conductor.

In Fig. 101B, all the states in the lower level are occupied, there is a big gap between this level and the next higher one and the upper level is empty. This means if motion is to be imparted to an electron, it must be raised from the lower level to the upper one. Since this requires considerable energy, the material is an insulator. (The energy-level representation gives an insight into the phenomenon of breakdown. If the force on an electron in an insulator becomes high enough because of an applied field, it can acquire enough energy to be raised to the upper level. When this happens, the material goes into a conducting state.)

A third condition is shown in Fig. 102. In the material associated with this diagram, the upper level is unoccupied but is very close to the occupied one. Hence, under conditions where the random electron motion is low (low temperature), the material acts as an insulator (Fig. 102A). However, as the random or thermal mo-

Fig. 104 — N- and P-type semiconductors.

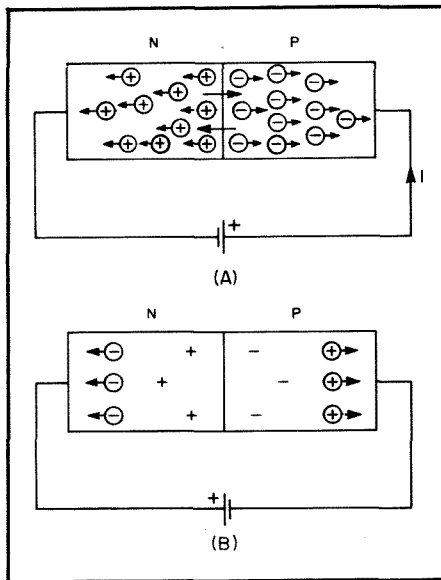

Fig. 105 — Elementary illustration of current flow in a semiconductor diode.

tion increases, some electrons acquire enough energy to move up to states in the upper level. Consequently, both levels are partially occupied, as shown in Fig. 102B.

The line marked  $W_f$  represents a statistical entity related to the average energy of electrons in the material and is called the Fermi Level. At absolute zero (no thermal motion),  $W_f$  is just at the top of the lower energy level. As electrons attain enough energy to move to the upper level,  $W_f$  is approximately halfway between the two levels.

### The PN Junction

The material for the diagram shown in Fig. 102 is called an intrinsic semiconductor. Examples are the elements germanium and silicon. As such, the materials do not have any rectifying properties by themselves. However, if certain elements are mixed into the intrinsic semiconductor in trace amounts, a mechanism for rectification exists. This is shown in Fig. 103A. If an element with an occupied energy level such as arsenic is introduced into germanium, a transformation in conductivity takes place. Electrons in the new occupied level are very close to the upper partially filled band of the intrinsic germanium. Consequently, there are many extra charge

Fig. 106 — Potential diagram of an electron in atomic orbit.

carriers available when thermal energy is sufficient to raise some of the electrons in the new level to the partially filled one. Germanium with an excess of mobile electrons is called an N-type semiconductor.

By introducing an element with an empty or unoccupied energy level near the lower partially filled level (such as boron), a somewhat different transformation in conductivity occurs. This is shown in Fig. 103B. Electrons from the lower level can move into the new unoccupied level if the thermal energy is sufficient. This means there is an excess of unoccupied states in the germanium lower energy level. Germanium treated this way is called P-type semiconductor.

A physical picture of both effects is shown in Fig. 104. The trace elements or impurities are spread throughout the intrinsic crystal. Since the distance of separation is much greater for atoms of the trace elements than it is for ones of the intrinsic crystal, there is little interaction between the former. Because of this lack of coupling, the distribution of energy states is a single level rather than a band. In Fig. 104A, atoms of the trace element are represented by the + signs since they have lost an electron to the higher energy level. Consequently, such elements are called donors. In Fig. 104B, the impurity atoms that have trapped an electron in the new state are indicated by the - signs. Atoms of this type are called acceptor impurities.

While it is easy to picture the extra free electrons by the circled minus charges in Fig. 104A, a conceptual difficulty exists with the freed positive charges shown in Fig. 104B. In either case, it is the motion of electrons that is actually taking place and the factor that is responsible for any current. However, it is convenient to consider that a positive charge carrier, called a hole, exists. It would seem as though a dislocation in the crystal-lattice structure was moving about and contributing to the total current.

If a section of N-type material is joined

to another section made from P-type, a one-way current flow results. This is shown in Fig. 105. A positive potential applied to the P-type electrode attracts any electrons that diffuse in from the N-type end. Likewise, holes migrating from the P-type end into the N-type electrode are attracted to the negative terminal. Note that the diagram indicates not all the carriers reach the terminals. This is because some carriers combine with ones of the opposite sign while enroute. In the case of a diode, this effect doesn't present much of a problem since the total current remains the same. Other carriers take the place of those originally injected from the opposite regions. However, such recombination degrades the performance of transistors considerably and will be discussed shortly.

If a voltage of the opposite polarity to that of Fig. 105A is applied to the terminals, the condition in Fig. 105B results. The mobile charge carriers migrate to each end as shown leaving only the fixed charges in the center near the junction. Consequently, little current flows and the PN junction is back biased. It can be seen that the PN junction constitutes a diode since current can flow readily only in one direction. While this simple picture suffices for introductory purposes, proper treatment of many important effects in semiconductors requires a more advanced analysis than the elementary model affords. Returning to Figs. 100, 101 and 102, it would be convenient if the diagrams were in terms of voltage rather than energy. As pointed out earlier, the relation between energy and voltage associated with an electron is given by

$$W = eV = (-1.6 \times 10^{-19}) V$$

Because the electron has been assigned a minus charge, a somewhat upside-down world results. However, if it is kept in mind that it requires the expenditure of energy to move an electron from a point of higher potential to one at a lower value, this confusion can be avoided. As an illustration, suppose an electron is moved from an atomic orbit indicated by I in Fig. 106 to orbit II. This would mean the electron would have had to have been moved against the force of attraction caused by the positive nucleus resulting in an increase in potential energy. (In other words, orbit II is at a higher energy level than orbit I.) However, note that the electrostatic potential around the nucleus decreases with distance and that orbit II is at a lower potential than orbit I.

Consequently, the energy-level diagram in terms of voltage becomes inverted as shown in Fig. 107. It is now possible to approach the problem of the PN junction diode in terms of the energy-level diagrams presented previously. If a section of N-type and P-type material is considered separately, the respective energy (or voltage) levels would be the same. However, if the two

Fig. 107 — Energy-level diagram in terms of potential.

sections were joined together and connected by an external conductor as shown in Fig. 108, a current would flow initially. This is because the voltage corresponding to the statistical entity referred to previously (Fermi Level) is not the same for P- and N-type materials at the same temperature.

At the Fermi Level, the probability that a particular energy state is occupied is one half. For N-type material, the Fermi Level is shifted upward toward the conduction band (Fig. 108A). In a P-type material, it is shifted downward toward the valence band. Although the theory behind the Fermi Level and definitions concerning the conduction and valence bands won't be dealt with here, it is sufficient to know that the band structure shifts so that the Fermi Levels are the same in both parts of the joined sections (Fig. 108).

The reasoning behind this effect is as follows. Consider conditions for hole flow only for the moment. Since there is an excess of holes in the P region (Fig. 108), there is a tendency for them to move over into the adjacent N region because of diffusion. The process of diffusion is demonstrated easily. If a small amount of dye is dropped into some water, it is concentrated in a small area at first. However, after a period of time has passed, it spreads out completely through the entire volume.

Once the holes diffuse into the N region, they recombine with the electrons present and produce a current in the external terminals denoted by  $I_D$  (Fig. 108). But a paradox results because of this current. If S1 is opened so that  $I_D$  flows through R, where does the energy that is transferred (irreversibly) to this resistance come from? In effect, it represents a perpetual-motion dilemma or else the semiconductor will cool down since the diffusion process is the result of a form of thermal motion. Both conclusions are against the laws of physics, so a third alternative is necessary. It is then assumed that the Fermi Levels align so that the potential across the terminals becomes zero, and no current will flow in the external circuit.

However, if the Fermi Levels are the same, the conduction and valence bands in either section will no longer align. As a consequence, a difference in potential between the two levels exists and is indicated by  $V_B$

Fig. 108 — Energy-level diagrams for unbiased (A), forward-biased (B) and reversed-biased diode (C). Illustration D shows the resultant characteristics of the diode.

in Fig. 108. The formation of this junction or barrier voltage is of prime importance in the operation of PN-junction devices. Note that holes in the P region must overcome the barrier voltage that impedes the flow of the diffusion current. It will also be recalled that both holes and electrons were generated in the intrinsic semiconductor because of thermal effects (Fig. 102B). The addition of either donor or acceptor atoms modifies this effect somewhat. If donor atoms are present (N-type material), fewer holes are generated. On the other hand, if acceptor atoms represent the impurities, fewer electrons are generated in comparison to conditions in an intrinsic semiconductor. In the case of P-type material, holes predominate and are termed the majority carriers. Since there are fewer electrons in P-type material they are termed the minority carriers.

Referring to Fig. 108A, there are some holes in the N region (indicated by the + signs) because of the thermal effects mentioned earlier. Those near the junction will experience a force caused by the electric field associated with the barrier voltage. This field will produce a flow of holes into

the P region and the current is denoted by  $I_T$ . Such a current is called a drift current as compared to the diffusion current  $I_D$ . Under equilibrium conditions, the two currents are equal and just cancel each other. This is consistent with the assumption that no current flows in the external circuit because of the fact that the Fermi Levels are the same and no voltage is produced.

So far, only conditions for the holes in the upper (or conduction) band have been considered, but identical effects take place with the motion of electrons in the lower energy band (valence band). Since the flow of charge carriers is in opposition, but because holes and electrons have opposite signs, the currents add.

#### The Forward-Biased Diode

If an external EMF is applied to the diode terminals as shown in Fig. 108B, the equilibrium conditions no longer exist and the Fermi Level voltage in the right-hand region is shifted upward. This means the barrier voltage is decreased and considerable numbers of carriers may now diffuse across the junction. Consequently,  $I_D$  becomes very large while  $I_T$  decreases in

value because of the decrease in barrier voltage. The total current under forward-bias conditions then becomes

$$I = I_s \left( e^{\frac{qV_x}{kt}} - 1 \right)$$

where

$q = 1.6 \times 10^{-19}$  coulombs (the fundamental charge of an electron)

$k = 1.38 \times 10^{-23}$  joules/kelvin (Boltzmann's constant)

$t$  = junction temperature in kelvins

$e = 2.718$  (natural logarithmic base)

$V_x$  = applied EMF and  $I_s$  = reverse-bias saturation current.

This equation is discussed in greater detail

in the section dealing with common silicon diodes.

### The Reverse-Biased Diode

If the source,  $V_x$ , is reversed as shown in Fig. 108C, the barrier voltage is increased. Consequently, charge carriers must overcome a large potential hill and the diffusion current becomes very small. However, the drift current caused by the thermally generated carriers returns to the value it had under equilibrium conditions. For large values of  $V_x$ , the current approaches  $I_s$ , defined as the reverse saturation current,  $I_s$  is the sum of  $I_T$  and its counterpart in the lower or "valence" band. Finally, the characteristic curves of

the forward- and reversed-bias diode can be constructed and are shown in Fig. 108D.

It is obvious that  $I_s$  should be as small as possible in a practical diode since it would only degrade rectifier action. Also, since it is the result of the generation of thermal carriers, it is quite temperature sensitive, which is important when the diode is part of a transistor. If the reverse voltage is increased further, an effect called avalanche breakdown occurs as indicated by the sudden increase in current at  $V_b$ . In such an instance, the diode might be damaged by excessive current. However, the effect is also useful for regulator purposes and devices used for this purpose are called Zener diodes.

# Vacuum-Tube Principles

This chapter covers the principles of vacuum-tube operation. Additional material on vacuum tubes may be found in Chapter 15. The outstanding difference between the vacuum tube and most other electrical devices is that the electric current does not flow through a conductor, but through empty space — a vacuum. This is only possible when free electrons — that is, electrons that are not attached to atoms — are somehow introduced into the vacuum. Free electrons in an evacuated space will be attracted to a positively charged object within the same space, or will be repelled by a negatively charged object. The movement of the electrons under the attraction or repulsion of such charged objects constitutes the current in the vacuum.

### Thermionic Emission

The most practical way to introduce a sufficiently large number of electrons into the evacuated space is by thermionic emission. If a piece of metal is heated to incandescence in a vacuum, electrons near the surface are given enough energy of motion to fly off into the surrounding space. The higher the temperature, the greater the number of electrons emitted. In a vacuum tube, the electron-emitting material is called the cathode.

If the cathode is the only electrode in the vacuum, most of the emitted electrons stay in its immediate vicinity, forming a cloud about the cathode. The reason for this is that the electrons in the space, being negative electricity, form a negative charge (space charge) in the region of the cathode. The space charge repels those electrons nearest the cathode, tending to make them fall back on it.

Now suppose a second conductor is introduced into the vacuum, but not connected to anything else inside the tube. If this second conductor is given a positive charge by connecting a voltage source between it and the cathode, as indicated in Fig. 1, electrons emitted by the cathode are attracted to the positively charged conductor. An electric current then flows through the circuit formed by the cathode, the charged conductor and the voltage source. In Fig. 1 this voltage source is a battery (B battery); a second battery (A battery) is also indicated for heating the cathode to the

Transmitting tubes are shown in the back and center rows. Receiving tubes are in the front row (l to r): miniature, pencil, planar triode (two), Nuvistor and 1-inch-diameter cathode-ray tube.

proper operating temperature.

The positively charged conductor is usually a metal plate or cylinder (surrounding the cathode) and is called the anode or plate. Like the other working parts of a tube, the plate is a tube element or electrode. The tube shown in Fig. 1 is

Fig. 1 — Conduction by thermionic emission in a vacuum tube. The A battery is used to heat the cathode to a temperature that will cause it to emit electrons. The B battery makes the plate positive with respect to the cathode, thereby causing the emitted electrons to be attracted to the plate. Electrons captured by the plate flow back through the B battery to the cathode.

Fig. 2 — Types of cathode construction. Directly heated cathodes or filaments are shown at A, B and C. The inverted V filament is used in small receiving tubes, the M in both receiving and transmitting tubes. The spiral filament is a transmitting tube type. The indirectly heated cathodes at D and E show two types of heater construction, one a twisted loop and the other bunched heater wires. Both types tend to cancel the magnetic fields set up by the current through the heater.

Fig. 3 — The diode, or two-element tube, and a typical curve showing how the plate current depends on the voltage applied to the plate.

a two-element or two-electrode tube (a diode), one element being the cathode and the other the anode or plate.

Since electrons have a negative charge, they will be attracted to the plate only when the plate is given a positive charge. If the plate is given a negative charge, the electrons will be repelled back to the cathode and no current will flow. The vacuum tube therefore can conduct only in one direction.

### Cathodes

Before electron emission can occur, the cathode must be heated to a high temperature. However, it is not essential that the heating current flow through the actual material that does the emitting; the heating filament or heater can be electrically separate from the emitting cathode. Such a cathode is said to be indirectly heated, while an emitting filament is called a directly heated cathode. Fig. 2 shows both types in the forms they commonly take.

Much greater electron emission can be obtained, at relatively low temperatures, by using special cathode materials rather than pure metals. One of these is thoriated tungsten (tungsten in which thorium is dissolved). Still greater efficiency is obtained in the oxide-coated cathode, a cathode in which rare-earth oxides form a coating over a metal base.

Although the oxide-coated cathode has the highest efficiency, it can be used successfully only in tubes that operate at low plate voltages. Its use is therefore confined to receiving-type tubes and to the smaller varieties of transmitting tubes. The thoriated filament, on the other hand, will

operate well in high-voltage tubes.

### Plate Current

If there is only a small positive voltage on the plate, the number of electrons reaching it will be small because the space charge (which is negative) prevents those electrons nearest the cathode from being attracted to the plate. As the plate voltage is increased, the effect of the space charge is increasingly overcome and the number of electrons attracted to the plate becomes larger. That is, the plate current increases with increasing plate voltage.

Fig. 3 shows a typical plot of plate current vs. plate voltage for a two-element tube or diode. A curve of this type can be obtained with the circuit shown, if the plate voltage is increased in small steps and a current reading is taken by means of the current-indicating instrument (a milliammeter) at each voltage. The plate current is zero with no plate voltage and the curve rises until a saturation point is reached. This is where the positive charge on the plate has substantially overcome the space charge and almost all the electrons are going to the plate. At higher voltages the plate current stays at practically the same value.

The plate voltage multiplied by the plate current is the power input to the tube. In a circuit like that of Fig. 3 this power is all used in heating the plate. If the power input is large, the plate temperature may rise to a very high value (the plate may become red or even white hot). The heat developed in the plate is radiated to the bulb of the tube, and in turn to the surrounding air.

### Rectification

Since current can flow through a tube in only one direction, a diode can be used to change alternating current into direct current. It does this by permitting current flow only when the anode is positive with respect to the cathode. There is no current flow when the plate is negative.

Fig. 4 shows a representative circuit. Alternating voltage from the secondary of the transformer, T, is applied to the diode tube in series with a load resistor, R. The

Fig. 4 — Rectification in a diode. Current flows only when the plate is positive with respect to the cathode, so that only half cycles of current flow through the load resistor, R.

voltage varies as is usual with ac, but current flows through the tube and R only when the plate is positive with respect to the cathode — that is, during the half cycle when the upper end of the transformer winding is positive. During the negative half cycle there is simply a gap in the current flow. This rectified alternating current therefore is an intermittent direct current.

The load resistor, R, represents the actual circuit in which the rectified alternating current does work. All tubes work with a load of one type or another; they must cause power to be developed in a load in order to serve a useful purpose. Also, to be efficient, most of the power must do useful work in the load rather than in heating the plate of the tube. Thus, the voltage drop across the load should be much higher than the drop across the diode.

With the diode connected as shown in Fig. 4, the polarity of the current through the load, R, is as indicated. If the diode were reversed, the polarity of the voltage developed across the load would be reversed.

## VACUUM-TUBE AMPLIFIERS

### Triodes

If a third element — called the control grid or, simply, grid — is inserted between the cathode and plate as in Fig. 5, it can be used to control the effect of the space charge. If the grid is given a positive voltage with respect to the cathode, the positive charge will tend to neutralize the negative space charge. The result is that, at any selected plate voltage, more electrons will flow to the plate than if the grid were not present. On the other hand, if the grid is made negative with respect to the cathode the negative charge on the grid will add to the space charge. This will reduce the number of electrons that can reach the plate

Fig. 5 — Construction of a basic triode vacuum tube, showing the directly heated cathode (filament), grid (with an end view of the grid wires) and plate. The relative density of the space charge is indicated roughly by the dot density.

at any selected plate voltage.

The grid is inserted in the tube to control the space charge and not to attract electrons to itself, so it is made in the form of a wire mesh or spiral. Electrons then can pass through the open spaces in the grid to reach the plate.

### Characteristic Curves

For any particular tube, the effect of the grid voltage on the plate current can be shown by a set of characteristic curves. A typical set of curves is shown in Fig. 6, together with the circuit that is used for determining them. For each value of plate voltage, there is a value of negative grid voltage that will reduce the plate current to zero; that is, there is a value of negative grid voltage that will cut off the plate current.

The curves could be extended by making the grid voltage positive as well as negative. When the grid is negative, it repels electrons and therefore none of them reaches it; in other words, no current flows in the grid circuit. When the grid is positive, however, it attracts electrons and a current (grid current) flows, just as current flows to the positive plate. Whenever there is grid current there is an accompanying power loss in the grid circuit, but as long as the grid is negative no power is used.

The grid can act as a valve to control the flow of plate current. Actually, the grid has a much greater effect on plate current flow than does the plate voltage. A small change in grid voltage is just as effective in bringing about a given change in plate current as is a large change in plate voltage.

The fact that a small voltage change on the grid is equivalent to a large voltage change on the plate indicates the possibility of amplification with the triode tube. The

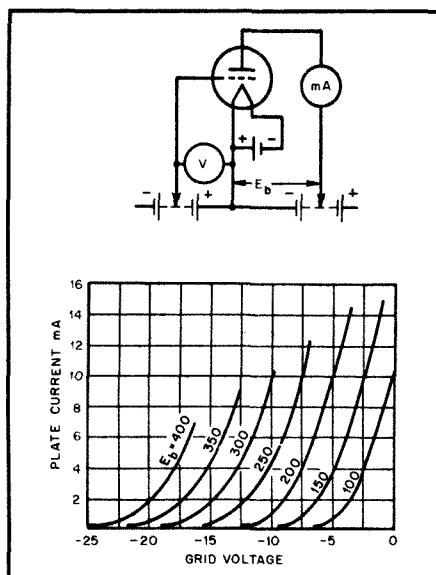

Fig. 6 — Curves of grid voltage vs. plate current at various fixed values of plate voltage ( $E_b$ ) for a typical small triode. Characteristic curves of this type can be taken by varying the battery voltages in the circuit shown.

many uses of the electron tube are nearly all based on this amplifying characteristic. The amplified output is not obtained from the tube itself, but from the voltage source connected between its plate and cathode. The tube simply controls the power from this source, changing it to the desired form.

To utilize the controlled power, a load must be connected in the plate or output circuit, just as in the diode case. The load may be either a resistance or an impedance. The term impedance is frequently used even when the load is purely resistive.

### Tube Characteristics

The physical construction of a triode determines the relative effectiveness of the grid and plate in controlling the plate current. The control of the grid increases by moving it closer to the cathode or by making the grid mesh finer.

The plate resistance of a vacuum tube is the ac resistance of the path from cathode to plate. For a given grid voltage, it is the quotient of a small change in plate voltage divided by a resultant change in plate current. Thus, if a 1-volt change in plate voltage caused a plate-current change of 0.01 mA (0.00001 or  $1 \times 10^{-5}$  ampere), the plate resistance would be 100,000 ohms.

The amplification factor (usually designated by the Greek letter  $\mu$ ) of a vacuum tube is defined as the ratio of the change in plate voltage to the change in grid voltage to effect equal changes in plate current. If, for example, an increase of 10 plate volts raised the plate current 1.0 mA, and an increase in (negative) grid voltage of 0.1 volt were required to return the plate current to its original value, the amplification factor of this triode tube would be 100. The amplification factors of triode tubes range from 2 to 100 or so. A high- $\mu$  tube

is one with an amplification of perhaps 30 or more. Medium- $\mu$  tubes have amplification factors in the approximate range 8 to 30, and low- $\mu$  tubes in the range below 7 or 8. The  $\mu$  of a triode is useful in computing stage gains.

The best all-around indication of the effectiveness of a tube as an amplifier is its grid-plate transconductance — also called mutual conductance or  $g_m$ . It is the change in plate current divided by the change in grid voltage that caused the change; it can be found by dividing the amplification factor by the plate resistance. Since current divided by voltage is conductance, transconductance is measured in the unit of conductance, the siemens.

Practical values of transconductance are very small, so the microsiemens (one millionth of a siemens) is the commonly used unit. Different types of tubes have transconductance values ranging from a few hundred to several thousand. The higher the transconductance the greater the possible amplification.

### Amplification

The way in which a tube amplifies is best shown by a type of graph called the dynamic characteristic. Such a graph, together with the circuit used for obtaining it, is shown in Fig. 7. The curves are taken with the plate supply voltage fixed at the desired operating value. The difference between this circuit and the one shown in Fig. 6 is that in Fig. 7 a load resistance is connected in series with the plate of the tube. Fig. 7 thus shows how the plate current will vary, with different grid voltages, when the plate current is made to flow through a load and thus do useful work.

The several curves in Fig. 7 are for various values of load resistance. When the resistance is small (as in the case of a 5-k $\Omega$  load) the plate current changes rapidly with a given change in grid voltage. If the load resistance is high (as in the 100,000-k $\Omega$  curve), the change in plate current for the same grid-voltage change is relatively small; also, the curve tends to be straighter.

Fig. 7 — Dynamic characteristics of a small triode with various load resistances from 5 k $\Omega$  to 100 k $\Omega$ .

Fig. 8 shows the same type of curve, but the circuit is arranged so that a source of alternating voltage (signal) is inserted between the grid and the grid battery (C battery in this example). The voltage of the grid battery is fixed at  $-5$  volts, and from the curve it may be seen that the plate current at this grid voltage is 2 milliamperes. This current flows when the load resistance is  $50,000 \times 0.002 = 100$  volts, leaving 200 volts between the plate and cathode.

When a sine-wave signal having a peak value of 2 volts is applied in series with the bias voltage in the grid circuit, the instantaneous voltage at the grid will swing to  $-3$  volts when the signal reaches its positive peak, and to  $-7$  volts when the signal reaches its negative peak. The maximum plate current will occur at the instant the grid voltage is  $-3$  volts. As shown by the graph, it will have a value of 2.65 milliamperes. The minimum plate current occurs at the instant the grid voltage is  $-7$  volts, and has a value of 1.35 mA. At intermediate values of grid voltage, intermediate plate current values will occur.

The instantaneous voltage between the plate and cathode of the tube is also shown on the graph. When the plate current is maximum, the instantaneous voltage drop in  $R_p$  is  $50,000 \times 0.00265 = 132.5$  volts; when the plate current is minimum the instantaneous voltage drop in  $R_p$  is  $50,000 \times 0.00135 = 67.5$  volts. The actual voltage between plate and cathode is the difference between the plate supply potential, 300 volts, and the voltage drop in the load resistance. The plate-to-cathode voltage is therefore 167.5 volts at maximum plate current and 232.5 volts at minimum plate current.

This varying plate voltage is an ac voltage superimposed on the steady plate-cathode potential of 200 volts (as previously determined for no-signal conditions). The peak value of this ac output voltage is the difference between either the maximum or minimum plate-cathode voltage and the no-signal value of 200 volts. In the illustration this difference is  $232.5 - 200$  or  $200 - 167.5$ ; that is, 32.5 volts in either case. Since the grid signal voltage has a peak value of 2 volts, the voltage-amplification ratio of the amplifier is  $32.5/2$  or 16.25. That is, approximately 16 times as much voltage is obtained from the plate circuit as is applied to the grid circuit.

As shown by the drawings in Fig. 8, the alternating component of the plate voltage swings in the negative direction (with reference to the no-signal value of plate-cathode voltage) when the grid voltage swings in the positive direction, and vice versa. This means that the alternating component of plate voltage (that is, the amplified signal) is 180 degrees out of phase with the signal voltage on the grid.

#### Bias

The fixed negative grid voltage (called

Fig. 8 — Amplifier operation. When the plate current varies in response to the signal applied to the grid, a varying voltage drop appears across the load,  $R_p$ , as shown by the dashed curve,  $E_p$ .  $I_p$  is the plate current.

Fig. 9 — Distortion resulting from the choice of an operating point on the curved part of the tube characteristic. The lower half cycle of plate current does not have the same shape as the upper half cycle.

Fig. 10 — An elementary power amplifier circuit in which the power-consuming load is coupled to the plate circuit through an impedance-matching transformer.

grid bias) in Fig. 8 serves a very useful purpose. One purpose of the type of amplification shown in this drawing is to obtain, from the plate circuit, an alternating voltage that has the same wave shape as the signal voltage applied to the grid. To do so, an operating point on the straight part of

the curve must be selected. The curve must be straight in both directions from the operating point at least far enough to accommodate the maximum value of the signal applied to the grid. If the grid signal swings the plate current back and forth over a part of the curve that is not straight as shown in Fig. 9, the shape of the ac wave in the plate circuit will not be the same as the shape of the grid-signal wave. In such a case the output wave shape will be distorted.

A second reason for using negative grid bias is that any signal whose peak positive voltage does not exceed the fixed voltage on the grid cannot cause grid current to flow. With no current flow there is no power consumption, so the tube will amplify without taking any power from the signal source. (However, if the positive peak of the signal does exceed the negative bias, current will flow in the grid circuit during the time the grid is positive.)

Distortion of the output wave shape that results from working over a part of the curve that is not straight (that is, a nonlinear part of the curve) has the effect of transforming a sine-wave grid signal into a more complex waveform. As explained in an earlier chapter, a complex wave can be resolved into a fundamental frequency and a series of harmonics. In other words, distortion from nonlinearity causes the generation of harmonic frequencies — frequencies that are not present in the signal applied to the grid. Harmonic distortion is undesirable in most amplifiers, although there are occasions when harmonics are deliberately generated and used.

#### Class-A Amplifiers

An amplifier in which voltage gain is the primary consideration is called a voltage amplifier. Maximum voltage gain is obtained when the load resistance or impedance is made as high as possible in comparison with the plate resistances of the tube. In such a case, the major portion of the voltage generated will appear across the load.

Voltage amplifiers belong to a group called class-A amplifiers. A class-A amplifier is one operated so that the wave shape of the output voltage is the same as that of the signal voltage applied to the grid. If a class-A amplifier is biased so that the grid is always negative, even with the largest signal to be handled by the grid, it is called a class-A<sub>1</sub> amplifier. Voltage amplifiers are always class-A<sub>1</sub> amplifiers.

#### Power Amplifiers

Fig. 10 shows an elementary power amplifier circuit. It is simply a transformer-coupled amplifier with the load connected to the secondary. Although the load is shown as a resistor, it actually would be some device, such as an antenna, that employs the power usefully. Every power tube requires a specific value of load

resistance from plate to cathode, usually some thousands of ohms, for optimum operation. The resistance of the actual load is rarely the right value for matching this optimum load resistance, so the turns ratio of the transformer is chosen to reflect the power value of resistance into the primary. The transformer may be either step up or step down, depending on whether the actual load resistance is higher or lower than the tube wants.

The power amplification ratio of an amplifier is the ratio of the power output obtained from the plate circuit to the power required from the ac signal in the grid circuit. There is no power lost in the grid circuit of a class-A<sub>1</sub> amplifier, so such an amplifier has an infinitely large power amplification ratio. However, it is quite possible to operate a class-A amplifier in such a way that current flows in the grid circuit during at least part of the cycle. In such a case, power is used up in the grid circuit and the power amplification ratio is not infinite. A tube operated in this fashion is known as a class-A<sub>2</sub> amplifier. It is necessary to use a power amplifier to drive a class-A<sub>2</sub> amplifier, because a voltage amplifier cannot deliver power without serious distortion of the wave shape.

Another term used in connection with power amplifiers is power sensitivity. In the case of a class-A<sub>1</sub> amplifier, the term means the ratio of power output to the grid signal voltage. If grid current flows, the term usually means the ratio of plate power output to grid power input.

The ac power that is delivered to a load by an amplifier tube has to be paid for in power taken from the source of plate voltage and current. In fact, there is always more power going into the plate circuit of the tube than is coming out as useful output. The difference between the input and output power is used up in heating the plate of the tube, as explained previously. The ratio of useful power output to dc plate input is called the plate efficiency. The higher the plate efficiency, the greater the amount of power that can be taken from a tube having a given plate dissipation rating.

### Parallel and Push-Pull Amplifiers

When it is necessary to obtain more power output than one tube is capable of giving, two or more similar tubes may be connected in parallel. In this case the similar elements in all tubes are connected together. This method is shown in Fig. 11 for a transformer-coupled amplifier. The power output is in proportion to the number of tubes used; the grid signal or exciting voltage required, however, is the same as for one tube. If the amplifier operates in such a way as to consume power in the grid circuit, the grid power required is in proportion to the number of tubes used.

An increase in power output also can be had by connecting two tubes in push-pull.

Fig. 11 — Parallel and push-pull AF amplifier circuits.

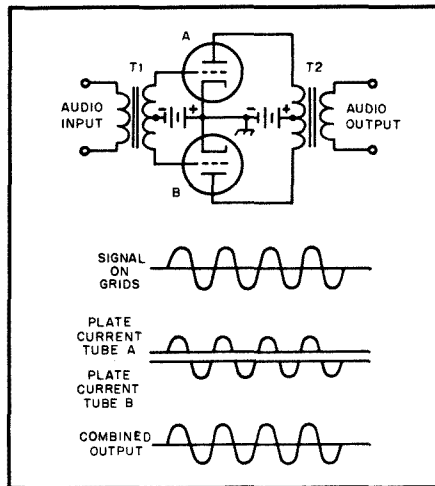

Fig. 12 — Class-B amplifier operation.

In this case the grids and plates of the two tubes are connected to opposite ends of a balanced circuit, as shown in Fig. 11. At any instant the ends of the secondary winding of the input transformer, T1, will be at opposite polarity with respect to the cathode connection, so the grid of one tube is swung positive at the same instant that the grid of the other is swung negative. Hence, in any push-pull connected amplifier the voltages and currents of one tube are out of phase with those of the other tube.

In push-pull operation the even-harmonic distortion (second, fourth, etc.) is balanced out in the plate circuit. This means that for the same power output the distortion will be less than with parallel operation.

The excitation voltage measured between the two grids must be twice that required for one tube. If the grids consume power, the driving power for the push-pull amplifier is twice that taken by either tube alone.

### Cascade Amplifiers

It is readily possible to take the output of one amplifier and apply it as a signal to

the grid of a second amplifier, then take the second amplifier's output and apply it to a third, and so on. Each amplifier is called a stage, and stages used successively are said to be in cascade.

### Class-B Amplifiers

Fig. 12 shows two tubes connected in a push-pull circuit. If the grid bias is set at the point where the plate current is just cut off (when no signal is applied) then a signal can cause plate current to flow in either tube only when the signal voltage applied to that particular tube is positive with respect to the cathode. Since in the balanced grid circuit the signal voltages on the grids of the two tubes always have opposite polarities, plate current flows only in one tube at a time.

The graphs show the operation of such an amplifier. The plate current of tube B is drawn inverted to show that it flows in the opposite direction, through the primary of the output transformer, to the plate current of tube A. Thus each half of the output-transformer primary works alternately to induce a half cycle of voltage in the secondary. In the secondary of T2, the original waveform is restored. This type of operation is called class-B amplification.

The class-B amplifier has considerably higher plate efficiency than the class-A amplifier. Furthermore, the dc plate current of a class-B amplifier is proportional to the signal voltage on the grids, so the power input is small with small signals. The dc plate power input to a class-A amplifier is the same whether the signal is large, small or absent altogether; therefore the maximum dc plate input that can be applied to a class-A amplifier is equal to the rated plate dissipation of the tube or tubes. Two tubes in a class-B amplifier can deliver approximately 12 times as much audio power as the same two tubes in a class-A amplifier.

A class-B amplifier usually is operated in such a way as to provide the maximum possible power output. This requires large values of plate current. To obtain these currents, the signal voltage must completely overcome the grid bias during at least part of the cycle, so grid current flows and the grid circuit consumes power. While the power requirements are fairly low (as compared with the power output), the fact that the grids are positive during only part of the cycle means the load on the preceding amplifier or driver stage varies in magnitude during the cycle. The effective load resistance is high when the grids are not drawing current, and is relatively low when they do take current. This must be allowed for when designing the driver.

Certain types of tubes have been designed specifically for class-B service and can be operated without fixed or other form of grid bias (zero-bias tubes). The amplification factor is so high that the plate current is small without signal. Because there is no fixed bias, the grids start

drawing current immediately whenever a signal is applied, so the grid-current flow is continuous throughout the cycle. This makes the load on the driver much more constant than is the case with tubes of lower  $\mu$  biased to plate-current cutoff.

Class-B amplifiers used at radio frequencies are known as linear amplifiers, because they are adjusted to operate in such a way that the power output is proportional to the square of the RF excitation voltage. This permits amplification of a modulated RF signal without distortion. Push-pull is not required in this type of operation; a single tube can be used equally well.

### Class-AB Amplifiers

Class-AB audio amplifiers are push-pull amplifiers with higher bias than would be normal for pure class-A operation, but less than the cutoff bias required for class-B. At low signal levels the tubes operate as class-A amplifiers, and the plate current is the same with or without signal. At higher signal levels, the plate current of one tube is cut off during part of the negative cycle of the signal applied to its grid, and the plate current of the other tube rises with the signal. The total plate current for the amplifier also rises above the no-signal level when a large signal is applied.

In a properly designed class-AB amplifier the distortion is as low as with a class-A stage, but the efficiency and power output are considerably higher than with pure class-A operation. A class-AB amplifier can be operated either with or without driving the grids into the positive region. A class-AB<sub>1</sub> amplifier is one in which the grids are never positive with respect to the cathode; therefore no driving power is required — only voltage. A class-AB<sub>2</sub> amplifier is one that has grid-current flow during part of the cycle if the applied signal is large; it takes a small amount of driving power. The class-AB<sub>2</sub> amplifier will deliver somewhat more power (using the same tubes), but the class-AB<sub>1</sub> amplifier avoids the problem of designing a driver that will deliver power without distortion into a load of highly variable resistance.

### Conduction Angle

Inspection of Fig. 12 shows that either of the two vacuum tubes is working for only half the ac cycle and idling during the other half. It is convenient to describe the amount of time during which plate current flows in terms of electrical degrees. In Fig. 12 each tube has 180-degree excitation, a half cycle being equal to 180 degrees. The number of degrees during which plate current flows is called the conduction angle of the amplifier. From the description given above, it should be clear that a class-A amplifier has 360-degree excitation, because plate current flows during the whole cycle. In a class-AB amplifier the conduction angle is between 180 and 360 degrees (in each tube), depending on the particular operating conditions chosen. The

greater the amount of negative grid bias, the smaller the conduction angle becomes.

A conduction angle of less than 180 degrees leads to a considerable amount of distortion, because there is no way for the tube to reproduce even a half cycle of the signal on its grid. Using two tubes in push-pull, as in Fig. 12, would merely put together two distorted half cycles. A conduction angle of less than 180 degrees therefore cannot be used if distortionless output is wanted.

### Class-C Amplifiers

In power amplifiers operating at radio frequencies, distortion of the RF waveform is relatively unimportant. Tuned circuits are usually used to filter out the RF harmonics resulting from distortion.

A radio-frequency power amplifier therefore can be used with a conduction angle of less than 180 degrees. This is called class-C operation. The advantage is that the plate efficiency is increased because the loss in the plate is proportional, among other things, to the amount of time during which the plate current flows. This time is reduced by decreasing the operating angle.

Depending on the type of tube, the optimum load resistance for a class-C amplifier ranges from about 1.5 k $\Omega$  to 5 k $\Omega$ . Tuned-circuit arrangements are normally used to transform the resistance of the actual load to the value required by the tube. The grid is driven well into the positive region, so grid current flows and power is consumed in the grid circuit. The smaller the conduction angle, the greater the driving voltage and the larger the grid driving power required to develop full output in the load resistance. The best compromise between driving power, plate efficiency and power output usually results when the minimum plate voltage is just equal to the peak positive grid voltage. These conditions must exist at the peak of the driving cycle, when the plate current reaches its highest value. Under such conditions the conduction angle is usually between 120 and 150 degrees, and the plate efficiency lies in the range of 60 to 80 percent. While higher plate efficiencies are possible, attaining them requires excessive driving power and grid bias, together with higher plate voltage than is normal for the particular tube type.

### Feedback

It is possible to take a part of the amplified energy in the plate circuit of an amplifier and insert it into the grid circuit. This is called feedback.

If the voltage that is inserted in the grid circuit is 180 degrees out of phase with the signal voltage acting on the grid, the feedback is called negative or degenerative. On the other hand, if the voltage is fed back in phase with the grid signal, the feedback is called positive or regenerative.

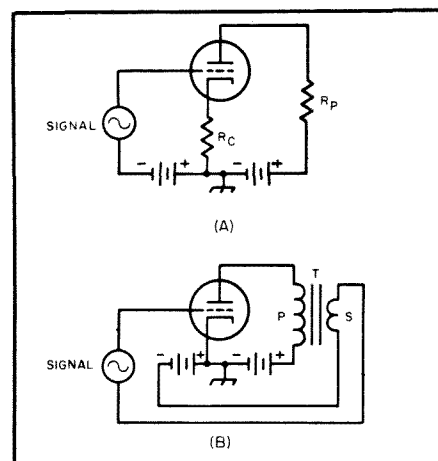

Fig. 13 — Simple circuits for producing feedback.

### Negative Feedback

With negative feedback the voltage that is fed back opposes the signal voltage. This decreases the amplitude of the voltage acting between the grid and cathode and thus has the effect of reducing the voltage amplification. That is, a larger exciting voltage is required for obtaining the same output voltage from the plate circuit.

The greater the amount of negative feedback (when properly applied), the more independent the amplification becomes of tube characteristics and circuit conditions. This tends to make the frequency-response characteristic of the amplifier flat — that is, the amplification tends to be the same at all frequencies within the range for which the amplifier is designed. Also, any distortion generated in the plate circuit of the tube tends to “buck itself out.” Amplifiers with negative feedback therefore have lower harmonic distortion. These advantages are worthwhile if the amplifier otherwise has enough voltage gain for its intended use.

In the circuit shown at A in Fig. 13 resistor  $R_C$  is in series with the regular plate resistor,  $R_P$  and this is a part of the load for the tube. Therefore, part of the output voltage will appear across  $R_C$ .  $R_C$  also is connected in series with the grid circuit, however, so the output voltage that appears across  $R_C$  is in series with the signal voltage. The output voltage across  $R_C$  opposes the signal voltage, so the actual ac voltage between the grid and cathode is equal to the difference between the two voltages.

The circuit shown at B in Fig. 13 can be used to give either negative or positive feedback. The secondary of a transformer is connected back into the grid circuit to insert a desired amount of feedback voltage. Reversing the terminals of either transformer winding (but not both simultaneously) will reverse the phase.

### Positive Feedback

Positive feedback increases the ampli-

cation because the feedback voltage adds to the original signal voltage, and the resulting larger voltage on the grid causes a larger output voltage. The amplification tends to be greatest at one frequency (which depends on the particular circuit arrangement) and harmonic distortion is increased. If enough energy is fed back, a self-sustaining oscillation will be set up — one in which energy at essentially one frequency is generated by the tube itself. In such cases all the signal voltage on the grid can be supplied from the plate circuit. No external signal is needed because any small irregularity in the plate current (and there are always some irregularities) will be amplified and thus give the oscillation an opportunity to build up. Positive feedback finds a major application in oscillators, and in addition is used for selective amplification at both audio and radio frequencies, the feedback being kept below the value that causes self-oscillation.

### Interelectrode Capacitances

Each pair of elements in a tube forms a small capacitor. There are three such capacitances in a triode — that between the grid and cathode, that between the grid and plate, and that between the plate and cathode. The capacitances are very small, only a few picofarads at most, but they frequently have a pronounced effect on the operation of an amplifier circuit.

### Input Capacitance

It was explained previously that the ac grid voltage and ac plate voltage of an amplifier having a resistive load are 180 degrees out of phase, using the cathode of the tube as a reference point. However, these two voltages are in phase going around the circuit from plate to grid as shown in Fig. 14. This means that their sum is acting between the grid and plate — that is, across the grid-plate capacitance of the tube.

As a result, a capacitive current flows around the circuit, its amplitude being directly proportional to the sum of the ac grid and plate voltages and to the grid-plate capacitance. The source of the grid signal must furnish this amount of current, in addition to the capacitive current that flows in the grid-cathode capacitance. Hence the signal source sees an effective capacitance that is larger than the grid-cathode capacitance. This is known as the Miller effect.

The greater the voltage amplification, the greater the effective input capacitance. The input capacitance of a resistance-coupled amplifier is given by the formula

$$C_{\text{input}} = C_{gk} + C_{gp} (A + 1)$$

where

$C_{gk}$  is the grid-to-cathode capacitance

$C_{gp}$  is the grid-to-plate capacitance

$A$  is the voltage amplification.

The input capacitance may be as much as several hundred picofarads when the

Fig. 14 — The ac voltage appearing between the grid and plate of the amplifier is the sum of the signal voltage and the output voltage, as shown by this simplified circuit. Instantaneous polarities are indicated.

voltage amplification is large, even though the interelectrode capacitances are quite small.

### Output Capacitance

The principal component of the output capacitance of an amplifier is the actual plate-to-cathode capacitance of the tube. The output capacitance usually need not be considered in audio amplifiers, but becomes of importance at radio frequencies.

### Tube Capacitance at RF

At radio frequencies the reactances of even very small interelectrode capacitances drop to very low values. A resistance-coupled tube amplifier gives very little amplification at RF, for example, because the reactances of the interelectrode capacitors are so low that they practically short circuit the input and output circuits, and thus the tube is unable to amplify. This is overcome at radio frequencies by using tuned circuits for the grid and plate, making the tube capacitances part of the tuning capacitances. In this way the circuits can have the high resistive impedances necessary for satisfactory amplification.

The grid-plate capacitance is important at radio frequencies because its reactance, relatively low at RF, offers a path over which energy can be fed back from the plate to the grid. In practically every case the feedback is in the right phase and of sufficient amplitude to cause self-oscillation, so the circuit becomes useless as an amplifier.

Special neutralizing circuits can be used to prevent feedback but they are, in general, not too satisfactory when used in radio receivers. They are used in transmitters, however.

### Tetrodes

The grid-plate capacitance can be greatly reduced by inserting a second grid between the control grid and the plate, as indicated in Fig. 15. The second grid, called the screen grid, acts as an electrostatic shield to reduce capacitive coupling between the control grid and plate. It is made in the form of a grid or coarse screen so electrons can pass through it. A tube having a

Fig. 15 — Representative arrangement of elements in a screen-grid tetrode, with part of plate and screen cut away. This shows single-ended construction with a button base, typical of miniature receiving tubes. To reduce capacitance between control grid and plate, the leads from these elements are brought out at opposite sides. Actual tubes probably would have additional shielding between these leads.

cathode, control grid, screen grid and plate (four elements) is called a tetrode.

Because of the shielding action of the screen grid, the positively charged plate cannot easily attract electrons from the cathode as it does in a triode. In order to enhance electron flow to the plate, it is necessary to apply a positive voltage to the screen (with respect to the cathode). The screen then attracts electrons much as does the plate in a triode tube. In traveling toward the screen the electrons acquire such velocity that most of them shoot between the screen wires and then are attracted to the plate. A small proportion does strike the screen, however, with the result that some current also flows in the screen-grid circuit.

To be a good shield, the screen grid must be connected to the cathode through a circuit that has low impedance at the frequency being amplified. A bypass capacitor from screen grid to cathode, having a reactance of not more than a few hundred ohms, is generally used.

### Pentodes

When an electron traveling at appreciable velocity through a tube strikes the plate, it dislodges other electrons, which splash from the plate into the interelement space. This is called secondary emission. In a triode the negative grid repels the secondary electrons back into the plate and they cause no disturbance. In the screen-grid tube, however, the positively charged screen attracts the secondary electrons, causing a reverse current to flow between screen and plate.

To overcome the effects of secondary emission, a third grid, called the suppressor grid, may be inserted between the screen and plate. This grid, negatively charged with respect to the screen and plate, acts as a shield between the screen grid and plate so the secondary electrons cannot be at-

tracted by the screen grid. They are hence attracted back to the plate without appreciably obstructing the regular plate-current flow. A five-element tube of this type is called a pentode.

Although the screen grid in either the tetrode or pentode greatly reduces the influence of the plate voltage on plate-current flow, the control grid still can control the plate current in essentially the same way that it does in a triode. Consequently, the grid-plate transconductance (or mutual conductance) of a tetrode or pentode will be of the same order of value as in a triode of corresponding structure. On the other hand, since a change in plate voltage has very little effect on the plate-current flow, both the amplification factor and plate resistance of a pentode or tetrode are very high. Because of the high plate resistance, the actual voltage amplification possible with a pentode is very much less than the large amplification factor might indicate. A voltage gain in the vicinity of 50 to 200 is typical of a pentode stage.

In practical screen-grid tubes, the grid-plate capacitance is only a small fraction of a picofarad. This capacitance is too small to cause an appreciable increase in input capacitance by means of the Miller effect, so the input capacitance of a screen-grid tube is equal to the capacitance between the plate and screen.

The chief function of the screen grid is to serve as an accelerator of electrons, so that large values of plate current can be drawn at relatively low plate voltages. Tetrodes and pentodes have high power sensitivity compared with triodes of the same power output, although harmonic distortion is somewhat greater.

### Beam Tubes

A beam tetrode is a four-element screen-grid tube constructed in such a way that the electrons are formed into concentrated beams on their way to the plate. Additional design features overcome the effects of secondary emission so that a suppressor grid is not needed. The beam construction makes it possible to draw large plate currents at relatively low plate voltages, and increases the power sensitivity of the tube.

For power amplification at radio frequencies, beam tetrodes have largely supplanted the nonbeam types. This is because large power outputs can be secured with very small amounts of grid driving power.

### Input and Output Impedances

The input impedance of a vacuum-tube amplifier is the impedance seen by the signal source when connected to the input terminals of the amplifier. In the types of amplifiers previously discussed, the input impedance is the impedance measured between the grid and cathode of the tube with operating voltages applied. At audio frequencies the input impedance of a class-A1 amplifier is for all practical purposes the input impedance of the stage. If the tube

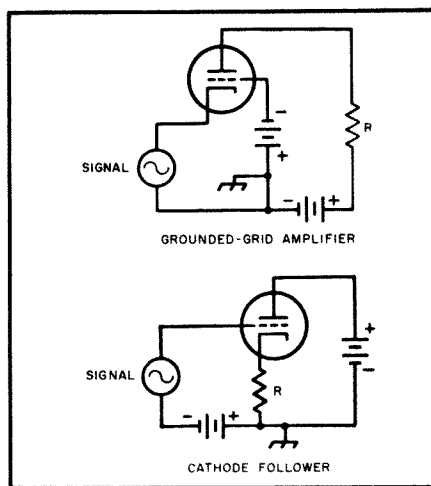

Fig. 16 — In each circuit shown, R represents the load. In the upper circuit, the grid is the junction point between the input and output circuits. In the lower drawing, the plate is the junction. In either case the output is developed in the load resistor, and may be coupled to a following amplifier by the usual methods.

is driven into the grid-current region, there is in addition a resistance component in the input impedance. The resistance has an average value equal to  $E^2/P$ , where E is the RMS driving voltage and P is the power in watts consumed in the grid. The resistance usually will vary during the ac cycle, because grid current may flow only during part of the cycle. Also, the grid-voltage/grid-current characteristic is seldom linear.

The output impedance of amplifiers of this type consists of the plate resistance of the tube shunted by the output capacitance.

At radio frequencies, when tuned circuits are employed, the input and output impedances are usually pure resistances; any reactive components are tuned out in the process of adjusting the circuits to resonance at the operating frequency.

### Other Types of Amplifiers

In the amplifier circuits discussed so far, the signal has been applied between the grid and cathode, and the amplified output has been taken from the plate-to-cathode circuit. That is, the cathode has been the meeting point for the input and output circuits. However, it is possible to use any one of the three principal elements as the common point. This leads to two additional kinds of amplifiers, commonly called the grounded-grid amplifier and the cathode follower.

These two circuits are shown in simplified form in Fig. 16. In both circuits, R represents the load into which the amplifier works. The actual load may be resistance-capacitance coupled, transformer coupled, or may be a tuned circuit if the amplifier operates at radio frequencies. Also, in both circuits the batteries that supply grid bias and plate power are assumed to have such

negligible impedance that they do not enter into the operation of the circuits.

### Grounded-Grid Amplifier

In the grounded-grid amplifier the input signal is applied between the cathode and grid, and the output is taken between the plate and grid. The grid is thus the common element. The ac component of the plate current has to flow through the signal source to reach the cathode. The source of signal is in series with the load through the plate-to-cathode resistance of the tube, so some of the power in the load is supplied by the signal source. In transmitting applications this fed-through power is of the order of 10 percent of the total power output, using tubes suitable for grounded-grid service.

The input impedance of the grounded-grid amplifier consists of a capacitance in parallel with an equivalent resistance that would absorb the power furnished by the driving source to the grid and to the load. This resistance is of the order of a few hundred ohms. The output impedance, neglecting the interelectrode capacitances, is equal to the plate resistance of the tube. This is the same as in the case of the grounded-cathode amplifier.

The grounded-grid amplifier is widely used at radio frequencies. With a triode tube designed for this type of operation, an RF amplifier can be built that is free from the type of feedback that causes oscillation. This requires that the grid act as a shield between the cathode and plate, reducing the plate-cathode capacitance to a very low value.

### Cathode Follower

The cathode follower uses the plate of the tube as the common element. The input signal is applied between the grid and plate (assuming negligible impedance in the batteries) and the output is taken between cathode and plate. This circuit is degenerative; in fact, all of the output voltage is fed back into the input circuit out of phase with the grid signal. The input signal therefore has to be larger than the output voltage; that is, the cathode follower gives a loss in voltage, although it gives the same power gain as other circuits under equivalent operating conditions.

An important feature of the cathode follower is its low output impedance, which is given by the formula (neglecting interelectrode capacitances)

$$Z_{out} = \frac{r_p}{1 + \mu}$$

where

$r_p$  is the tube plate resistance  
 $\mu$  is the amplification factor.

Low output impedance is a valuable characteristic in an amplifier designed to cover a wide band of frequencies. In addition, the input capacitance is only a frac-

tion of the grid-to-cathode capacitance of the tube, a feature of further benefit in a wide-band amplifier. The cathode follower is useful as a step-down impedance transformer, since the input impedance is high and the output impedance is low.

### Cathode Circuits and Grid Bias

Most of the equipment used by amateurs is powered by the ac line. This includes the filaments or heaters of vacuum tubes. Supplies for the plate (and sometimes the grid) are usually ac that is rectified and filtered to give pure dc — that is, direct current that is constant and without a superimposed ac component. The relatively large currents required by filaments and heaters however, usually make a rectifier-type dc supply impractical. Therefore, alternating current is almost always used to heat the tube cathode.

### Filament Hum

Alternating current is just as good as direct current from the heating standpoint, but some of the ac voltage is likely to be coupled to the grid and cause ac hum to be superimposed on the output. Hum troubles are worst with directly heated cathodes (filaments), because with such

Fig. 18 — Cathode biasing. R is the cathode resistor and C is the cathode bypass capacitor.

cathodes there has to be a direct connection between the source of heating power and the rest of the circuit.

Hum can be minimized by either of the connections shown in Fig. 17. In both cases the grid- and plate-return circuits are connected to the electrical midpoint (center tap) of the filament supply. Thus, as far as the grid and plate are concerned, the voltage and current on one side of the filament are balanced by an equal and opposite voltage and current on the other side. The balance is never quite perfect, however, so filament-type tubes are never completely hum free. For this reason directly heated filaments are employed for the most part in power tubes, where the hum introduced is extremely small in comparison with the power-output level.

With indirectly heated cathodes the chief problem is the magnetic field set up by the heater. Occasionally, also, there is leakage between the heater and cathode, allowing a small ac voltage to reach to the grid. If hum appears, grounding one side of the heater supply usually will help to reduce it, although sometimes better results are obtained if the heater supply is center-tapped and the center-tap grounded, as shown in Fig. 17.

### Cathode Bias

In the simplified amplifier circuits discussed in this chapter, grid bias has been supplied by a battery. In equipment that operates from the power line, however, cathode bias is almost universally used for tubes that are operated in class-A (constant dc input).

The cathode-bias method uses a resistor (cathode resistor) connected in series with the cathode, R in Fig. 18. The direction of plate-current flow is such that the end of the resistor nearest the cathode is positive. The voltage drop across R therefore places a negative voltage on the grid with respect to the cathode. This negative bias is obtained from the steady dc plate current.

If the alternating component of plate current flows through R when the tube is

Fig. 19 — Screen-voltage supply for a pentode tube through a dropping resistor, R. The screen bypass capacitor, C, must have low enough reactance to bring the screen to ground potential for the frequency or frequencies being amplified.

amplifying, the voltage drop caused by the ac will be degenerative (note the similarity between this circuit and that of Fig. 13A). To prevent this, the resistor is bypassed by the capacitor, C, that has very low reactance compared with the resistance of R. Depending on the type of tube and the particular kind of operation, R may be between about 100 and 3000 ohms. For good bypassing at radio frequencies, capacitances of about 100 pF to 0.1  $\mu$ F are used; the small values are sufficient at very high frequencies and the largest at low and medium frequencies. In the range 3 to 30 megahertz a capacitance of 0.01  $\mu$ F is satisfactory.

The value of cathode resistor for an amplifier having negligible dc resistance in its plate circuit (transformer or impedance coupled) can be calculated from the known operating conditions of the tube.

### Screen Supply

In practical circuits using tetrodes and pentodes, the voltage for the screen frequently is taken from the plate supply through a resistor. A typical circuit for an RF amplifier is shown in Fig. 19. R is the screen dropping resistor, and C is the screen bypass capacitor. In flowing through R, the screen current causes a voltage drop in R that reduces the plate-supply voltage to the proper value for the screen. When the plate-supply voltage and the screen current are known, the value of R can be calculated from Ohm's Law.

The reactance of the screen bypass capacitor, C, should be low compared with the screen-to-cathode impedance. For radio-frequency applications between 3 and 30 MHz, a capacitance in the vicinity of 0.01  $\mu$ F is amply large.

In some vacuum-tube circuits the screen voltage is obtained from a voltage divider connected across the plate supply. The design of voltage dividers is discussed in Chapter 6.

Fig. 21 — Simplified diagram of a traveling-wave-tube (TWT) amplifier. Like the klystron, this tube requires a focusing magnet.

## Tubes for UHF and Microwaves

Earlier discussions in this chapter have assumed that the time it takes for the electrons to travel from the cathode to the plate does not affect the performance of vacuum-tube operation. As the frequency of operation is raised, this time becomes increasingly important. Called the transit time, this time depends on the voltage from the cathode to the plate and the spacing between them. The higher the voltage and the smaller the spacing, the shorter the transit time. This is why tubes designed for VHF and UHF work have very small interelectrode spacings. The power handling capabilities also get smaller as the spacing decreases, however, so there is a frequency limit above which ordinary triode and pentode tubes cannot be operated efficiently.

Many different tubes have been developed which actually use transit-time effects to an advantage. Velocity modulation of the electron stream in a klystron is one example. A small voltage applied across the gap in a reentrant cavity resonator either retards or accelerates an electron stream by means of the resultant electric field. Initially, all the electrons are traveling at the same velocity, and the current in the beam is uniform. After the velocity fluctuations are impressed on the beam, the current is still uniform for a while, but then the electrons that were accelerated begin to catch up with the slower ones that passed through when the field was zero. These faster electrons are also catching up with ones that passed through the gap earlier but were retarded. The result is that the current in the beam is no longer uniform, but consists of a series of pulses.

If the beam now passes through another cavity gap, a current will be induced in the cavity walls and an electric field also will be set up across the gap. If the phase of the electric field is right, the electron pulses or bunches pass through the gap and are retarded, thus giving up energy to the electric field. When the electric field reverses, it would normally accelerate the same number of electrons and give back the

Fig. 22 — Cross-sectional view of a typical reflex klystron. The frequency of the cavity resonator is changed by varying the spacing between the grids using a tuning mechanism and a flexible bellows.

energy, but fewer electrons now pass through the gap and the energy is from the beam to the cavity. If the voltage produced across the output cavity is greater than that across the input cavity, amplification results (assuming the two cavity impedances are the same).

A four-cavity klystron is shown in Fig. 20. In this example, a pair of intermediate cavities has been added. These additional cavities reinforce the bunching of electrons within the electron beam, which in turn increases the gain.

Not shown in Fig. 20 is the magnet that must be used to keep the electron beam focused down the center of the tube. Beam electrons must be returned through the collector and not by way of the cavities or body of the tube.

### Traveling Wave Tube

As you can see in Fig. 21, a helix

Table 1

### Comparison of Klystrons and TWTs

Type	Gain (dB)	Efficiency (%)	Bandwidth (%)
Klystron	40-60	30-70	1-5
Helix TWT	30-50	20-40	30-120
Cavity TWT	30-50	20-40	5-40

traveling wave tube (TWT) looks much like a klystron. The major difference is that the klystron cavities have been replaced with a helix.

A signal traveling along the helix moves more slowly than the electrons in the beam. The signal on the helix tends to retard beam electrons. As beam electrons slow down they give up energy to the signal on the helix.

Another type of TWT uses a series of coupled cavities instead of a helix. Table 1 compares TWTs and klystrons.

### Microwave Oscillator Tubes

Another type of klystron is the reflex klystron oscillator, shown in Fig. 22. Here the input and output cavity are the same. The electron stream makes one pass through, becomes velocity modulated, and is turned around by the negative charge on an element called the repeller. During the second pass through, the stream is now bunched and delivers some of its energy to the cavity. The dissipated beam is then picked up by the cavity walls and the circuit is completed.

Other microwave oscillator wave tubes are the back wave oscillator (BWO) and the magnetron. The BWO works on the same principle as the TWT. The magnetron uses a magnetic field in conjunction with an electric field in its operation. Home microwave ovens use magnetrons to produce RF energy for cooking.

# Power Supplies

In most residential systems, three wires are brought in from the outside to the house distribution panel, although there are only two wires in older systems. In the three-wire system, the third wire is neutral and is grounded. The voltage between the two wires normally is 234. Half of this voltage appears between each of these wires and neutral, as indicated in Fig. 1A.

In systems of this type, the 117-volt household load is divided as evenly as possible between the two sides of the circuit. Half of the load is connected between one wire and neutral, and the other half of the load is connected between the other wire and neutral. Heavy appliances, such as electric stoves and heaters, are designed for 234-volt operation and are connected across the two ungrounded wires.

While both ungrounded wires should be fused, a fuse or switch should never be used in the neutral wire. The reason for this is that opening the neutral wire does not disconnect the equipment. It simply leaves the equipment on one side of the 234-volt circuit in series with whatever load may be across the other side of the circuit. Furthermore, with the neutral open, the voltage will then be divided between the two sides in inverse proportion to the load resistance. The voltage will drop below normal on one side and soar on the other side, unless the loads happen to be equal. More information on 117- and 234-V ac wiring for amateur stations may be found in Chapter 37.

The electrical power required to operate Amateur Radio equipment is usually taken from the alternating current (ac) lines when the equipment is operated where power is available. For mobile operation, the source of power is almost always the car storage battery.

Direct current (dc) voltages used in transmitters, receivers and other related equipment are derived from the commercial ac lines by using a transformer-rectifier-filter system. The transformer changes the ac voltage to a suitable value, and the rectifier converts the ac to pulsating dc. A filter is used to smooth out these pulsations to an acceptably low level. Essentially pure dc is required to prevent 60- or 120-Hz hum in most amateur equipment. If a constant voltage is required under conditions of changing load or ac-

line voltage, a regulator is used following the filter.

## Fusing

All transformer primary circuits should be fused properly. To determine the approximate current rating of the fuse or circuit breaker to be used, multiply each current being drawn from the supply in amperes by the voltage at which the current is being drawn. Include the current taken by bleeder resistors and voltage dividers. In the case of series resistors, use the source voltage, not the voltage at the equipment end of the resistor. Include filament power if the transformer is supplying filaments.

After multiplying the various voltages and currents, add the individual products. Then divide by the line voltage and add 10 or 20 percent. Use a fuse or circuit breaker with the nearest larger current rating.

When selecting fuses and circuit breakers for use in motor circuits (for example, blower lines) a slow-blow type should be used. When the motor is started, it can draw up to 10 times its normal operating current until the shaft reaches its normal operating speed. This can take up to 30 seconds on a large blower. Such an overload will usually open a fast- or normal-blow fuse.

For low-power semiconductor circuits, use fast-blow fuses. As the name implies, such fuses open very quickly once the cur-

rent rating is exceeded by more than 10%.

## TRANSFORMERS

### Volt-Ampere Rating

The number of volt-amperes (VA) delivered by a transformer depends on the type of filter used (capacitor or choke input), and on the type of rectifier used (full-wave center tap or full-wave bridge). With a capacitive-input filter, the heating effect in the secondary is higher because of the high ratio of peak-to-average current. The volt-amperes handled by the transformer may be several times the watts delivered to the load. The primary volt-amperes will be somewhat higher because of transformer losses.

### Broadcast and Television Replacement Transformers

Small power transformers sold for replacement in broadcast and television receivers are usually designed for service in terms of use for several hours continuously with capacitor-input filters. In the usual type of amateur transmitter service, where most of the power is drawn intermittently for periods of several minutes with equivalent intervals in between, the published ratings can be exceeded without excessive transformer heating.

With a capacitor-input filter, it should be safe to draw 20 to 30 percent more current than the rated value. With a choke-input filter, an increase in current of about

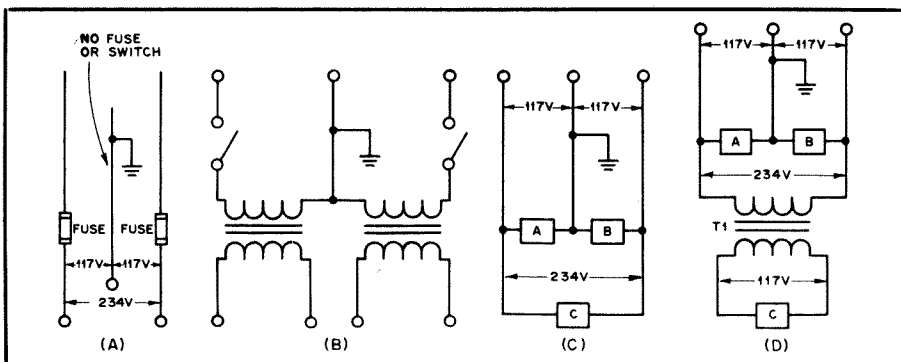

Fig. 1 — Three-wire power-line circuits. At A, normal three-wire-line termination. No fuse should be used in the grounded (neutral) line. At B, a switch in the neutral line would not remove voltage from either side of the line; C, connections for both 117- and 234-volt transformers; D, operating a 117-volt plate transformer from the 234-volt line to avoid light blinking. T1 is a 2:1 step-down transformer.

Fig. 2 — One method of equalizing two transformers connected in parallel.

Fig. 3 — Cross-sectional drawings of a typical power transformer. Multiplying the height (or thickness of the laminations) by the width of the central core area in inches gives the value to be applied to Fig. 4.

50 percent is permissible. If a bridge rectifier is used, the output voltage will be approximately doubled. In this case, it should be possible in amateur transmitter service to draw the rated current, thus obtaining about twice the rated output power from the transformer. This does not apply, of course, to amateur transmitter plate transformers, which usually are rated for intermittent service.

### Transformers in Parallel

The secondary windings of power transformers can be connected in parallel to obtain a greater current rating than can be had with a single transformer. A common application might be a high-current, 12-V supply for a transceiver. One potential problem is equalizing the current between the two transformers.

A timeless scheme for paralleling nominally-equal transformers is shown in Fig. 2. An inductor, in this case the center-tapped secondary winding of a low-voltage filament transformer, is used to equalize the current. This winding will only see the difference between voltages  $E_1$  and  $E_2$ .

In the ideal case ( $E_1 = E_2$ ), the currents are equal but opposite in the center-tapped winding. There is no net flux, and therefore no inductive voltage drop. Ideally, there is no loss.

When  $E_1$  is not equal to  $E_2$ , the open-circuit voltage at the center tap is  $E_2 + 1/2(E_1 - E_2)$ . If the difference between  $E_1$  and  $E_2$  is very small, the currents will

Fig. 4 — Power-handling capability of a transformer versus cross-sectional area of core.

be approximately equal, and there will be essentially only the normal transformer losses.

### Rewinding Power Transformers

Although the home winding of power transformers is a task that few amateurs undertake, the rewinding of a transformer secondary to give some desired voltage is not difficult. It involves a matter of only a small number of turns, and the wire is large enough to be handled easily. Often a receiver power transformer with a burned-out high-voltage winding or the power transformer from a discarded TV set can be converted into an entirely satisfactory transformer without great effort and with little expense.

The average TV power transformer for a 17-inch or larger vacuum-tube set is capable of delivering from 350 to 450 watts, continuous duty. If an amateur transmitter is being powered, the service is not continuous, so the ratings can be increased by 40 or 50 percent without danger of overloading the transformer.

The primary volt-ampere rating of the transformer to be rewound, if known, can be used to determine its power-handling capability. The secondary volt-ampere rating will be 10 to 20 percent less than the primary rating. The power rating may also be determined approximately from the cross-sectional area of the core that is inside the windings. Fig. 3 shows the method of determining the area, and Fig. 4 may be used to convert this information into a power rating.

Before disconnecting the winding leads from their terminals, each should be marked for identification. In removing the core laminations, care should be taken to

note how the core is assembled, so the reassembling will be done in the same manner. Most transformers have secondaries wound over the primary, while in some the order is reversed. In case the secondaries are on the inside, the turns can be pulled out from the center after slitting and removing the fiber core.

The turns removed from one of the original filament windings of known voltage should be carefully counted as the winding is removed. This will give the number of turns per volt; the same figure should be used in determining the number of turns for the new secondary. For instance, if the old filament winding was rated at 5 volts and had 15 turns, this is  $15/5 = 3$  turns per volt. If the new secondary is to deliver 18 volts, the required number of turns on the new winding will be  $18 \times 3 = 54$  turns.

In winding a transformer, the size of wire is an important factor in the heat developed in operation. A cross-sectional area of 1000 circular mils per ampere (cmil/A) is conservative. A value commonly used in amateur-service transformers is 700 cmil/A. The larger the cmil/A figure, the cooler the transformer will run. The current rating in amperes of various wire sizes is shown in the copper-wire table in Chapter 35. If the transformer being rewound is a filament transformer, it may be necessary to choose the wire size carefully to fit the small available space. On the other hand, if the transformer is a power unit with the high-voltage winding removed, there should be plenty of room for a size of wire that will conservatively handle the required current.

After the first layer of turns is put on during rewinding, secure the ends with

cellulose tape. Each layer should be insulated from the next. Ordinary household waxed paper can be used; a single layer is adequate. Sheets cut to size beforehand may be secured over each layer with tape. Be sure to bring all leads out the same side of the core so the covers will go in place when the unit is completed. When the last layer of the winding is put on, use two sheets of waxed paper, and then cover those with vinyl electrical tape, keeping the tape as taut as possible. This will add mechanical strength to the assembly.

The laminations and housing are assembled in just the opposite sequence to that followed in disassembly. Use a light coating of shellac between each lamination. During reassembly, the lamination stack may be compressed by clamping in a vise. If the last few lamination strips cannot be replaced, it is better to omit them than to force the unit together.

## RECTIFIERS

### Half-Wave Rectifier

Fig. 5 shows a simple half-wave rectifier circuit. As explained in Chapter 4, a rectifier (in this case a semiconductor diode) will conduct current in one direction but not the other. During one half of the ac cycle, the rectifier will conduct and current will flow through the rectifier to the load (indicated by the solid line in Fig. 5B). During the other half cycle, the rectifier is reverse biased and no current will flow (indicated by the broken line in Fig. 5B) to the load. As shown, the output is in the form of pulsed dc, and current always flows in the same direction. A filter can be used to smooth out these variations and provide a higher average dc voltage from the circuit. This idea will be covered in the section on filters.

The average output voltage — the voltage read by a dc voltmeter — with this circuit (no filter connected) is 0.45 times the RMS value of the ac voltage delivered by the transformer secondary. Because the frequency of the pulses is low (one pulsation per cycle), considerable filtering is required to provide adequately smooth dc output. For this reason the circuit is usually limited to applications where the current required is small, as in a transmitter bias supply.

The peak inverse voltage (PIV), the voltage that the rectifier must withstand when it isn't conducting, varies with the load. With a resistive load, it is the peak ac voltage ( $1.4 E_{RMS}$ ). With a capacitor filter and a load drawing little or no current, it can rise to  $2.8 E_{RMS}$ . The reason for this is shown in Figs. 5C and 5D. With a resistive load as shown at C, the amount of voltage applied to the diode is that voltage on the lower side of the zero-axis line, or  $1.4 E_{RMS}$ . A capacitor connected to the circuit (shown at D) will store the peak positive voltage when the diode conducts on the positive pulse. If the circuit is not supplying any current, the voltage across the capacitor will remain at that

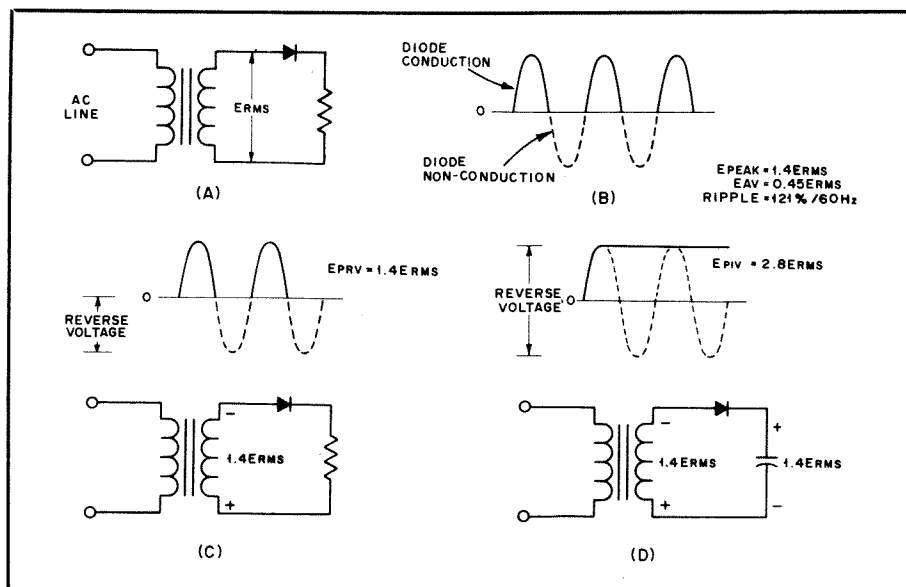

Fig. 5 — Half-wave rectifier circuit. A illustrates the basic circuit, and B displays the diode conduction and nonconduction periods. The peak-inverse voltage impressed across the diode is shown at C and D with a simple resistor load at C and a capacitor load at D.  $E_{PIV}$  is  $1.4 E_{RMS}$  for the resistor load and  $2.8 E_{RMS}$  for the capacitor load.

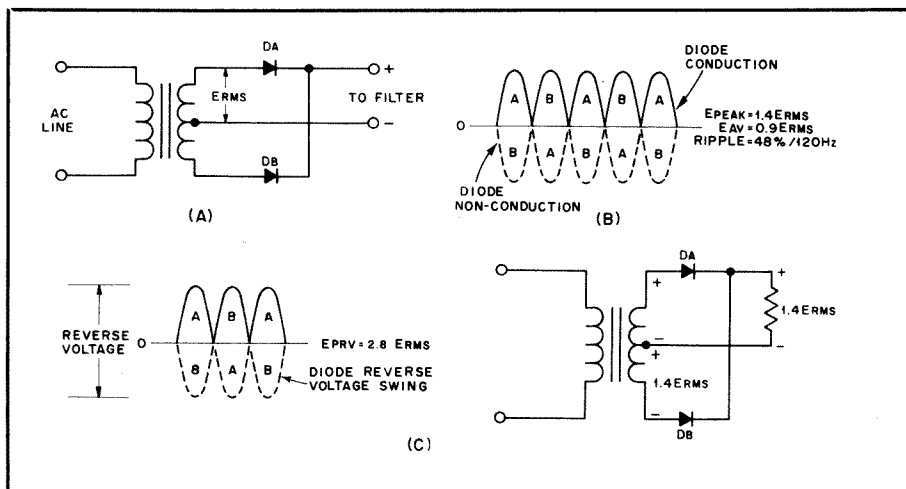

Fig. 6 — Full-wave center-tap rectifier circuit. A illustrates the basic circuit. Diode conduction is shown at B with diodes A and B alternately conducting. The peak-inverse voltage for each diode is  $2.8 E_{RMS}$  as depicted at C.

same level. The peak inverse voltage impressed across the diode is now the sum of the voltage stored in the capacitor plus the peak negative swing of voltage from the transformer secondary. In this case the PIV is  $2.8 E_{RMS}$ .

### Full-Wave Center-Tap Rectifier

A commonly-used rectifier circuit is shown in Fig. 6. Essentially an arrangement in which the outputs of two half-wave rectifiers are combined, it makes use of both halves of the ac cycle. A transformer with a center-tapped secondary is required with the circuit.

The average output voltage is 0.9 times the RMS voltage of half the transformer secondary; this is the maximum that can be obtained with a suitable choke-input filter. The peak output voltage is 1.4 times

the RMS voltage of half the transformer secondary; this the maximum voltage that can be obtained from a capacitor-input filter.

As can be seen in Fig. 6C, the PIV impressed on each diode is independent of the type of load at the output. This is because the peak inverse voltage condition occurs when diode A conducts and diode B does not conduct. The positive and negative voltage peaks occur at precisely the same time, a condition different from that in the half-wave circuit. As the cathodes of diodes A and B reach a positive peak ( $1.4 E_{RMS}$ ), the anode of diode B is at a negative peak, also  $1.4 E_{RMS}$ , but in the opposite direction. The total peak inverse voltage is therefore  $2.8 E_{RMS}$ .

Fig. 6B shows that the frequency of the output pulses is twice that of the half-wave

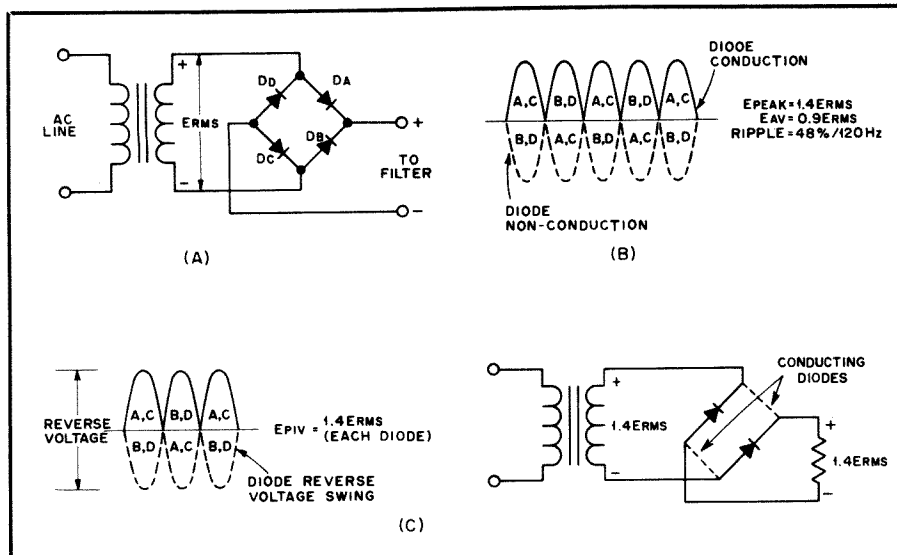

Fig. 7 — Full-wave bridge rectifier circuit. The basic circuit is illustrated at A. Diode conduction and nonconduction times are shown at B. Diodes A and C conduct on one half of the input cycle while diodes B and D conduct on the other. C displays the peak inverse voltage for one-half cycle. Since this circuit reverse-biases two diodes essentially in parallel,  $1.4 E_{RMS}$  is applied across each diode.

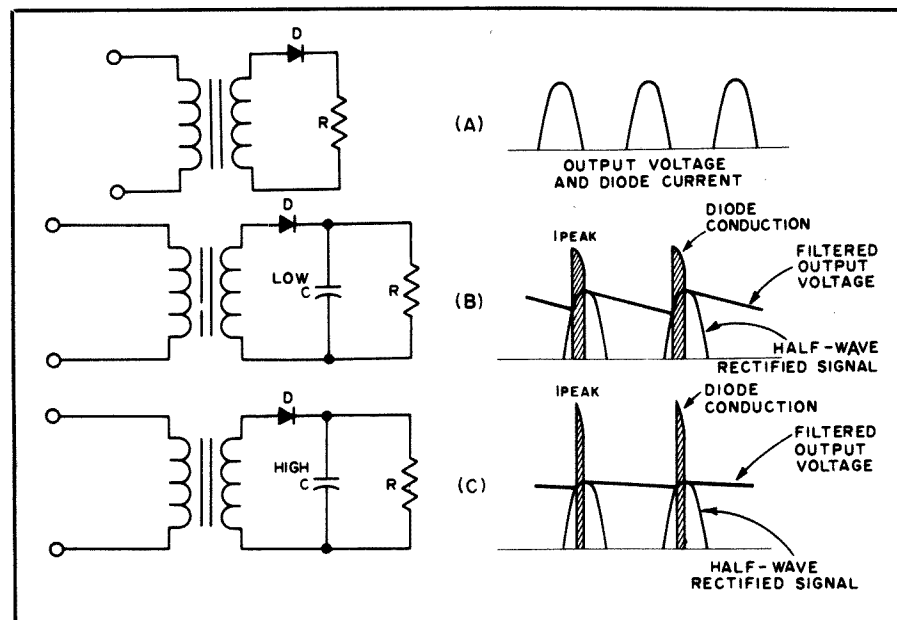

Fig. 8 — The circuit shown at A is a simple half-wave rectifier with a resistive load. The waveform shown to the right is that of output voltage and diode current. B illustrates how the diode current is modified by the addition of a capacitor filter. The diode conducts only when the rectified voltage is greater than stored capacitor voltage. Since this time period is usually only a short portion of a cycle, the peak current will be quite high. C shows an even higher peak current. This is caused by the larger capacitor, which effectively shortens the conduction period of the diode.

rectifier. Comparatively less filtering is required. Since the rectifiers work alternately, each handles half of the load current. The current rating of each rectifier need be only half the total current drawn from the supply.

### Full-Wave Bridge Rectifier

Another commonly used rectifier circuit is illustrated in Fig. 7. In this arrangement, two rectifiers operate in series on each half of the cycle, one rectifier being in the lead

to the load, the other being the return lead. As shown in Fig. 7A and B, when the top lead of the transformer secondary is positive with respect to the bottom lead, diodes A and C will conduct while diodes B and D are reverse biased. On the next half cycle, when the top lead of the transformer is negative with respect to the bottom, diodes B and D will conduct while diodes A and C are reverse biased.

The output wave shape is the same as that from the simple full-wave center-tap

rectifier circuit. The maximum output voltage into a resistive load or choke-input filter is 0.9 times the RMS voltage delivered by the transformer secondary; with a capacitor filter and a light load, the output voltage is 1.4 times the secondary RMS voltage.

Fig. 7C shows the inverse voltage to be  $1.4 E_{RMS}$  for each diode. When an alternate pair of diodes (such as  $D_A$  and  $D_C$ ) is conducting, the other diodes are essentially connected in parallel in a reverse-biased direction. The reverse stress is then  $1.4 E_{RMS}$ . Each pair of diodes conducts together on alternate half cycles with the full load current flowing through each diode during its conducting half cycle. Since each diode is not conducting during the other half cycle the average current is one half the total load current drawn from the supply.

Comparing the full-wave center-tap rectifier circuit and the full-wave bridge-rectifier circuit, it can be seen that both circuits have almost the same rectifier requirement since the center tap has half the number of rectifiers as the bridge, but these rectifiers have twice the inverse voltage rating requirement of the bridge diodes. The diode current ratings are identical for the two circuits. The bridge makes better use of the transformer's secondary than the center tap, since the transformer's full winding supplies power during both half cycles, while each half of the center tap's secondary provides power only during its positive half-cycle. The bridge rectifier often takes second place to the full-wave center tap rectifiers in high-current low-voltage applications, however, since the two forward-conducting series-diode drops in the bridge introduce an additional volt or more of voltage loss, and thus more heat to be dissipated, than does the single diode drop of the center tap.

### Semiconductor Rectifier Ratings

Silicon rectifiers are being used almost exclusively in power supplies designed for amateur equipment. They are available in a wide range of voltage and current ratings. In peak inverse voltage (PIV) ratings of 600 or less, silicon rectifiers carry current ratings as high as 400 amperes. At 1000 PIV, the current ratings may be several amperes. The extreme compactness of silicon rectifiers makes feasible the stacking of several units in series for higher voltages. Stacks are available commercially that will handle up to 10,000 PIV at a dc load current of 1 A or more.

### Protection of Silicon Power Diodes

The important specifications of a silicon diode are:

- 1) PIV, the peak inverse voltage.
- 2)  $I_O$ , the average dc current rating.
- 3)  $I_{REP}$ , the peak repetitive forward current.
- 4)  $I_{SURGE}$ , a nonrepetitive, peak half-sine wave of 8.3 ms duration (one-half cycle

of 60 Hz line frequency).

The first two specifications appear in most catalogs. The last two often do not, but they are very important.

Because the rectifier never allows current to flow more than half the time, when it does conduct it has to pass at least twice the average direct current. With a capacitor-input filter, the rectifier conducts much less than half the time, so that when it does conduct, it may pass as much as 10 to 20 times the average dc current, under certain conditions. This is shown in Fig. 8. At A is a simple half-wave rectifier with a resistive load. The waveform to the right of the drawing shows the output voltage along with the diode current. At B and C there are two periods of operation to consider. After the capacitor is charged to the peak-rectified voltage, a period of diode nonconduction elapses while the output voltage discharges through the load. As the voltage begins to rise on the next positive pulse, a point is reached where the rectified voltage equals the stored voltage in the capacitor. As the voltage rises beyond that point, the diode begins to supply current. The diode will continue to conduct until the waveform reaches the crest, as shown. Since the diode must pass a current equal to that of the load over a short period of a cycle, the current will be high. The larger the capacitor for a given load, the shorter the diode conduction time and the higher the peak repetitive current ( $I_{REP}$ ).

When the supply is first turned on, the discharged input capacitor looks like a dead short, and the rectifier passes a very heavy current. This is  $I_{SURGE}$ . The maximum  $I_{SURGE}$  rating is usually for a duration of one-half cycle (at 60 Hz), or about 8.3 milliseconds.

If a manufacturer's data sheet is not available, an educated guess about a diode's capability can be made by using these rules of thumb for silicon diodes of the type commonly used in amateur power supplies:

Rule 1) The maximum  $I_{REP}$  rating can be assumed to be approximately four times the maximum  $I_o$  rating.

Rule 2) The maximum  $I_{SURGE}$  rating can be assumed to be approximately 12 times the maximum  $I_o$  rating. (This figure should provide a reasonable safety factor. Silicon rectifiers with 750-mA dc ratings, for example, seldom have 1-cycle surge ratings of less than 15 amperes; some are rated up to 35 amperes or more.) From this it can be seen that the rectifier should be selected on the basis of  $I_{SURGE}$  and not on  $I_o$  ratings.

### Thermal Protection

The junction of a diode is quite small; hence it must operate at a high current density. The heat-handling capability is, therefore, quite small. Normally, this is not a prime consideration in high-voltage, low-current supplies. Use of high-current rectifiers at or near their maximum ratings

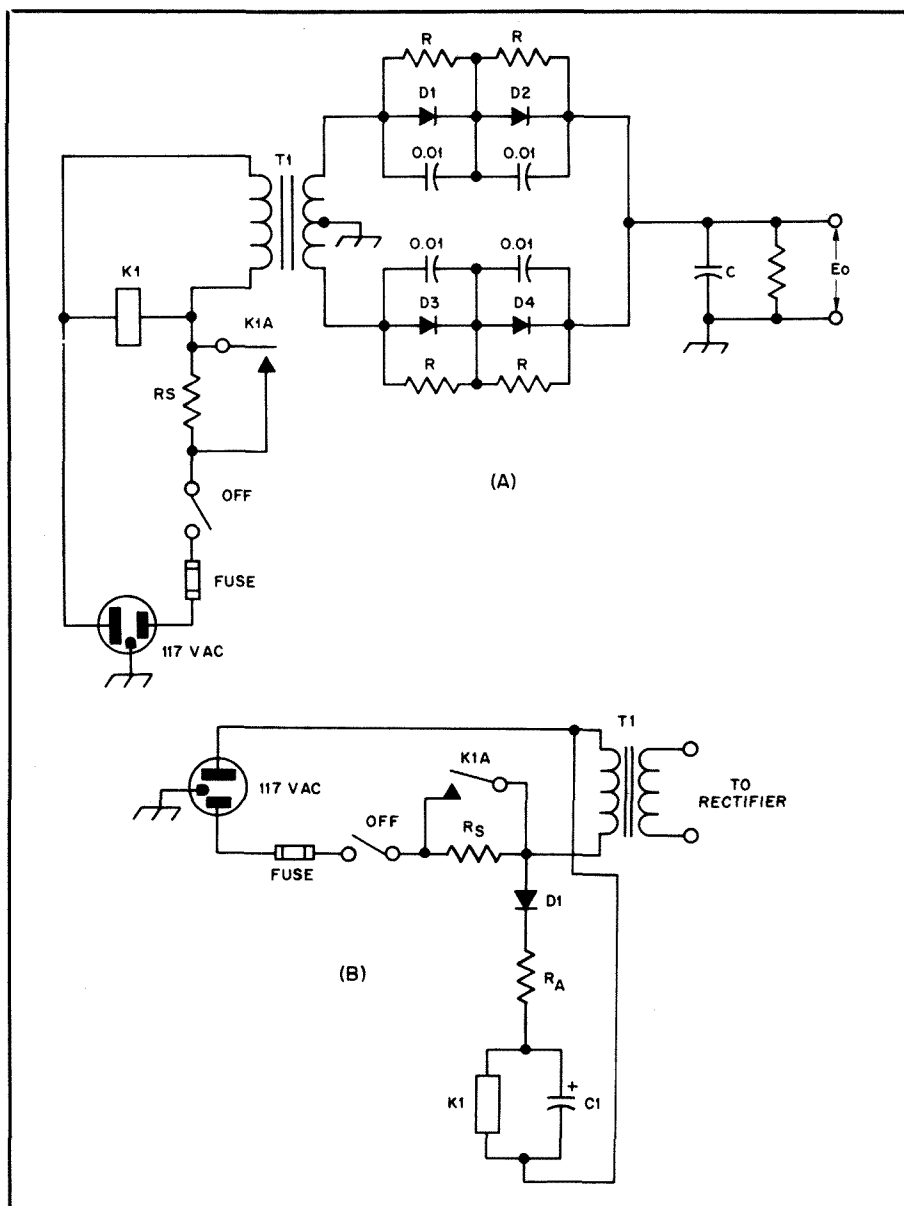

Fig. 9 — The primary circuit of T1 at A shows how a 117-volt ac relay and a series-dropping resistor,  $R_S$ , can provide surge protection while C charges. At B is an alternative primary circuit using an RC time delay. When silicon rectifiers are connected in series for high-voltage operation, the inverse voltage does not divide equally. The inverse voltage drops can be equalized with resistors, as shown in the secondary circuit. To protect against voltage spikes that may damage an individual rectifier, each rectifier should be bypassed by a 0.01- $\mu$ F capacitor. Connected as shown, two 400-PIV silicon rectifiers can be used as an 800-PIV rectifier, although it is preferable to include a safety factor and call it a 750-PIV rectifier. The rectifiers, D1 through D4, should be of the same type number and ratings.

(usually 2-ampere or larger stud-mount rectifiers) requires some form of heat sinking. Frequently, mounting the rectifier on the main chassis — directly, or with thin mica insulating washers — will suffice. If insulated from the chassis, a thin layer of silicone grease should be used between the diode and the insulator, and between the insulator and the chassis, to assure good heat conduction. Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling is sometimes used as a further aid. Safe case temperatures are usually given in the manufacturer's data sheets and should be observed if the maxi-

mum capabilities of the diode are to be realized. See the thermal design section presented later in this chapter for more information.

### Surge Protection

Each time the power supply is activated, assuming the input filter capacitor has been discharged, the rectifiers must look into what represents a dead short. Some form of surge protection is usually necessary to protect the diodes until the input capacitor becomes nearly charged, unless the diodes used have a very high surge-current rating (several hundred amperes). Although the dc resistance of the transformer secondary

can sometimes be relied on to provide ample surge-current limiting, this is seldom true on high-voltage power supplies. Series resistors can be installed between the secondary and the rectifier strings, but are a deterrent to good voltage regulation.

The best method of protecting the rectifiers is to apply low primary voltage to the transformer for a short period (typically 0.5 to 1 second) until the capacitors charge. After the capacitors have charged, full primary voltage may be applied. A variable autotransformer (Variac or Powerstat are common trade names) may be used to increase the voltage gradually. Some transformers are wound with multiple primaries, and a relay-switching scheme may be employed to step the primary up to full potential.

Fig. 9 illustrates several ways to limit in-rush current automatically at turn-on. In each case,  $R_S$  is a 25-watt resistor with a resistance of between 15 and 50 ohms, depending on power-supply characteristics. At power supply turn-on,  $R_S$  introduces a voltage drop into the primary feed to T1 until the coil of K1 is energized, closing the contacts and shorting out  $R_S$  for normal operation.

In the circuit shown in Fig. 9A, K1 has an ac coil rated for the same voltage as the primary of T1. As C becomes nearly charged, the voltage drop across  $R_S$  lessens, allowing K1 to pull in. At Fig. 9B, an RC time constant determines the time between application of primary voltage and closure of K1. In this circuit, K1 has a dc coil. The delay time may be calculated using the equation

$$\tau = R_{TH}C$$

where

$t$  = time in seconds

$$R_{TH} = \frac{R_A R_C}{R_A + R_C}$$

$R_A$  = resistance of  $R_A$  in ohms

$R_C$  = coil resistance of K1 in ohms

$C$  = capacitance of C1 in farads

A third method of energizing K1 is with a fixed time-delay relay having appropriate ratings.

### Transient Problems

A common cause of trouble is transient voltages on the ac power line. These are short spikes, mostly, that can temporarily increase the voltage seen by the rectifier to values much higher than the normal transformer voltage. They come from distant lightning strokes, electric motors turning on and off, and so on. Transients cause unexpected, and often unexplained, failure of silicon rectifiers.

It's always wise to suppress line transients, and it can be done easily. Fig. 10A shows one way. C1 looks like 280 k $\Omega$  at 60 Hz, but to a sharp transient (which has only high-frequency components), it is an

Fig. 10 — Methods of suppressing line transients. See text.

effective bypass. C2 provides additional protection on the secondary side of the transformer. It should be 0.01  $\mu$ F for transformer voltages of 100 or less, and 0.001  $\mu$ F for high-voltage transformers.

Fig. 10B shows another transient-suppression method using metal-oxide varistor (MOV) suppressors. The MOVs do not conduct unless the peak voltage becomes abnormally high. Then they clip the transient peaks.

Transient voltages can go as high as twice the normal line voltage before the suppressor diodes clip the peaks. Capacitors cannot give perfect suppression either. Thus, it is a good idea to use power supply rectifiers rated at about twice the expected PIV.

### Diodes in Series

When the PIV rating of a single diode is not sufficient for the application, similar diodes may be used in series. (Two 500-PIV diodes in series will withstand 1000 PIV, and so on.) When this is done, a resistor and a capacitor should be placed across each diode in the string to equalize the PIV drops and to guard against transient voltage spikes, as shown in Fig. 11A. Even though the diodes are of the same type and have the same PIV rating, they may have widely different back resistances when they are cut off. The inverse voltage divides according to Ohm's Law, and the diode with the higher back resistance will have the higher voltage developed across it. The diode may break down.

If we put a swamping resistor across each diode,  $R$  as shown in Fig. 11A, the resultant resistance across each diode will be almost the same, and the back voltage will divide almost equally. A good rule of thumb for resistor size is this: Multiply the PIV rating of the diode by 500 ohms. For

Fig. 11 — (A) Diodes connected in series should be shunted with equalizing resistors and spike-suppressing capacitors. (B) Diodes connected in parallel should have series current equalizing resistors.

example, a 500-PIV diode should be shunted by  $500 \times 500$ , or 250,000 ohms. Metal film resistors are generally rated for working voltage as follows:  $\frac{1}{4}$  W — 250 V (RMS);  $\frac{1}{2}$  W — 350 V; 1 W — 500 V; 2 W — 750 V.

The shift from forward conduction to high back resistance does not take place instantly in a silicon diode. Some diodes take longer than others to develop high back resistance. To protect the fast-switching diodes in a series string until all the diodes are properly cut off, a 0.01- $\mu$ F capacitor should be placed across each diode. Fig. 11A shows the complete series-diode circuit. The capacitors should be noninductive (ceramic disc, for example) and should be well matched. Use 10-percent-tolerance capacitors if possible.

### Diodes in Parallel

Diodes can be placed in parallel to

increase current-handling capability. Equalizing resistors should be added as shown in Fig. 11B. Without the resistors, one diode may take most of the current. The resistors should be selected to have about a 1-volt drop at the expected peak current.

## FILTERING

The pulsating dc waves from the rectifiers are not sufficiently constant in amplitude to prevent hum corresponding to the pulsations. Filters are required between the rectifier and the load to smooth out the pulsations into an essentially constant dc voltage. The design of the filter depends to a large extent on the dc voltage output, the voltage regulation of the power supply and the maximum load current rating of the rectifier. Power-supply filters are low-pass devices using series inductors and shunt capacitors.

### Load Resistance

In discussing the performance of power-supply filters, it is sometimes convenient to express the load connected to the output terminals of the supply in terms of resistance. The load resistance is equal to the output voltage divided by the total current drawn, including the current drawn by the bleeder resistor.

### Voltage Regulation

The output voltage of a power supply always decreases as more current is drawn, not only because of increased voltage drops in the transformer and filter chokes, but also because the output voltage at light loads tends to soar to the peak value of the transformer voltage as a result of charging the first capacitor. Proper filter design can eliminate the soaring effect. The change in output voltage with load is called voltage regulation, and is expressed as a percentage.

$$\text{Percent regulation} = \frac{100 (E_1 - E_2)}{E_2}$$

where

$E_1$  = the no-load voltage

$E_2$  = the full-load voltage

A steady load, such as that represented by a receiver, speech amplifier or unkeyed stages of a transmitter, does not require good (low) regulation as long as the proper voltage is obtained under load conditions. However, the filter capacitors must have a voltage rating safe for the highest value to which the voltage will soar when the external load is removed.

A power supply will show more (higher) regulation with long-term changes in load resistance than with short temporary changes. The regulation with long-term changes is often called the static regulation, to distinguish it from the dynamic regulation (short temporary load changes). A load that varies at a syllabic or keyed rate, as represented by some audio and RF

amplifiers, usually requires good dynamic regulation (15 percent or less) if distortion products are to be held to a low level. The dynamic regulation of a power supply can be improved by increasing the value of the output capacitor.

When essentially constant voltage regardless of current variation is required (for stabilizing an oscillator, for example), special voltage-regulating circuits described later in this chapter are used.

### Bleeder

A bleeder resistor is a resistance connected across the output terminals of the power supply. Its functions are to discharge the filter capacitors as a safety measure when the power is turned off and to improve voltage regulation by providing a minimum load resistance. When voltage regulation is not of importance, the resistance may be as high as 100 ohms per volt. The resistance value to be used for voltage-regulating purposes is discussed in later sections. From the consideration of safety, the power rating of the resistor should be as conservative as possible, since a burned-out bleeder resistor is dangerous!

### Ripple Frequency and Voltage

Pulsations at the output of the rectifier can be considered to be the result of an alternating current superimposed on a steady direct current. From this viewpoint, the filter may be considered to consist of shunt capacitors that short circuit the ac component while not interfering with the flow of the dc component. Series chokes will readily pass dc but will impede the flow of the ac component.

The alternating component is called ripple. The effectiveness of the filter can be expressed in terms of percent ripple, which is the ratio of the RMS value of the

ripple to the dc value in terms of percentage.

$$\text{Percent ripple (RMS)} = \frac{100 E_1}{E_2}$$

where

$E_1$  = the RMS value of ripple voltage

$E_2$  = the steady dc voltage

Any multiplier or amplifier supply in a CW transmitter should have less than five percent ripple. A linear amplifier can tolerate about three percent ripple on the plate voltage. Bias supplies for linear amplifiers should have less than one-percent ripple. VFOs, speech amplifiers and receivers may require a ripple reduction to 0.01 percent.

Ripple frequency is the frequency of the pulsations in the rectifier output wave — the number of pulsations per second. The frequency of the ripple with half-wave rectifiers is the same as the frequency of the line supply — 60 Hz with 60-Hz supply. Since the output pulses are doubled with a full-wave rectifier, the ripple frequency is doubled — to 120 Hz with a 60-Hz supply.

The amount of filtering (values of inductance and capacitance) required to give adequate smoothing depends on the ripple frequency. More filtering is required as the ripple frequency is lowered.

### TYPES OF FILTER

Power supply filters fall into two classifications: capacitor input and choke input. Capacitor-input filters are characterized by relatively high output voltage with respect to the transformer voltage. Capacitor-input filters are especially useful with silicon rectifiers.

The output voltage of a properly de-

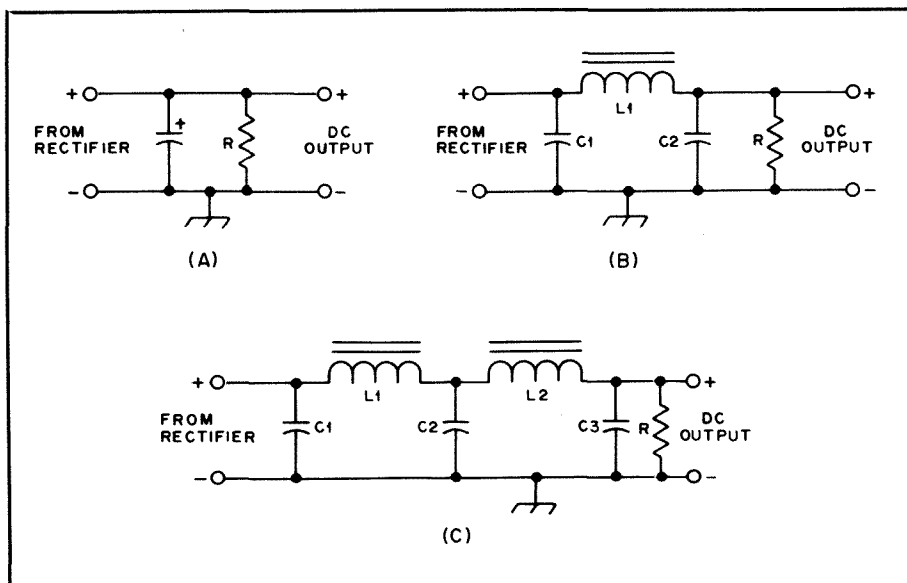

Fig. 12 — Capacitor-input filter circuits. At A is a simple capacitor filter. B and C are single- and double-section filters, respectively.

(A)

(B)

Fig. 13 — Dc output voltages from a half- and full-wave rectifier circuit as a function of the filter capacitance and load resistance (half-wave shown at A and full-wave shown at B).  $R_s$  includes transformer winding resistance and rectifier forward resistance. For the ratio  $R_s/R$ , both resistances are in ohms; for the RC product, R is in ohms and C is in microfarads. These curves are adapted from those published by Otto H. Schade in "Analysis of Rectifier Operation," *Proceedings of the I.R.E.*, July 1943.

signed choke-input power supply is less than would be obtained with a capacitor-input filter from the same transformer. Generally speaking, a choke-input filter will permit a higher load current to be drawn from a thermionic rectifier without exceeding the peak rating of the rectifier. This is a result of the greatly reduced peak current that the rectifier is subjected to.

### Capacitor-Input Filters

Capacitor-input filter systems are shown in Fig. 12. Disregarding voltage drops in the chokes, all have the same characteristics except with respect to ripple. Better ripple reduction will be obtained when LC sections are added as shown in Figs. 12B and C.

### Output Voltage

To determine the approximate dc voltage output when a capacitor-input filter is used, the graphs shown in Fig. 13 will be helpful. An example of how to use the graph is given below.

Example:

Full-wave rectifier (use graph at B)

Transformer RMS voltage = 350

Load resistance = 2000 ohms

Series resistance = 200 ohms

Input capacitance = 20  $\mu\text{F}$

$$\frac{R_s}{R} = \frac{200}{2000} = 0.1$$

$$\frac{377 RC}{1,000,000} = \frac{377 \times 2000 \times 20}{1,000,000} = 15.08$$

From curve 0.1 and  $377 RC/1,000,000 = 15$ , the dc voltage is  $(350 \times 1.04) = 364$ .

In many cases it is desirable to know the amount of capacitance required for a power supply, given certain performance criteria. This is especially true when designing a power supply for an application such as a solid-state transceiver. The following example shows the builder how to arrive at circuit values for a power supply using a single capacitor filter.

Fig. 14 is the circuit diagram of the power supply to be used.

Requirements:

Output voltage = 12.6

Output current = 1 ampere

Maximum ripple = 2 percent

Load regulation = 5 percent

The RMS secondary voltage of T1 must be the desired output voltage plus the voltage drops across D2 and D4 divided by 1.41.

$$E_{SEC} = \frac{12.6 + 1.4}{1.41} = 9.93$$

In practice, the nearest standard transformer (10 V) would work fine. Alternatively, the builder could wind his own transformer, or remove secondary turns from a 12-volt transformer to obtain the desired RMS secondary voltage.

A two-percent ripple referenced to 12.6 volts is 0.25 V RMS. The peak-to-peak value is therefore  $0.25 \times 2.8 = 0.7$  V. This

value is necessary to calculate the required capacitance for C1.

Also needed for determining the value of C1 is the time interval (t) between the full-wave rectifier pulses, which is calculated as follows:

$$t = \frac{1}{f(\text{Hz})} = \frac{1}{120} = 8.3 \times 10^{-3}$$

where

t = the time between pulses

f = the ripple frequency in Hz

Since the circuit makes use of a full-wave rectifier, a pulse occurs twice during each cycle. With half-wave rectification, a pulse would occur only once a cycle. Thus 120 Hz is used as the frequency for this calculation.

C1 is calculated from

$$C_{(\mu\text{F})} = \left[ \frac{I_L t}{E_{\text{rip}}(P-P)} \right] 10^6$$

$$= \left[ \frac{1 \text{ A} \times 8.3 \times 10^{-3}}{0.7} \right] 10^6$$

$$= 11,857 \mu\text{F}$$

where  $I_L$  is the current taken by the load. The nearest standard capacitor value is 12,000  $\mu\text{F}$ . This value is acceptable, although the tolerance of electrolytic capacitors is rather loose, so the builder may elect to use the next larger standard value.

Diodes D1-D4, inclusive, should have a PIV rating of at least two times the transformer secondary peak voltage. Assuming a transformer secondary RMS value of 10 volts, the PIV should be at least 28 volts. Four diodes rated at 50 volts will provide a margin of safety. Although the minimum current rating needed is one-half the load current, the forward current rating of the diodes should be at least twice the load current for safety. For a 1-A load, the diodes should be rated for at least 2 A.

The load resistance,  $R_L$ , is determined by  $E_o/I_L$ , which in this example is  $12.6/1 = 12.6$  ohms. This factor must be known in order to find the necessary series resistance for five-percent regulation. Calculate as follows:

$$R_{s(\text{max})} = \text{load regulation} \times R_L$$

$$= 0.05 \times 12.6 = 0.63 \text{ ohm}$$

Therefore, the transformer secondary dc resistance should be no greater than 0.63 ohm. The secondary current rating should be equal to or greater than the  $I_L = 1$  ampere. C1 should have a minimum working voltage of 1.4 times the output voltage. In this power supply the capacitor should be rated for at least 18 volts.

### Choke-Input Filters

Better voltage regulation results when a choke-input filter, as shown in Fig. 15, is

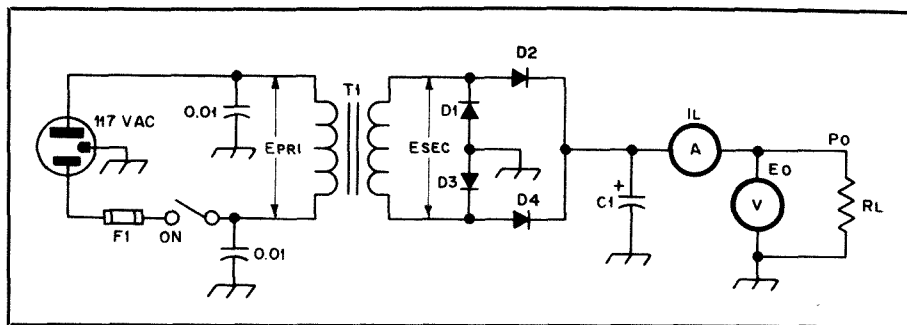

Fig. 14 — This figure illustrates how to design a simple unregulated power supply. See text for a thorough discussion.

Fig. 15 — Diagram showing various voltage drops that must be taken into consideration in determining the required transformer voltage to deliver the desired output voltage.

used. Choke input permits better utilization of thermionic rectifiers, because a higher load current can be drawn without exceeding the peak current rating. Choke-input filters are generally not used with silicon rectifiers.

### Minimum Choke Inductance

A choke-input filter will tend to act as a capacitor-input filter unless the input choke has at least a certain minimum value of inductance called the critical value. For full-wave 60-Hz supplies, this critical value is given by

$$L_{\text{crit}} (\text{henrys}) = \frac{E (\text{volts})}{I (\text{mA})}$$

where

E = the supply output voltage

I = the current being drawn through the filter

If the choke has at least the critical value, the output voltage will be limited to the average value of the rectified wave at the input to the choke when the current drawn from the supply is small. This is in contrast to the capacitor-input filter in which the output voltage tends to soar toward the peak value of the rectified wave at light loads.

### Minimum-Load — Bleeder Resistance

From the above formula for critical inductance, it is obvious that if no current is drawn from the supply, the critical inductance will be infinite. So that a practical value of inductance may be used, some current must be drawn from the supply at all

times the supply is in use. From the formula we find that this minimum value of current is

$$I(\text{mA}) = \frac{E(\text{volts})}{L_{\text{crit}}}$$

In the majority of cases, it will be most convenient to adjust the bleeder resistance so that the bleeder will draw the required minimum current. From the formula, it may be seen that the value of critical inductance becomes smaller as the load current increases.

### Swinging Chokes

Less costly chokes are available that will maintain at least the critical value of inductance over the range of current likely to be drawn from practical supplies. These chokes are called swinging chokes. As an example, a swinging choke may have an inductance rating of 5/25 H and a current rating of 200 mA. If the supply delivers 1000 volts, the minimum load current should be  $1000/25 = 40$  mA. When the full load current of 200 mA is drawn from the supply, the inductance will drop to 5 H. The critical inductance for 200 mA at 1000 volts is  $1000/200 = 5$  H. Therefore the 5/25-H choke maintains the critical inductance at the full current rating of 200 mA. At all load currents between 40 mA and 200 mA, the choke will adjust its inductance to the approximate critical value.

### Output Voltage

Provided the input-choke inductance is at least the critical value, the output voltage

may be calculated quite closely by

$$E_o = 0.9E_t - (I_B + I_L) \times (R1 + R2) - E_r$$

where

$E_o$  = output voltage

$E_t$  = RMS voltage applied to the rectifier (RMS voltage between center-tap and one end of the secondary in the case of the center-tap rectifier)

$I_B$  = bleeder current (A)

$I_L$  = load current (A)

$R1$  = first filter choke resistance

$R2$  = second filter choke resistance

$E_r$  = voltage drop across the rectifier

The various voltage drops are shown in Fig. 15. At no load,  $I_L$  is zero; hence the no-load voltage may be calculated on the basis of bleeder current only. The voltage regulation may be determined from the no-load and full-load voltages using the formulas previously given.

### Output Capacitance

Whether the supply has a choke- or capacitor-input filter, the reactance of the output capacitor should be low for the lowest audio frequency if it is intended for use with a class-A AF amplifier. For vacuum-tube loads,  $16 \mu\text{F}$  or more is usually adequate. When the supply is used with a class-B amplifier (for modulation or for SSB amplification) or a CW transmitter, increasing the output capacitance will result in improved dynamic regulation of the supply. However, a region of diminishing returns can be reached, and  $20$  to  $30 \mu\text{F}$  will usually suffice for any supply subjected to large changes at a syllabic (or keying) rate.

### Resonance

Resonance effects in the series circuit across the output of the rectifier, formed by the first choke and first filter capacitor, must be avoided, because the ripple voltage would build up to large values. This not only is the opposite action to that for which the filter is intended, but also may cause excessive rectifier peak currents and abnormally high peak-inverse voltages. For full-wave rectification, the ripple frequency will be  $120 \text{ Hz}$  for a  $60\text{-Hz}$  supply; resonance will occur when the product of choke inductance in henrys times capacitor capacitance in microfarads is equal to  $1.77$ . At least twice this product of inductance and capacitance should be used to ensure against resonance effects. With a swinging choke, the minimum rated inductance of the choke should be used. If too high an LC filter product is used, the resonance may occur at the radio-telegraph keying or voice syllabic rate, and large voltage excursions (filter bounce) may be experienced at that rate.

### Ratings of Filter Components

In a power supply using a choke-input filter and properly designed choke and bleeder resistor, the no-load voltage across

the filter capacitors will be about nine-tenths of the ac RMS voltage. Nevertheless, it is advisable to use capacitors rated for the peak transformer voltage. This large safety factor is suggested because the voltage across the capacitors can reach this peak value if the bleeder should burn out and there is no load on the supply.

In a capacitor-input filter, the capacitors should have a working-voltage rating at least as high, and preferably somewhat higher, than the peak voltage from the transformer. Thus, in the case of a center-tap rectifier having a transformer delivering  $550$  volts each side of the center tap, the minimum safe capacitor voltage rating will be  $550 \times 1.41$ , or  $775$  volts. An  $800\text{-volt}$  capacitor should be used, or preferably a  $1000\text{-volt}$  unit.

### Filter Capacitors in Series

Filter capacitors are made in several different types. Electrolytic capacitors, which are available for peak voltages up to about  $800$ , combine high capacitance with small size. This is possible because the dielectric is an extremely thin film of oxide on aluminum foil. Capacitors of this type may be connected in series for higher voltages, although the filtering capacitance will be reduced to the resultant of the two capacitances in series.

If this arrangement is used, it is important that each capacitor be shunted with a resistor of about  $100$  ohms per volt of supply voltage applied to the individual capacitors, with an adequate power rating.

These resistors may serve as all or part of the bleeder resistance. Capacitors with higher voltage ratings are usually made with a dielectric of thin paper impregnated with oil. The working voltage of a capacitor is the voltage that it will withstand continuously.

### Filter Chokes

Filter chokes or inductances are wound on iron cores, with a small gap in the core to prevent magnetic saturation of the iron at high currents. When the iron becomes saturated, its permeability decreases, and consequently the inductance also decreases. Despite the air gap, the inductance of a choke usually varies to some extent with the direct current flowing in the winding; hence it is necessary to specify the inductance at the current which the choke is intended to carry. Its inductance with little or no direct current flowing in the winding will usually be considerably higher than the value when full load current is flowing.

### Negative-Lead Filtering

For many years it has been almost universal practice to place filter chokes in the positive leads of plate power supplies. This means that the insulation between the choke winding and its core (which should be grounded to chassis as a safety measure) must be adequate to withstand the output voltage of the supply. This voltage requirement is removed if the choke is placed in the negative lead, as shown in Fig. 16. With this connection, the capacitance of the

Fig. 16 — In most applications, the filter choke may be placed in the negative instead of the positive side of the circuit. This reduces the danger of a voltage breakdown between the choke winding and core. The ripple voltage developed across the choke can be rectified to provide a free negative bias supply.

Fig. 17 — The "economy" power-supply circuit is a combination of the full-wave and bridge-rectifier circuits.

transformer secondary to ground appears in parallel with the filter chokes, tending to bypass the chokes. However, this effect will be negligible in practical application except in cases where the output ripple must be reduced to a very low figure. Choke terminals, negative capacitor terminals and the transformer center-tap terminal should be well protected against accidental contact, since these will assume full supply voltage to chassis should a choke burn out or the chassis connection fail.

A free negative supply of about 60% of the plate potential can be obtained by rectifying the ripple voltage developed across the filter choke. The voltage across the choke has an effective value of the peak secondary voltage (measured with respect to the center tap) minus the main dc output voltage. Rectification multiplies the choke voltage by 1.4.

### The Economy Power Supply

In many transmitters of the 100-watt class, an excellent method for obtaining plate and screen voltages without wasting power in voltage-dropping resistors is use of the economy power supply circuit. Shown in Fig. 17, it is a combination of the full-wave and bridge-rectifier circuits. The voltage at B2 is the normal voltage obtained with the full-wave circuit, and the voltage at B1 is that obtained with the bridge circuit. The total dc power obtained from the transformer is, of course, the sum of the power used at each voltage. In CW and SSB applications, additional power can usually be drawn without excessive heating, especially if the transformer has a rectifier filament winding that isn't being used. When negative-lead choke filtering is used, the free negative bias supply scheme described above can be incorporated, making all of a transmitting tube's operating potentials available from a single transformer. The entire peak secondary voltage is used to calculate the resulting bias voltage.

## VOLTAGE MULTIPLICATION

### Half-Wave Voltage Doubler

Fig. 18 shows the circuit of a half-wave voltage doubler. B, C and D of Fig. 18 illustrate the circuit operation. For clarity, assume the transformer voltage polarity at the moment the circuit is activated is that shown at B. During the first negative half cycle,  $D_A$  conducts ( $D_B$  is in a nonconductive state), charging  $C_1$  to the peak rectified voltage ( $1.4 E_{RMS}$ ).  $C_1$  is charged with the polarity shown at B. During the positive half cycle of the secondary voltage,  $D_A$  is cut off and  $D_B$  conducts, charging capacitor  $C_2$ . The amount of voltage delivered to  $C_2$  is the sum of peak secondary voltage of the transformer plus the voltage stored in  $C_1$  ( $1.4 E_{RMS}$ ). On the next negative half cycle,  $D_B$  is nonconducting and  $C_2$  will discharge into the load. If no load is connected across  $C_2$ , the

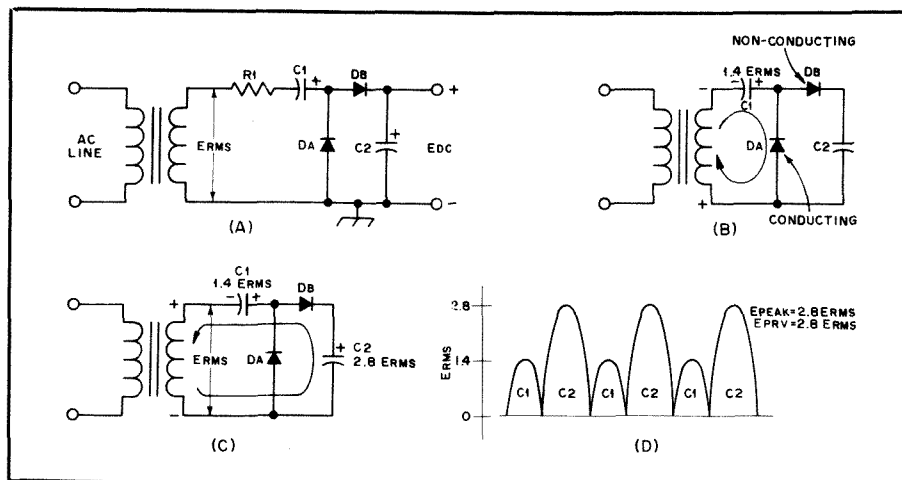

Fig. 18 — Illustrated at A is a half-wave voltage-doubler circuit. B displays how the first half cycle of input voltage charges  $C_1$ . During the next half cycle (shown at C), capacitor  $C_2$  is charged with the transformer secondary voltage plus that voltage stored in  $C_1$  from the previous half cycle. D illustrates the levels to which each capacitor is charged throughout the cycle.

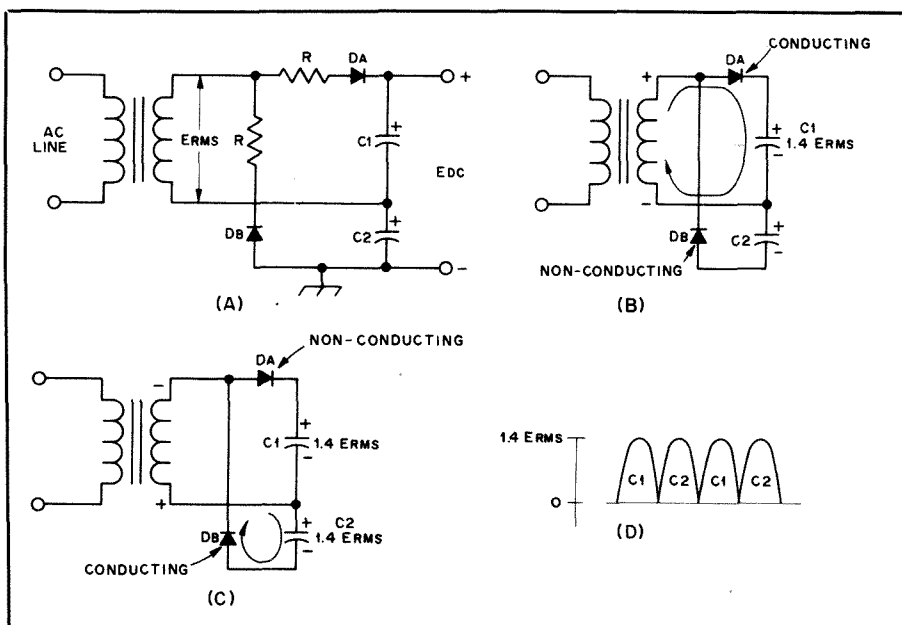

Fig. 19 — A full-wave voltage doubler is displayed at A. One half cycle is shown at B and the next half cycle at C. Each capacitor receives a charge during every cycle of input voltage. D illustrates how each capacitor is charged alternately.

capacitors will remain charged —  $C_1$  to  $1.4 E_{RMS}$  and  $C_2$  to  $2.8 E_{RMS}$ . When a load is connected to the output of the doubler, the voltage across  $C_2$  drops during the negative half cycle and is recharged up to  $2.8 E_{RMS}$  during the positive half cycle. The output waveform across  $C_2$  resembles that of a half-wave rectifier circuit in that  $C_2$  is pulsed once every cycle. Fig. 18D illustrates the levels to which the two capacitors are charged throughout the cycle. In actual operation, the capacitors will not discharge all the way to zero as shown.

### Full-Wave Voltage Doubler

Shown in Fig. 19 is the circuit of a full-wave voltage doubler. The circuit operation

can best be understood by following B, C and D of Fig. 19. During the positive half cycle of transformer secondary voltage, as shown at B,  $D_A$  conducts charging capacitor  $C_1$  to  $1.4 E_{RMS}$ .  $D_B$  is not conducting at this time.

During the negative half cycle, as shown at C,  $D_B$  conducts, charging capacitor  $C_2$  to  $1.4 E_{RMS}$ , while  $D_A$  is nonconducting. The output voltage is the sum of the two capacitor voltages, which will be  $2.8 E_{RMS}$  under no-load conditions. Fig. 19D illustrates that each capacitor alternately receives a charge once per cycle. The effective filter capacitance is that of  $C_1$  and  $C_2$  in series, which is less than the capacitance of either  $C_1$  or  $C_2$  alone.

Resistors R in Fig. 19A are used to limit

Fig. 20 — Dc output voltages from a full-wave voltage-doubling circuit as a function of the filter capacitances and load resistance. For the ratio  $R_s/R$  and for the RC product, resistances are in ohms and capacitance is in microfarads. Equal resistance values for  $R_s$  and equal capacitance values for C are assumed. These curves are adapted from those published by Otto H. Schade in "Analysis of Rectifier Operation," *Proceedings of the I.R.E.*, July 1943.

the surge current through the rectifiers. Their values are based on the transformer voltage and the rectifier surge-current rating, since at the instant the power supply is turned on the filter capacitors look like a short-circuited load. Provided the limiting resistors can withstand the surge current, their current-handling capacity is based on the maximum load current from the supply. Output voltages approaching twice the peak voltage of the transformer can be obtained with the voltage doubling circuit shown in Fig. 19. Fig. 20 shows how the voltage depends upon the ratio of the series resistance to the load resistance, and the load resistance times the filter capacitance. The peak inverse voltage across each diode is  $2.8 E_{RMS}$ .

### Voltage Tripling and Quadrupling

A voltage-tripling circuit is shown in Fig. 21A. On one half of the ac cycle, C1 and C3 are charged to the source voltage through D1, D2 and D3. On the opposite half of the cycle, D2 conducts and C2 is charged to twice the source voltage, because it sees the transformer plus the charge in C1 as its source (D1 is cut off during this half cycle.) At the same time, D3 conducts, and with the transformer and the charge in C2 as the source, C3 is charged to three times the transformer voltage.

The voltage-quadrupling circuit of Fig. 21B works in substantially similar

fashion. In either of the circuits of Fig. 21, the output voltage will approach an exact multiple of the peak ac voltage when the output current drain is low and the capacitance values are high.

In the circuits shown, the negative leg of the supply is common to one side of the transformer. The positive leg can be made common to one side of the transformer by reversing the diodes and capacitors.

## VOLTAGE STABILIZATION

### Zener Diode Regulation

A Zener diode (named after Dr. Carl Zener) can be used to maintain the voltage applied to a circuit at a practically constant value, regardless of the voltage regulation of the power supply or variations in load current. The typical circuit is shown in Fig. 22A. Note that the cathode side of the diode is connected to the positive side of the supply. The electrical characteristics of a Zener diode under conditions of forward and reverse voltage are given in Chapter 4.

Zener diodes are available in a wide variety of voltages and power ratings. The voltages range from less than two to a few hundred, while the power ratings (power the diode can dissipate) run from less than 0.25 watt to 50 watts. The ability of the Zener diode to stabilize a voltage depends on the conducting impedance of the diode. This can be as low as one ohm or less in a low-voltage, high-power diode or as high

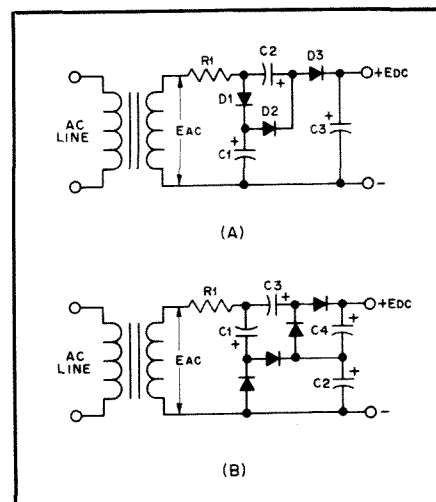

Fig. 21 — Voltage-multiplying circuits with one side of the transformer secondary used as common. A, voltage tripler; B, voltage quadrupler. Capacitances are typically 20 to 50  $\mu F$  depending on output current demand. Dc ratings of capacitors are related to  $E_{peak}$  ( $1.4 E_{ac}$ ).

- C1 — Greater than  $E_{peak}$
- C2 — Greater than  $2E_{peak}$
- C3 — Greater than  $3E_{peak}$
- C4 — Greater than  $2E_{peak}$

as a thousand ohms in a high-voltage, low-power diode.

### Diode Power Dissipation

Zener diodes of a particular voltage rating have varied maximum current capabilities, depending on the power ratings of each of the diodes. The power dissipated in a diode is the product of the voltage across it and the current through it. Conversely, the maximum current a particular diode may safely conduct is equal to its power rating divided by its voltage rating. Thus, a 10-V, 50-W Zener diode, if operated at its maximum dissipation rating, would conduct 5 amperes. A 10-V, 1-W diode, on the other hand, could safely conduct no more than 0.1 A, or 100 mA. The conducting impedance of a diode is its voltage rating divided by the current flowing through it. In the above examples, the conducting impedance would be 2 ohms for the 50-W diode, and 100 ohms for the 1-W diode. Disregarding small voltage changes which may occur, the conducting impedance of a given diode is a function of the current flowing through it, varying in inverse proportion.

The power-handling capability of most Zener diodes is rated at 25°C, or approximately room temperature. If the diode is operated in a higher ambient temperature, its power capability must be derated. A typical 1-watt diode can safely dissipate only  $\frac{1}{2}$  watt at 100°C.

Part C of Fig. 22 illustrates a method for multiplying the effective power-handling capability of a small Zener diode. When the diode conducts, it supplies base current to a power transistor. This causes collector

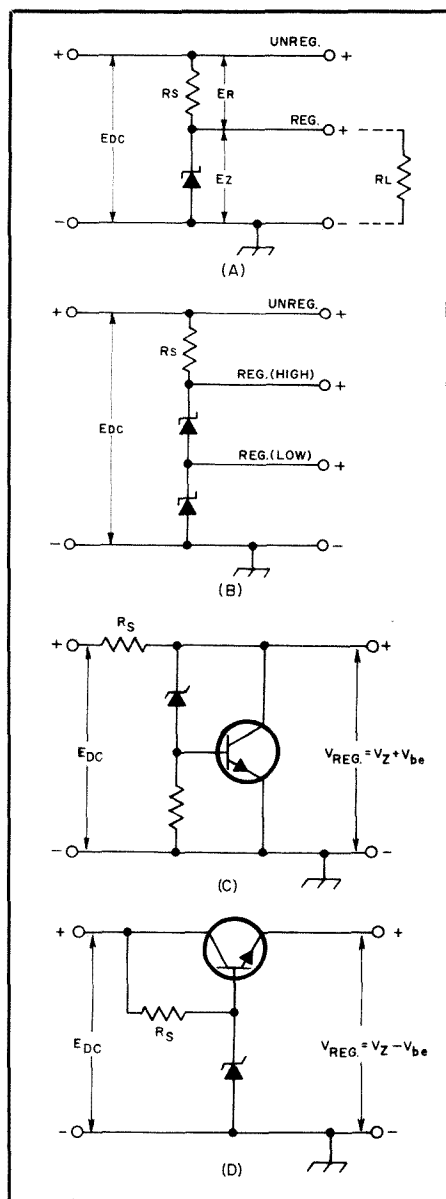

Fig. 22 — Zener-diode voltage regulation. The voltage from a negative supply may be regulated by reversing the power-supply connections and the diode and transistor polarities. The operation of these circuits is discussed in the text.

Fig. 23 — Voltage stabilization circuit using a VR tube. A negative-supply output may be regulated by reversing the polarity of the power-supply connections and the VR-tube connections from those shown here.

current to be drawn through the series-limiting resistance (see next section). This current drops the diode voltage ( $V_Z + V_{be}$ ) to the conduction threshold. When load current is drawn through  $R_S$ , the output voltage tends to drop below the conduction threshold. But when the diode ceases to conduct, the transistor collector ceases to draw current. This negative feedback, or servo action, stabilizes the current in the limiting resistor and regulates the output voltage at  $V_Z + V_{be}$ . With this approach, the conducting impedance of the Zener diode is divided by the transistor beta.

When high load current is required, a Zener diode shunt regulator is grossly inefficient because of the voltage dropped and power dissipated by the current-limiting resistor. This deficiency can be overcome by using the emitter follower arrangement of Fig. 22D. A Zener diode establishes a reference voltage for the transistor base, and the load current flows in the collector-emitter circuit. The limiting resistor is selected to provide the maximum load current divided by the minimum transistor beta, plus the desired Zener current. As with the shunt current boosting circuit described above, the output impedance of this voltage regulator will be the Zener impedance divided by the transistor beta. The output voltage is  $V_Z - V_{be}$ .

#### Limiting Resistance

The value of  $R_S$  in Fig. 22 is determined by the load requirements. If  $R_S$  is too large, the diode will be unable to regulate at large values of  $I_L$  (the current through  $R_L$ ). If  $R_S$  is too small, the diode dissipation rating may be exceeded at low values of  $I_L$ . The optimum value for  $R_S$  can be calculated by

$$R_S = \frac{E_{dc(min)} - E_Z}{I_L I_{L(max)}}$$

When  $R_S$  is known, the maximum dissipation of the diode,  $P_D$ , may be determined by

$$P_D = \left[ \frac{E_{dc(max)} - E_Z}{R_S} - I_{L(min)} \right] E_Z$$

In the first equation, conditions are set up for the Zener diode to draw 1/10 the maximum load current. This assures diode regulation under maximum load.

Example: A 12-volt source is to supply a circuit requiring 9 volts. The load current varies between 200 and 350 mA.

$$E_Z = 9.1 \text{ V (nearest available value)}$$

$$R_S = \frac{12 - 9.1}{1.1 \times 0.35} = \frac{2.9}{0.385} = 7.5 \text{ ohms}$$

$$P_D = \left[ \frac{12 - 9.1}{7.5} - 0.2 \right] 9.1$$

$$= 0.185 \times 9.1 = 1.7 \text{ W}$$

The nearest available dissipation rating above 1.7 W is 5; therefore, a 9.1-V,

5-W Zener diode should be used. Such a rating, it may be noted, will cause the diode to be in the safe dissipation range even though the load is completely disconnected [ $I_L(\min) = 0$ ].

#### Obtaining Other Voltages

Fig. 22B shows how two Zener diodes may be used in series to obtain regulated voltages not normally obtainable from a single Zener diode, and also to give two values of regulated voltage. The diodes need not have equal breakdown voltages, because the arrangement is self equalizing. However, the current-handling capability of each diode should be taken into account. The limiting resistor may be calculated as above, taking the sum of the diode voltages as  $E_Z$ , and the sum of the load currents as  $I_L$ .

#### Gaseous Regulator Tubes

Although at first glance it may seem inappropriate to discuss gaseous voltage-regulator tubes (commonly called VR tubes) in a modern Handbook, they do offer advantages over their solid-state counterparts in some applications. Tube-type amplifier screen supplies often call for regulated voltages between 200 and 400. To obtain these voltages with Zener diodes, series combinations of four to six devices are often required. The cost can add up quickly. In addition to being far less expensive than solid-state devices, gaseous regulator tubes are much more forgiving of line transients, application of overvoltage and reverse screen current.

Gaseous regulator tubes (0A2/VR150, 0B2/VR105, etc.) can be used to good advantage. The voltage drop across such tubes is constant over a moderately wide current range. Tubes are available for regulated voltages near 150, 105, 90 and 75 volts.

The fundamental circuit for a gaseous regulator is shown in Fig. 23. The tube is connected in series with a limiting resistor,  $R_1$ , across a source of voltage that must be higher than the starting voltage. The starting voltage is about 30 to 40 percent higher than the operating voltage. The load is connected in parallel with the tube. For stable operation, a minimum tube current of 5 to 10 mA is required. The maximum permissible current with most types is 40 mA; consequently, the load current cannot exceed 30 to 35 mA if the voltage is to be stabilized over a range from zero to maximum load. A single VR tube may also be used to regulate the voltage to a load current of almost any value as long as the variation in the current does not exceed 30 to 35 mA. If, for example, the average load current is 100 mA, a VR tube may be used to hold the voltage constant provided the current does not fall below 85 mA or rise above 115 mA.

The value of the limiting resistor must lie between that which just permits minimum tube current to flow and that

which just passes the maximum permissible tube current when there is no load current. The latter value is generally used. It is given by the equation

$$R = \frac{E_s - E_r}{I}$$

where

$R$  = limiting resistance in ohms

$E_s$  = voltage of the source across which the tube and resistor are connected

$E_r$  = rated voltage drop across the regulator tube

$I$  = maximum tube current in amperes (usually 40 mA, or 0.04 A)

Two tubes may be used in series to give a higher regulated voltage than is obtainable with one, and also to give two values of regulated voltage. Regulation of the order of one percent can be obtained with these regulator tubes when they are operated within their proper current range. The capacitance in shunt with a VR tube should be limited to 0.1  $\mu$ F or less. Larger values may cause the tube drop to oscillate between the operating and starting voltages.

Do not use any of the unconnected tube-socket pins as circuit tie points even though such pins are unconnected. They penetrate the tube envelope and terminate abruptly. Depending on the voltage applied to the pin, intermittent breakdown may be experienced.

## ELECTRONIC VOLTAGE REGULATION

When extremely low ripple is required, or when the supply voltage must be constant with large fluctuations of load current and line voltage, a closed-loop amplifier is used to regulate the supply. There are two main categories of electronic regulators: linear regulators, in which the condition of a control element is varied in direct proportion to the line voltage or load current; and switching regulators, in which the control device is switched on and off, with the duty cycle proportional to the line or load conditions. Each system has relative advantages and disadvantages, and there are applications for both types in Amateur Radio equipment.

### Linear Regulators

The two basic forms of linear regulators are sketched in Fig. 24. A series regulator, shown at A, is used in applications requiring efficient use of the primary power source. A stable reference voltage is established by a Zener diode. In critical applications a temperature-compensated reference diode (discussed in Chapter 4) would be used. The output voltage is sampled by the error amplifier, which compares the output (usually attenuated by a voltage divider) to the reference. If the scaled-down output voltage is higher than

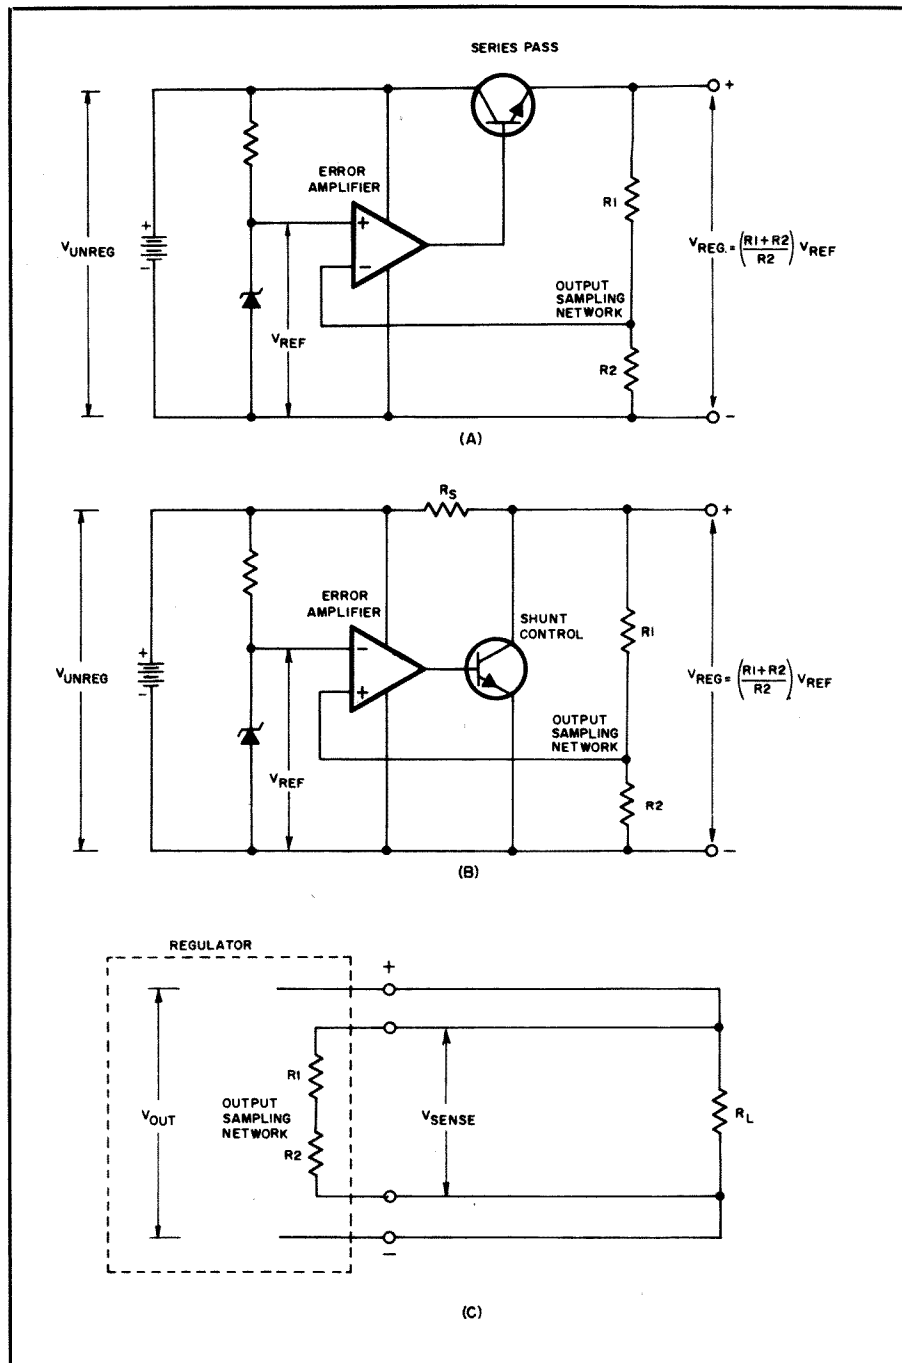

Fig. 24 — Linear electronic voltage regulator circuits. In these diagrams batteries represent the unregulated input voltage source. A transformer, rectifier and filter would serve this function in most applications. (A) Series regulator. (B) Shunt regulator. (C) Remote sensing overcomes poor load regulation caused by  $IR$  drop in the connecting wires by bringing them inside the feedback loop.

the reference voltage, the error amplifier reduces the drive current to the pass transistor. Conversely, if the load pulls the output voltage below the value called for, the amplifier drives the pass transistor into increased conduction. The series pass transistor forms a voltage divider with the load resistance. In a series regulator, the power dissipation of the pass transistor is directly proportional to the load current and input-output voltage differential. The series-pass element can be located in either leg of the supply. Either NPN or PNP

devices can be used, depending on the ground polarity of the unregulated input.

Fig. 24B shows a simple shunt regulator circuit. Such a system would be used when the load on the unregulated voltage source must be kept constant. The operation is similar to that of the series regulator, except that the control element is in parallel with the output load. As the load current varies, the control transistor changes resistance in opposition to the load such that the resistance of the parallel combination remains constant, drawing a constant

current through  $R_S$ . Note that the input polarity of the error amplifier is reversed with respect to the series regulator configuration. This is a result of the inversion caused by the common-emitter control transistor. The power dissipation in the control transistor is greatest when the output is unloaded.

The "stiffness" or tightness of regulation of a linear regulator depends on the gain of the error amplifier and the ratio of the output scaling resistors. The resistor scaling is usually the most significant because high-gain IC op amps can be used in the error amplifier. If the reference potential is 1 volt and the scaling resistors are selected to produce an output of 10 volts, the loop gain is reduced (hence output impedance increased) by a factor of 10. Increasing the reference potential to 5 volts and rescaling the sampling divider for the same 10-volt output will improve the regulation by a factor of five compared to the previous example. Thus, if the 10-volt supply using a 1-volt reference produced an output change of 5 mV for a certain load variation, the supply having the 5-volt reference will produce only a 1-mV change. The same rule applies to output ripple. However, this characteristic can be controlled independently of the load regulation by shunting  $R_1$  in Fig. 24 (A and B) with a capacitor. This allows the regulator to function at maximum loop gain for the ac component of the output.

The above discussion leads to the conclusion that the reference voltage in a linear regulator should be as high as possible. However, solid-state physics and fabrication technology dictate that the best temperature stability is obtained with reference diodes having operating potentials in the 6-volt region.

In any regulator, the output is cleanest and regulation stiffest at the point where the sampling network or error amplifier is connected. If heavy load current is drawn through long leads, the voltage drop can degrade the regulation at the load. To combat this effect, the feedback connection to the error amplifier can be made directly to the load. This technique, called remote sensing, moves the point of best regulation to the load by bringing the connecting loads inside the feedback loop. This is shown in Fig. 24C.

Linear voltage regulators are called for in applications requiring tight regulation with very low output noise and ripple. The trade-offs for these traits are bulk, weight and heat dissipation. Several examples of linear regulator design are given in Chapter 27.

#### Safe Operating Area

In choosing a suitable transistor for use as the series pass device in a linear regulator, care must be taken to ensure that the transistor chosen will survive any possible combination of voltage and current stress that may occur during normal or

Fig. 25 — Graph of the safe operating area of a 2N3055 transistor. See text for details. This graph is based on material presented in RCA Power Devices Data Book SSD-220C.

short-circuit operation. Although the transistor's listed wattage rating is an indicator of its power-handling capability, it must be understood that this rating usually applies only to low forward voltage drops and high collector currents. As the collector-to-emitter voltage is increased, the power-handling capability of the transistor can decrease. This decrease, known as the forward-biased second-breakdown limit, depends greatly upon the processes used in the manufacture of the transistor.

To assist the circuit designer in choosing a transistor that will meet power ratings, transistor manufacturers provide curves relating collector current and voltage limits. These curves are referred to as safe-operating-area (SOAR) curves.

A typical SOAR curve (for a 2N3055 transistor) is shown in Fig. 25. Line A is maximum emitter current that can be handled by the device without damage to the emitter lead. Line B shows the constant power region of operation, which is the transistor's maximum power rating. Finally, line C is the second breakdown limit. Also shown are plots that represent short-term or pulsed-power limitations for various pulse widths.

The power-supply designer should consult the data sheets for his choice of transistor and check to make sure that the safe operating area limits will not be exceeded during normal and short-circuit operation

of the power supply. The addition of a current limiter or foldback limiter will help to protect the pass transistor against destruction during overload conditions.

#### Current Limiting for Discrete-Component Regulators

Damage to a pass transistor can occur when the load current exceeds the safe amount. Fig. 26 illustrates a simple current-limiter circuit that will protect Q1. All of the load current is routed through  $R_1$ . A voltage difference will exist across  $R_1$ ; the value will depend on the exact load current at a given time. When the load current exceeds a predetermined safe value, the voltage drop across  $R_1$  will forward bias Q2 and cause it to conduct. Because Q2 is a silicon transistor, the voltage drop across  $R_1$  must exceed 0.6 V to turn Q2 on. This being the case,  $R_1$  is chosen for a value that provides a drop of 0.6 V when the maximum safe load current is drawn. In this instance, 0.6 volts will be seen when  $I_L$  reaches 0.5 A.  $R_2$  protects the base-emitter junction of Q2 from current spikes, or from destruction in the event of failure of Q1 under short-circuit conditions.

When Q2 turns on, some of the current through  $R_S$  flows through Q2, thereby depriving Q1 of some of its base current. This action, depending upon the amount of Q1 base current at a precise moment, cuts off Q1 conduction to some degree,

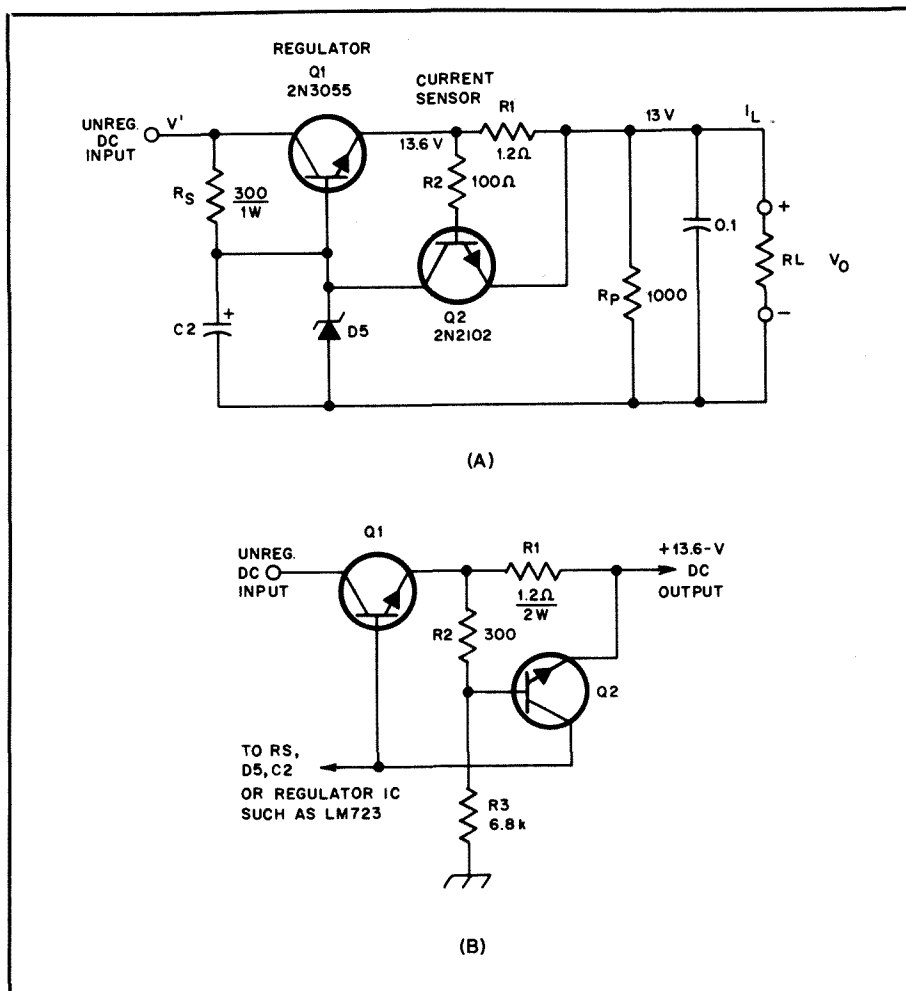

Fig. 26 — Overload protection for a regulated supply can be implemented by addition of a current-overload protective circuit, as shown at A. At B, the circuit has been modified to employ current foldback limiting.

thus limiting the flow of current through it.

### Foldback Limiting

Under short-circuit conditions, the previously described current limiter must withstand the full source voltage and short-circuit current simultaneously, which can impose a very high power dissipation or second breakdown stress on the series pass transistor. For example, a 12-volt regulator with current limiting set for 10 amperes and having a source of 16 volts will have a dissipation of 40 watts  $[(16 \text{ V} - 12 \text{ V}) \times 10 \text{ A}]$  at the point of current limiting (knee). But its dissipation will rise to 160 watts under short-circuit conditions  $(16 \text{ volts} \times 10 \text{ amps})$ .

A modification of the limiter circuit can cause the regulator's output current to decrease with decreasing load resistance after the knee. With the output shorted, the output current is only a fraction of the knee current value, which protects the series pass transistor from excessive dissipation and possible failure. Using the previous example of the 12-volt, 10-amp regulator, if the short-circuit current is designed to be 3 amperes (knee is still 10 amps), the trans-

sistor dissipation with short circuit will be only  $16 \text{ V} \times 3 \text{ A} = 48 \text{ watts}$ .

Fig. 26B shows how the current limiter example given in the previous section would be modified to incorporate foldback limiting. The divider string formed by R2 and R3 provides a negative bias to the base of Q2, which prevents Q2 from turning on until this bias is overcome by the drop in R1 caused by load current. Since this hold-off bias decreases as the output voltage drops, Q2 becomes more sensitive to current through R1 with decreasing output voltage. See Fig. 27.

The circuit is designed by first calculating the value of R1 for short-circuit current. For example, if 0.5 ampere is chosen, the value for R1 is simply  $0.6 \text{ volts}/0.5 \text{ amp} = 1.2 \text{ ohms}$  (with the output shorted, the amount of hold-off bias supplied by R2 and R3 is very small and can be neglected). The knee current is then chosen. For this example, the selected value will be 1.0 ampere. The divider string is then proportioned to provide a base voltage at the knee that is just sufficient to turn on Q2 (a value of 13.6 volts for 13.0 volts output). With 1.0 ampere flowing through

Fig. 27 — The 1-A regulator shown in Fig. 26B will fold back to 0.5 A under short-circuit conditions. See text.

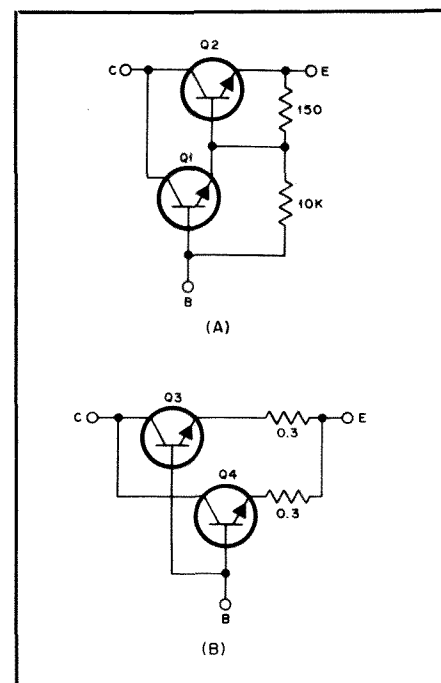

Fig. 28 — At A, a Darlington-connected pair for use as the pass element in a series-regulating circuit. At B, the method of connecting two or more transistors in parallel for high current output. Resistances are in ohms. The circuit at A may be used for load currents from 100 mA to 5 A, at B for currents from 6 to 10 A.

Q1 — Motorola MJE 340 or equiv.  
Q2-Q4 — Power transistor such as 2N3055 or 2N3772.

R1, the voltage across the divider will be 14.2 V. The voltage dropped by R2 must then be  $14.2 \text{ V} - 13.6 \text{ V}$ , or 0.6 volt. Choosing a divider current of 2 milliamperes, the value of R2 is then  $0.6 \text{ V}/0.002 \text{ A} = 300 \text{ ohms}$ . R3 is calculated to be  $13.6 \text{ V}/0.002 \text{ A} = 6800 \text{ ohms}$ .

### High-Current-Output Regulators

A simple Zener diode reference or IC op-amp error amplifier may not be able to source enough current to a pass transistor

that must conduct heavy load current. The Darlington configuration of Fig. 28A multiplies the pass transistor beta, thereby extending the control range of the error amplifier. If the Darlington arrangement is implemented with discrete transistors, resistors across the base-emitter junctions may be necessary to prevent collector-to-base leakage currents in Q1 from being amplified and turning on the transistor pair. These resistors are contained in the envelope of a monolithic Darlington device.

When a single pass transistor is not available to handle the current required from a regulator, the current-handling capability may be increased by connecting two or more pass transistors in parallel. The circuit at B of Fig. 28 shows the method of connection. The resistances in the emitter leads of each transistor are necessary to equalize the currents.

### IC Voltage Regulators

The modern trend in regulators is toward the use of three-terminal devices commonly referred to as three-terminal regulators. Inside each regulator is a reference, a high-gain error amplifier, temperature-compensated voltage-sensing resistors and transistors and a pass element. Many currently available units have thermal shutdown, overvoltage protection and current foldback, making them virtually destruction-proof. Several supplies using these ICs are featured in Chapter 27.

Three-terminal regulators (a connection for unregulated dc input, regulated dc output and ground) are available in a wide range of voltage and current ratings. Fairchild, National and Motorola are perhaps the three largest suppliers of these regulators at present. It is easy to see why regulators of this sort are so popular when one considers the low price and the number of individual components they can replace. The regulators are available in several different package styles, depending on current ratings. Low-current (100 mA) devices frequently use the plastic TO-92 and DIP-style cases. TO-220 packages are popular in the 1.5-A range, and TO-3 cases house the larger 3-A and 5-A devices.

Three-terminal regulators are available as positive or negative types. In most cases, a positive regulator is used to regulate a positive voltage and a negative regulator a negative voltage. However, depending on the systems ground requirements, each regulator type may be used to regulate the "opposite" voltage.

Fig. 29A and B illustrate how the regulators are used in the conventional mode. Several regulators can be used with a common-input supply to deliver several voltages with a common ground. Negative regulators may be used in the same manner. If no other common supplies operate off the input supply to the regulator, the circuits of Figs. 29C and D may be used to regulate positive voltages with a negative

regulator and vice versa. In these configurations the input supply is floated; neither side of the input is tied to the system ground.

Manufacturers have adopted a system of family numbers to classify three-terminal regulators in terms of supply polarity, output current and regulated voltage. For example, National Semiconductor uses the number LM7805C to describe a positive 5-V, 1.5-A regulator; the comparable unit from Texas Instruments is a UA7805KC. LM7812C describes a 12-V regulator of similar characteristics. LM7905C denotes a negative 5-V, 1.5-A device. There are many such families with widely varied ratings available from manufacturers. Fixed-voltage regulators are available with output ratings in most common values between 5 and 28 V. Other families include devices that can be adjusted from 1.25 to 50 V.

### Regulator Specifications

When choosing a three-terminal regulator for a given application, the most important specifications to consider are device output voltage, output current, input-to-output differential voltage, line regulation, load regulation and power dissipation. Output voltage and current requirements will be determined by the load the supply will ultimately be used with.

Input-to-output differential voltage is one of the most important three-terminal regulator specifications to consider when designing a supply. The differential value (the difference between the voltage applied to the input terminal and the voltage on the output terminal) must be within a specified range. The minimum differential value, usually about 2.5 V, is called the dropout voltage. If the differential value is less than the dropout voltage, no regulation will take place. At the other end of the scale, maximum input-output differential voltage is generally about 40 V. If this differential value is exceeded, maximum device dissipation may be reached.

Increases in either output current or differential voltage produce proportional increases in device power consumption. By employing a safety feature called current foldback, some manufacturers have ensured that maximum dissipation will never be exceeded in normal operation. Fig. 30 shows the relationship between output current, input-output differential and current limiting for a three-terminal regulator nominally rated for 1.5-A output current. Maximum output current is available with differential voltages ranging from about 2.5 V (dropout voltage) to 12 V. Above 12 V, the output current decreases, limiting the device dissipation to a safe value. If the output terminals are accidentally short circuited, the input-output differential will rise, causing current foldback, and thus preventing the power-supply components from being over-stressed. This protective feature makes three-terminal regulators

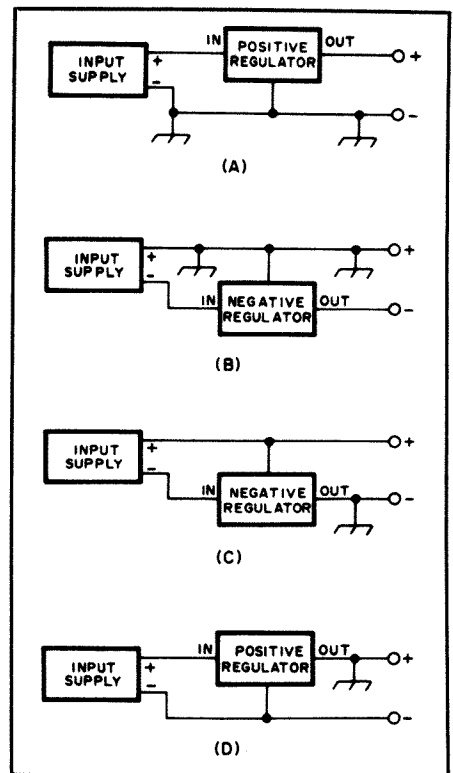

Fig. 29 — A and B illustrate the conventional manner in which three-terminal regulators are used. C and D show how one polarity regulator can be used to regulate the opposite polarity voltage.

Fig. 30 — Effects of input-output differential voltage on three-terminal regulator output current.

Fig. 31 — By varying the ratio of R2 to R1 in this simple LM317 schematic diagram, a wide range of output voltages is possible. See text for details.

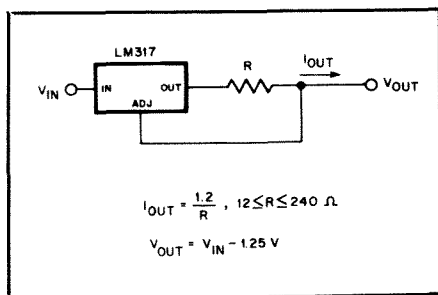

Fig. 32 — The basic LM317 voltage regulator is converted into a constant-current source by adding only one resistor.

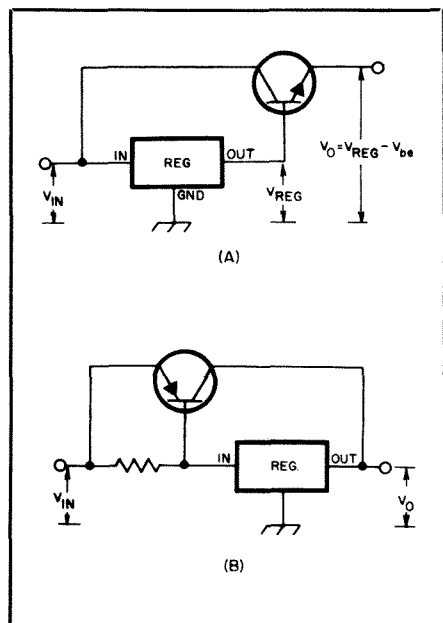

Fig. 33 — Two methods for boosting the current output capacity of an IC voltage regulator. (A) NPN emitter follower. (B) PNP "wraparound." Operation of these circuits is explained in the text.

particularly attractive in simple power supplies.

When designing a power supply around a particular three-terminal regulator, input-output voltage characteristics of the regulator should play a major role in selecting the transformer secondary and filter capacitor component values. The unregulated voltage applied to the input of the three-terminal device should be higher than the dropout voltage, yet low enough that the regulator does not go into current limiting caused by an excessive differential voltage. If, for example, the regulated output voltage of the device shown in Fig. 30 was 12, then unregulated input voltages of between 14.5 and 24 would be acceptable if maximum output current is desired.

In use, all but the lowest current regulators generally require an adequate external heat sink because they may be called on to dissipate a fair amount of power.

Also, because the regulator chip contains a high-gain error amplifier, bypassing of the input and output leads is essential for stable operation.

Most manufacturers recommend bypassing the input and output directly at the leads where they protrude through the heat sink. Tantalum capacitors are usually recommended because of their excellent bypass capabilities into the VHF range.

In addition to fixed-output-voltage ICs, high-current, adjustable voltage regulators are available. These ICs require little more than an external potentiometer for an adjustable output range from 5 to 24 V at up to 5 A. The unit price on these items is only a few dollars, making them ideal for test-bench power supplies. A very popular low-current, adjustable-output-voltage three-terminal regulator, the LM317, is shown in Fig. 31. It develops a steady 1.25-V reference,  $V_{ref}$ , between the output and adjustment terminals. By installing  $R_1$  between these terminals, a constant current,  $I_1$ , is developed, governed by the equation  $I_1 = V_{ref}/R_1$ . Both  $I_1$  and a  $100\text{-}\mu\text{A}$  error current,  $I_2$ , flow through  $R_2$ , resulting in output voltage  $V_o$ .  $V_o$  can be calculated using the equation

$$V_o = V_{ref} \left( 1 + \frac{R_2}{R_1} \right) + I_2 R_2$$

Any voltage between 1.2 and 37 volts may be obtained with a 40-volt input by changing the ratio of  $R_2$  to  $R_1$ .

Fig. 32 shows one of many flexible applications for the LM317. By adding only one resistor, the voltage regulator can be changed into a constant current source, capable of charging NiCd batteries, for example. Design equations are given in the figure. The same precautions should be taken with adjustable regulators as with the fixed-voltage units. Proper heat sinking and lead bypassing are essential for proper circuit operation.

When the maximum current output from an IC voltage regulator is insufficient to operate the load, discrete power transistors may be connected to increase the current capability. Fig. 33 shows two methods for boosting the current output of a positive regulator, although the same techniques can be applied to negative regulators.

In A, an NPN transistor is connected as an emitter follower, multiplying the output current capacity by the transistor beta. The shortcoming of this approach is that the base-emitter junction is not inside the feedback loop. The result is that the output voltage is reduced by the base-emitter drop, and the load regulation is degraded by variations in this drop.

The circuit at B has a PNP transistor "wrapped around" the regulator. The regulator draws current through the base-emitter junction, causing the transistor to conduct. The IC output voltage is un-

changed by the transistor because the collector is connected directly to the IC output (sense point). Any increase in output voltage is detected by the IC regulator, which shuts off its internal pass transistor, and this stops the boost-transistor base current.

Most IC regulators are internally configured as linear series regulators. However, the manufacturer's applications literature shows how to use these devices in shunt regulators and even in switching regulators.

### Thermal Design

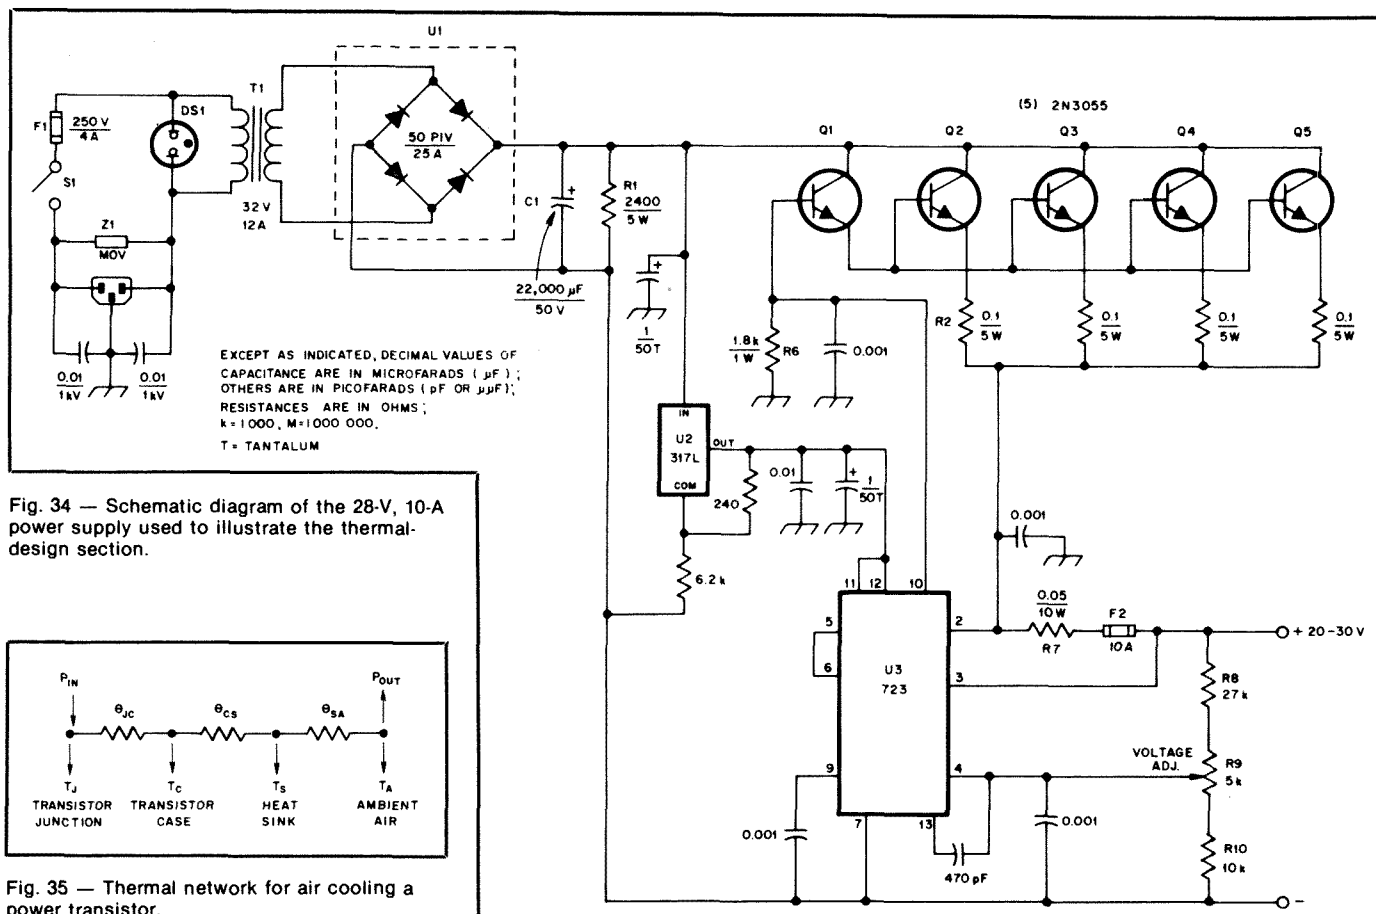

Just as important as power-supply electrical design is power-supply thermal design. Linear power supplies are inefficient. Rectifiers, regulators and pass transistors all dissipate heat, and this heat must be safely carried away to avoid device damage. Although the black-magic rule of thumb "bigger is better" applies to heat sinks, this section will show you how to calculate heat-sink requirements and choose the right shroud with mystery. This material was prepared by ARRL TA Dick Jansson, WD4FAB.

Creating the thermal design for a properly cooled power supply is a very well-defined process. To some amateurs experienced only in the electronic arts, heat transfer is a subject shrouded with mystery. The following information will remove these veils and show what is needed to make a good electronic design behave properly in the thermal world. An outline of the steps to be taken will show the logic to be applied:

- 1) Determine the expected power dissipation.
- 2) Identify the requirements for the dissipating elements.
- 3) Estimate heat-sinking requirements.
- 4) Rework the electronic device to meet the thermal requirements.
- 5) Select the heat exchanger.

To illustrate this discussion, a 28-V, 10-A power supply will be used as an example. Construction details of this supply may be found in Chapter 27. The steps described here were actually followed during the design of that supply.

The first step is to estimate the filtered, unregulated supply voltage under full load. A schematic diagram of this supply is shown in Fig. 34. The transformer has a secondary output of 32-V ac. Since this is the input to a full-wave bridge rectifier, the filtered dc output from C1 will follow those output characteristics shown in Fig. 7, presented earlier in this chapter. As a first guess, estimate 40 V as the filtered dc output at a 10-A load. The filter capacitor is 22,000  $\mu\text{F}$ , so the output is reasonably well filtered. We do not know the value of the series resistance/load resistance,  $R_s/R$ , but if the power supply is going to be worth its salt, that value needs to be low! Bracketing the series resistance,  $R_s$ , would

place the dc output of the filter between 34 V and 44 V. The estimate of 40 V output still looks good, so continue to use that value as the filtered dc value that will feed the regulator stage at a 10-A load.

The next step is to estimate the total pass-transistor power dissipation under full load. Allowing for some small voltage drops in the power-transistor emitter circuitry, the output of the series pass transistors (Q2-Q5) is about 29 V for a delivered 28 V under a 10-A load. With an unregulated voltage of 40-V, the total pass-transistor dissipation, in the form of heat, is  $(40 \text{ V} - 29 \text{ V}) \times 10 \text{ A}$ , or 110 W. The heat sink for this power supply must be able to handle that amount of dissipation and still keep the transistor junctions below the specified safe operating temperature limits.

The next consideration is the ratings of the pass transistors to be used. This supply calls for four 2N3055 pass transistors, even though a data sheet for that transistor shows that each 2N3055 is rated for 15-A service and 115-W dissipation. Why so many 2N3055s? Here we need to get past the big, bold type at the top of the specification data sheet, and on to such subtle characteristics as the junction-to-case thermal resistance,  $\theta_{jc}$ , and the maximum allowable junction temperature,  $T_j$ . Unfortunately, some of these characteristics are not contained in most elementary listings of transistor properties. Don't be

deluded by the specified maximum continuous device dissipation,  $P_d$ , as that value is the computed maximum dissipation at a case temperature of 25°C. It is not practical to try to keep the case of a power transistor at 25°C when room temperature can easily exceed that.

The Greek letter  $\theta$  is used to express values of thermal resistance, while R is used to express values of electrical resistance. Thermal resistance can be equated to electrical resistance, and thermal networks that look like electrical networks can be constructed. In fact, the basic equations are the same. Heat, measured in watts, flows in the network as does electrical current, measured in amperes. Temperature differences, in degrees Celsius, are equivalent to electrical potential in volts. Resistance to heat flow is expressed in °C/W, and is equivalent to resistance measured in ohms.

The concept of thermal resistance can be understood by reviewing basic heat-flow phenomena. A thermal network that describes the flow of heat from a transistor junction to the ambient air is shown in Fig. 35. The ambient air is considered here as the ultimate heat sink.  $\theta_{jc}$  describes the thermal resistance from the transistor junction to its case.  $\theta_{cs}$  is the resistance of the mounting interface between the transistor case and the heat sink.  $\theta_{sa}$  is the resistance of the heat sink to the ambient air.

Checking the specification sheet for

the 2N3055 shows that it is rated for  $\theta_{jc} = 1.52^\circ\text{C/W}$ , and a maximum case (and junction) temperature of 220°C. Industry experience has shown that silicon transistor reliability suffers substantially when junctions are operated at those elevated temperatures. Most commercial and military specifications will not permit design junction temperatures to exceed 125°C, and in some cases 110°C. A transistor operated above 125°C does not "go away" instantly, but will degrade slowly because of excessive thermal migration in the silicon material.

At some point, you need to decide how the power supply is going to be used. Thermal requirements (as well as other design requirements) vary significantly, depending on expected duty cycle. Continuous commercial service (CCS) is exactly what it sounds like: "Brick-on-the-key" operation, such as FM, Baudot RTTY or ATV. Amateur equipment designed primarily for CW and SSB operation is often designed for Intermittent Commercial and Amateur Service (ICAS), nominally considered to be a duty cycle of 33% of the CCS. To provide a power supply capable of performing any chore within its power output capability, the designer of the example supply has chosen to design for CCS operation, even though many amateur operators may never stress the supply to that extent. This philosophy is conservative and safe.

Other considerations in how the supply will be used include the maximum air temperature that the unit will see in service and the maximum junction temperature to be allowed for the design. A lot of deliberation of these subjects was done, with the conclusion that an ambient air temperature ( $T_a$ ) of 35°C (95°F),  $T_j = 125^\circ\text{C}$  for ICAS operation and  $T_j = 150^\circ\text{C}$  for CCS operation were safe assumptions. These assumptions allow design flexibilities, as will be shown later.

The electrical design for this supply originally called for two 2N3055 transistors in the regulator pass stage. This design was based on electrical characteristics only, and did not take thermal considerations into account. The equivalent thermal network for a two-transistor supply is shown in Fig. 36. Each of the 2N3055s would have to dissipate 55 W.

The total thermal resistance between the junction and the heat sink is equal to the junction-to-case thermal resistance ( $\theta_{jc}$ ), plus the thermal resistance associated with mounting of the transistor to the heat sink ( $\theta_{cs}$ ).

Proper mounting of most TO-3 power transistors requires that they have an electrical insulator between the transistor case and the heat sink. This electrical insulator must, however, provide for very good thermal contact between the two. To achieve a quality mounting, you should use thin polyimide or mica formed washers and a suitable thermal compound to exclude air from the interstitial space. "Thermal greases" are commonly available for this function. Silicone grease may be used, but

Fig. 36 — Thermal network for a power supply with two pass transistors.

Fig. 37 — Thermal network for a power supply with four pass transistors.

Fig. 38 — Graph of thermal resistance vs. heat-sink volume for natural-convection cooling of a heat sink with a 50°C temperature rise. This graph is based on engineering data from EG&G Wakefield.

filled silicone oils made specifically for this purpose are better.

A good starting value for mounting thermal resistance is  $\theta_{cs} = 0.50^\circ\text{C/W}$ . Lower values of  $\theta_{cs}$  are possible, but the techniques needed to achieve them are expensive and not generally available to the average amateur. Furthermore, serious work on lowering  $\theta_{cs}$  is not warranted in light of the somewhat higher value of  $\theta_{jc}$ , which cannot be lowered without going to a somewhat more exotic pass transistor.

The total value of the junction-to-sink resistances in this example is  $\theta_{js} = 2.02^\circ\text{C/W}$  ( $\theta_{jc} = 1.52 + \theta_{cs} = 0.5$ ). At a power dissipation ( $P_d$ ) of 55 W, the transistor junction can be expected to operate  $111^\circ\text{C}$  ( $55\text{ W} \times 2.02^\circ\text{C/W}$ ) above the heat-sink temperature ( $T_s$ ). If the maximum value for  $T_j$  is  $150^\circ\text{C}$ , then the heat-sink temperature could rise no higher than  $T_s = 39^\circ\text{C}$ . With a ambient air temperature ( $T_a$ ) estimated at  $35^\circ\text{C}$  (worst case), it would require an impossibly large heat sink to keep  $T_s$  within  $4^\circ\text{C}$  of  $T_a$  to keep the two 2N3055s cool. The conclusion to be drawn from this analysis is that use of two 2N3055s is not feasible from a thermal standpoint, although from an electrical standpoint two transistors are more than adequate.

At this point, the power-supply design was modified to use four 2N3055 pass transistors. This change divides the dissipation load by four, making  $P_d = 27.5\text{ W}$  for each transistor. The equivalent thermal network for four devices is shown in Fig. 37. Going through the steps described earlier, the junction-to-sink temperature difference is now  $T_j - T_s = 55.6^\circ\text{C}$ . Initially, it was hoped to keep the target maximum junc-

tion temperature below  $125^\circ\text{C}$ . At 27.5 W per transistor, that means a sink temperature of  $T_s = 69^\circ\text{C}$ . This temperature is possible to achieve with two large heat sinks (two devices per sink), or forced-air cooling of a single large heat sink.

Forced air cooling of a heat sink requires the use of a fan or blower to move the air. That means a "moving" part and thus a potential reduction in supply reliability. Also, blowers are noisy. If at all possible, the power-supply design should make use of natural-convection cooling and not rely on a blower. By reasoning that most operation would not be CCS, and that during occasional CCS operation junction temperatures of  $T_j = 150^\circ\text{C}$  are tolerable, a design is possible that offers heat-sink temperatures of  $T_s = 94^\circ\text{C}$  and a sink-to-air temperature difference  $T_s - T_a = 59^\circ\text{C}$ . It is possible to implement these parameters with a single heat sink of the "right" design. Please note that a heat-sink temperature of  $94^\circ\text{C}$  is substantially hotter than the allowable "finger-touch thermometer" temperature of  $52^\circ\text{C}$ . Do not attempt to use the finger thermometer with this design.

Now comes the big question: What is the "right" heat sink to use? We have established its requirements. It must be capable of dissipating 110 W, and it must allow a temperature rise no greater than  $59^\circ\text{C}$ , or  $\theta_{sa} = 0.54^\circ\text{C/W}$  ( $59^\circ\text{C}$  divided by 110 W).

From Fig. 38, the relationship of heat-sink volume and thermal resistance for a natural-convection operation can be seen. This relationship presumes the use of suitably spaced fins (0.35 inch or greater)

Fig. 39 — Graph of the natural convection characteristics under load of the EG&G Wakefield model no. 441 heat sink. This graph is based on actual testing performed by ARRL TA Dick Jansson, WD4FAB.

and provides a “rough order-of-magnitude” value for sizing a heat sink. The needs of the supply used for this example could be met with a heat-sink volume of approximately 120 in<sup>3</sup>, which is within the range of available heat sinks, although it certainly is not small. Unlike a heat sink for use on an RF amplifier, this application can use a heat sink where only “wire access” to the transistor connections is available. A heat sink with a “three-dimensional shape” can be used, allowing the selection of a more efficient design. Most RF designs require the transistor mounting surface to be completely exposed so that the PC board can be mounted close to the transistors.

A quick consultation with several manufacturer's catalogs reveals that Wakefield Engineering Co. model nos. 441 and 435 heat sinks meet the needs of this application.<sup>1</sup> A Thermalloy model no. 6441 is suitable as well. Data published in the catalogs of these manufacturers show that in natural-convection service, the expected temperature rise for 100 W dissipation would be just under 60°C, an almost perfect fit for this application. See Fig. 39. Moreover, the no. 441 heat sink can easily mount four TO-3-style 2N3055 transistors, as shown in Fig. 40.

<sup>1</sup>There are numerous manufacturers of excellent heat sinks. References to any one manufacturer are not intended to exclude the use of products of any others, nor to indicate any particular predisposition to one manufacturer. The catalogs and products referred to here are from: EG&G Wakefield Engineering, 60 Audubon Rd., Wakefield, MA 01880; and Thermalloy, Inc., 2021 West Valley View La., Dallas, TX 75234.

Thermal power-loading tests of a no. 441 heat sink showed a very close agreement with the manufacturer's data — a 58°C temperature rise for 110-W power dissipation. It is not necessary to test heat sinks used for every application. The tests were done just to illustrate that the data of reliable suppliers of heat sinks for transistor cooling can be believed. Once you determine the heat-sink requirements for your application, you can make use of the manufacturer's data to select the right cooler. Remember: heat sinks should be mounted with the fins and transistor mounting area vertical to promote convection cooling.

Another point here is that very satisfactory results can be obtained through the good application of “handbook and catalog engineering.” There is absolutely no need for you to conduct a lengthy, detailed computer thermal analysis of individual heat sinks. Such analysis is not needed if you use existing heat-sink designs.

### Switching Regulators

Just as the transistor has replaced the inefficient vacuum tube, the linear voltage regulator is rapidly being replaced by the switching regulator. This transition is being assisted by the availability of components made especially for switching supplies, such as high-speed switching transistors and diodes, capacitors, transformer cores, and so on. The introduction of switching-regulator integrated circuits has also lowered the complexity of switchers to a degree that rivals linear regulators, and new circuit design techniques have reduced regulator noise and ripple to acceptable levels for communications equipment.

(A)

(B)

Fig. 40 — The EG&G Wakefield 441 heat sink is a “three-dimensional” design that makes excellent use of space. The photo at A shows the heat sink with four 2N3055 transistors in place. At B, the wiring to the transistors is visible.

The switching regulator (also known as a switching-mode regulator, or SMR) offers several advantages over the linear type:

- 1) Much higher efficiency resulting from minimal regulator dissipation. Very desirable for battery-powered applications.
- 2) Lighter in weight as a result of less heat sink material.
- 3) Smaller in size.

These advantages are offset, however, by slower response to load transients, increased circuit complexity and higher cost.

The simplest type of SMR somewhat resembles a linear regulator in form and is known as the voltage-bucking (buck) con-

Fig. 41 — Schematic diagram of a simple switching regulator.

Fig. 42 — Waveforms seen at various points in the switching regulator shown in Fig. 41.

figuration. The circuit reduces (or “bucks”) the input voltage to produce a lower value of output voltage. By rearrangement of circuit components, the reverse can be made to occur; the output voltage can actually be higher than the input voltage. This is known as a boost configuration.

The basic elements of the buck regulator are shown in Fig. 41. They are switch transistor Q1, inductor L1, capacitor C1 and diode D1. A positive source voltage is applied to the collector of Q1, and the load is connected as shown. Some control circuitry for applying base drive to Q1 is also needed; for the present, assume that we can turn Q1 fully on and off at will.

Initially, ignore the presence of C1. As Q1 is turned on, all of the source voltage instantaneously appears across L1 since the initial current in L1 is zero. With time, the current in L1 begins to increase and  $V_{OUT}$  begins to rise;  $V_{OUT}$  is allowed to continue to rise until it reaches the desired output voltage. When  $V_{OUT}$  exceeds the desired voltage, switch Q1 is turned off and point A in Fig. 41 immediately goes negative in an effort to maintain the current flowing in L1, thereby causing D1 to conduct. As the energy which has become stored in L1 dissipates into the load through D1, the current in L1 decreases, as does the output voltage. When  $V_{OUT}$  drops to slightly less than the desired value, Q1 is turned on again, bringing point A to the source voltage level, and the cycle repeats.

Obviously, in this circuit, Q1 must switch on and off at an extremely fast rate to minimize the swing in output voltage around the desired value, since this voltage variation is directly related to the on and off times of Q1. This situation can be improved by adding C1, which supports the output voltage while the current decreases in L1, and reduces overshoot by absorbing the excess current in L1 while Q1 is on. See

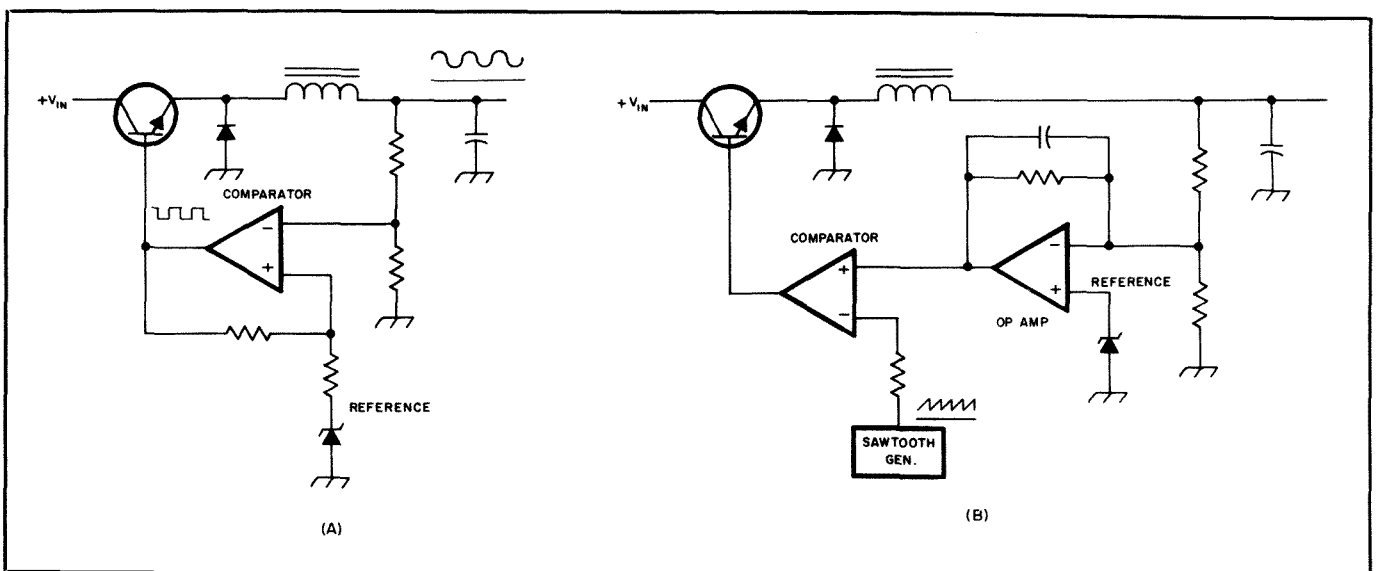

Fig. 43 — Two methods of implementing a pulse-width modulator. The circuit at A uses the ripple modulation technique, while the circuit at B employs fixed-frequency (duty-cycle) modulation.

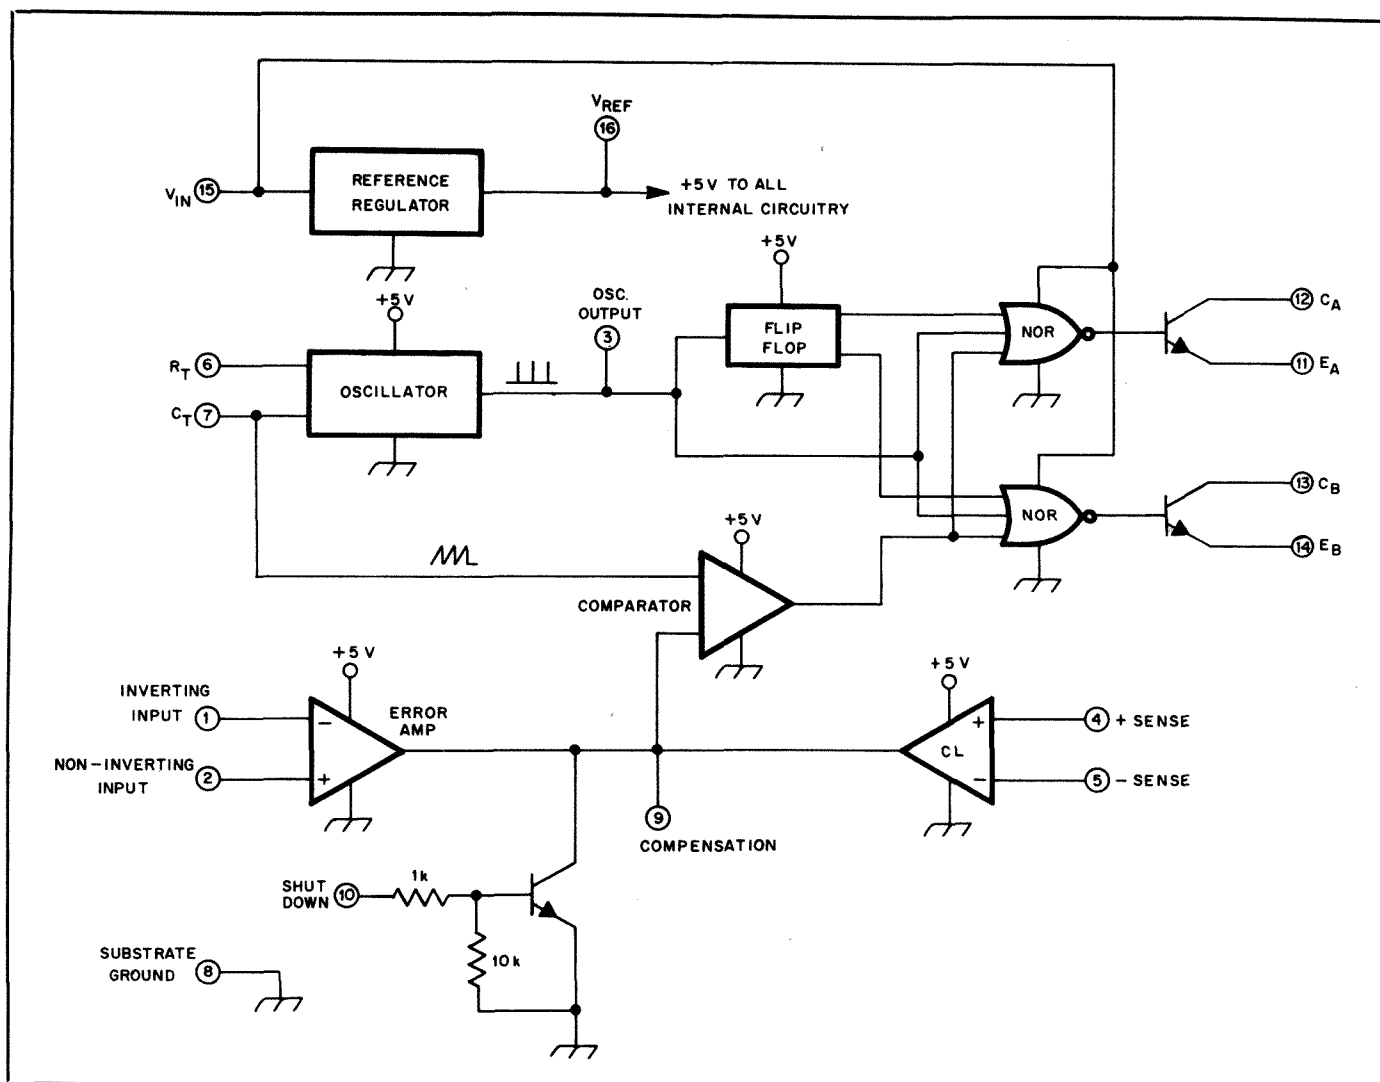

Fig. 44 — Block diagram of the Silicon General SG3524 regulating pulse-width modulator IC. This drawing is based on information presented in the *Silicon General Product Catalog*.

the waveforms in Fig. 42. The transistor can then be switched at a slower speed, and the inductance of L1 reduced because of the smoothing effect of C1.

In this example, power is only transmitted from the source when Q1 is on, but this power is distributed to the load continuously during the entire cycle. The power delivered to the load is  $V_{OUT} \times I_{LOAD}$ , which must equal the power obtained from the source while Q1 conducts. Since Q1 conducts for only a portion of the cycle at an average current during conduction of  $I_{LOAD}$ , the output voltage is then equal to the duty cycle  $\times V_{SOURCE}$  or

$$V_{OUT} = \frac{t_{ON}}{t_{CYCLE}} \times V_{SOURCE}$$

In actual practice, the losses in D1, forward drop in Q1, resistance in L1, and various other factors combine to affect the above formula, but except for very-low-output-voltage, high-current regulators, these losses can be neglected since the control circuits will automatically compensate for them.

The control circuit that must be added to the basic circuit in Fig. 41 has to be capable of turning the switch transistor on and off quickly and providing the proper ratio of on-time to off-time to maintain regulation. This portion of a switching regulator is referred to as a pulse-width modulator (PWM).

The simplest PWM is a comparator that has the dc output of the regulator applied through a divider to one input and a reference voltage applied to the alternate input. See Fig. 43A. A small amount of the comparator's output voltage is fed back to its non-inverting input to provide hysteresis, thereby ensuring that the comparator's output is either high or low. With the ripple-modulated PWM, there must be sufficient output ripple to overcome the hysteresis, which is why the term "ripple modulation" is used.

By forcing the regulator to switch at a fixed frequency that is much higher than the ripple modulator would produce, the output LC filter can become much more efficient. This can be done by injecting a

fixed-frequency sawtooth waveform to the comparator, as shown in Fig. 43B. The output voltage is now compared to the reference at the input to an op amp. Op-amp response is slowed by a capacitor between its output and inverting terminals so that it will not respond to switching ripple. As the output of the op amp rises and falls with output voltage variations, the comparator "chops off" more or less of the sawtooth that varies the duty cycle of the drive to the switching transistor's base.

Integrated circuits are now available that provide the op amp, comparator, reference and drive circuits all in one package. A block diagram of one of these ICs, a Silicon General SG3524, is shown in Fig. 44.

#### Dc-to-Dc Conversion

Dc-to-dc conversion is probably the oldest form of switching technology in the power-supply field, dating back to the vibrator supplies used in automobile radios and low-power surplus gear. The noisy and unreliable mechanical vibrators were eventually replaced by transistors or SCRs.

Fig. 45 — Schematic diagram of a basic dc-to-dc converter.

The dc-to-dc converter works on the principle of chopping the dc power source to produce an ac component and then using a transformer to obtain a different voltage level. The new voltage can then be rectified to produce a dc output voltage higher or lower than the source. In the case of the old vibrator supplies, the 6-volt or 12-volt car battery voltage was chopped, transformed up to several hundred volts ac, and rectified to provide plate voltage for the equipment. Another example, still used today, eliminated the output rectifiers and used a transformer wound to produce 120-V ac to power ac equipment. This type of circuit is often referred to as a dc-to-ac inverter, although nothing is really "inverted."

The operation of a dc-dc converter is as follows. Refer to Fig. 45. Q1 and Q2 are initially biased on by R3. One transistor (assume Q1), draws slightly more current than its mate (Q2). Because of the autotransformer effect of the transformer primary, the collector of Q1 goes toward ground, while the collector of Q2 goes more positive. This primary voltage swing is reflected into the base drive winding, which applies increased base drive to the heavily-conducting transistor (Q1) while removing bias from Q2. When Q1 is saturated, the voltage across the drive winding is equal to the ratio of drive winding turns to primary turns, multiplied by the source voltage.

$$V_{\text{DRIVE WINDING (END TO CENTER TAP)}} = \frac{N_D}{N_P} \times V_S$$

Since the base of Q1 does not permit the

forward-biased base voltage to be more than about 1 volt, the center tap of the drive winding is pushed negative until D1 conducts, again at less than 1 volt (negative). The remainder of the winding voltage across  $N_D$  is dropped across R1, and it is the current resulting from that drop across R1 that determines the drive current

$$I_B = \frac{V_{ND} - V_{BE}(Q1) - V_{FD}(D1)}{R1}$$

Usually  $V_{BE}$  and  $V_{FD}$  are about 0.8 volts, therefore

$$I_B \approx \frac{V_{ND} - 1.6}{R1}$$

Also,  $V_{ND}$  is usually designed to be 5 volts or less in order to prevent reverse conduction of the base-emitter junction of Q2.

Q1 remains in conduction, producing output power, until the core of the transformer saturates. At that point, it is incapable of transferring power, and the base drive to Q1 reduces. The collector current rises abruptly, pulling Q1 out of saturation, since the saturated transformer's primary looks like a short circuit to Q1.

As the base drive winding swings through zero volts, the base of Q2 is turned on and collector current in Q2 begins to flow. This helps Q1 to turn off and swings the excitation in the transformer primary in the opposite direction. Q2 saturates, with Q1 off, and remains in saturation until the transformer core once again saturates, initiating another cycle.

Power is delivered to the load during each half-cycle. Neglecting diode drops and transistor saturation voltages, the output voltage is

$$V_{OUT} = \frac{N_S}{N_P} \times V_S$$

This type of self-excited, single-transformer converter design is known as a Royer Oscillator. The frequency of oscillation is dependent upon the time required to saturate the core with the applied voltage and is given by the formula

$$F(\text{Hz}) = \frac{V_S \times 10^8}{4 \times N_P \times B_M \times A_C}$$

where

$V_S$  = voltage applied at the primary center tap

$N_P$  = no. of turns from primary center tap to one end

$B_M$  = saturation flux density of the core in gauss

$A_C$  = cross-sectional area of the core in  $\text{cm}^2$

The best cores for the Royer oscillator are tape-wound toroids using orthonol or square permalloy-type alloys. Some ferrite cores are also specifically made for this application.

Since the tape-wound toroids used for self-excited dc-dc converters become very lossy at frequencies above the audible range, the self-excited configuration is rarely used above about 15 to 20 kHz. For higher frequency use, an electronically driven type is usually employed. This consists of an electronic square-wave oscillator operating at the desired frequency to drive the bases of the switching transistors. The output transformer is made with a core material that does not have sharp saturation characteristics and is designed to be operated well within the maximum flux density rating to avoid saturation. High-flux-density ferrite is usually chosen for the core.

### Push-Pull Converter/Regulator

By reducing the width of the drive pulses applied to the transistor to less than 50% duty cycle, the push-pull converter just described can be made to regulate. Integrated circuits that contain most of the components necessary for the construction of a push-pull regulator are now available from several manufacturers (Silicon General, Unitrode, Texas Instruments). The popular Silicon General type SG3524 is one example.

These integrated circuits work on the basis of a constant switching frequency with variable duty cycle, and can also be used for making a much improved version of the single transistor buck regulator described earlier.

One of the big advantages of the regulating converter is the transformer isolation that it provides between the

primary and secondary circuits. Since the transformer is operating at high frequency, its size and weight can be much less than a 60-Hz transformer handling the same

power. To take advantage of this, the 117-V ac line is bridge rectified and capacitive-input filtered to produce about 170-V dc. This voltage is then applied to

a regulating converter to produce the desired regulated and isolated dc output voltage. This application is usually referred to as off-line conversion.

## Battery Power

The availability of solid-state equipment makes practical the use of battery power under portable or emergency conditions. Hand-held transceivers and instruments are obvious applications, but even fairly powerful transceivers (100 W or so output) may be practical users of battery power. Solid-state kilowatt mobile amplifiers exist, but these are intended for operation from an auxiliary battery that is constantly charged. The lower-power equipment can be powered from two types of batteries. The primary battery is intended for one-time use; the storage (or secondary) battery may be recharged many times.

A battery is a group of chemical cells, usually series-connected to give some desired multiple of the cell voltage. Each assortment of chemicals used in the cell gives a particular nominal voltage; this must be taken into account to make up a particular battery voltage.

### Primary Batteries

The most common primary cell is the carbon-zinc flashlight type, in which chemical oxidation converts the zinc into salts and electricity. When there is no current flow, the oxidation stops until the next time current is required. Some chemical action does continue, so stored batteries eventually will degrade or dry out to the point where the battery will no longer supply the desired current. The time taken for degradation without battery use is called shelf life.

The carbon-zinc battery has a nominal voltage of 1.5 volts, as does its heavy-duty or industrial brother. These latter types are capable (for a given size) of producing more milliampere hours and less voltage drop than a carbon-zinc battery of the same size. They also have longer shelf life. Alkaline primary batteries have even better characteristics and will retain more capacity at low temperatures. Nominal voltage is 1.5 volts.

Lithium primary batteries have a nominal voltage of about 3 volts per cell and by far the best capacity, discharge, shelf-life and temperature characteristics. Their disadvantages are high cost and the fact that they cannot be readily replaced by other types in an emergency.

Silver oxide (1.5 V) and mercury (1.4 V) batteries are very good where nearly constant voltage is desired at low currents for long periods. Their main use (in sub-miniature versions) is in hearing aids,

though they may be found in other mass-produced devices such as household smoke alarms.

### Rechargeable or Storage Batteries

Many of the chemical reactions in primary batteries are theoretically reversible if current is passed through the battery in the reverse direction. For instance, zinc may be plated back onto the negative electrode of a zinc-carbon battery. Recharging of primary batteries should not be done for two reasons: It may be dangerous because of heat generated within sealed cells, and even in cases where there may be some success, both the charge and life are limited. In the zinc-carbon example, the zinc may not replate in the locations that had been oxidized. Pinholes in the case result, with consequent fluid leakage that will damage the equipment powered by the batteries.

One type of alkaline battery is rechargeable, and is so marked. If the recommended charging rate is not marked on such a battery, the manufacturer's advice should be asked. In a number of cases, the manufacturer markets chargers and recommends that only those should be used.

The most common small-storage battery is the nickel-cadmium (NiCd) type, with a nominal voltage of 1.2 V per cell. Carefully used, these are capable of 500 or more charge and discharge cycles, compared to 50 or so for alkaline types. The NiCd battery must not be fully discharged for best life. Where there is more than one cell in the battery, the most-discharged cell may suffer polarity reversal, resulting in a short circuit, or seal rupture. All storage batteries have discharge limits, and nickel-cadmium types should not be discharged to less than 1.0 V per cell.

The most widely used storage battery is the lead-acid type. In automotive service, the battery is usually expected to discharge partially at a very high rate, and then to be recharged promptly while the alternator is also carrying the electrical load. If the conventional auto battery is allowed to discharge fully from its nominal 2 V per cell to 1.75 V per cell, only about 50 cycles of charge and discharge may be expected, with reduced storage capacity.

The most attractive battery for extended high-power electronic applications is the so-called "deep-cycle" battery (intended for such use as powering electrical fishing motors and the accessories in recreational vehicles). The size 24 and 27 batteries

furnish a nominal 12 volts and are about the size of small and medium automotive batteries. These batteries may furnish between 1000 and 1200 watt-hours per charge at room temperature. When properly cared for, they may be expected to last more than 200 cycles. They often have lifting handles and screw terminals, as well as the conventional truncated-cone automotive terminals. They may also be fitted with accessories such as plastic carrying cases, with or without built-in chargers.

Lead-acid batteries are also available with gelled electrolyte. Commonly called gel cells, these types may be mounted in any position if sealed, but some vented types are position sensitive.

Lead-acid batteries with liquid electrolyte usually fall into one of three classes — conventional with filling holes and vents, permitting the addition of distilled water lost from evaporation or during high-rate charge or discharge; maintenance-free, from which gas may escape but water cannot be added; and sealed. Generally, the deep-cycle batteries have filling holes and vents.

### Battery Capacity

The common rating of battery capacity is ampere hours (Ah), the product of current drain and time. The symbol "C" is commonly used; C/10, for example, would be the current available for 10 hours con-

Fig. 46 — Output capacity as a function of discharge rate for two sizes of lead-acid batteries.

tinuously. The value of C changes with the discharge rate and might be 110 at 2 amperes but only 80 at 20 amperes. Fig. 46 gives capacity-to-discharge rate for two standard-size lead-acid batteries. Capacity may vary from 35 mA hours for some of the small hearing-aid batteries to more than 100 ampere hours for a size 28 deep-cycle storage battery.

The primary cells, being sealed, usually benefit from intermittent (rather than continuous) use. The resting period allows completion of chemical reactions needed to dispose of by-products of the discharge.

All batteries will fall in output voltage as discharge proceeds. "Discharged" condition for a 12-V lead-acid battery, for instance, should not be less than 10.5 volts. It is also good to keep a running record of hydrometer readings, but the conventional readings of 1.265 charged and 1.100 discharged apply only to a long, low-rate discharge. Heavy loads may discharge the battery with little reduction in the hydrometer reading.

Batteries that become cold have less of their charge available, and some attempt to keep a battery warm before use is worthwhile. A battery may lose 70% or more of its capacity at cold extremes, but it will recover with warmth. All batteries have some tendency to freeze, but those with full charges are less susceptible. A full-charged lead-acid battery is safe to  $-30^{\circ}\text{F}$  ( $-26^{\circ}\text{C}$ ) or colder. Storage batteries may be warmed somewhat by charging. Blowtorches or other flame should never be used to heat any type of battery.

A practical limit of discharge occurs when the load will no longer operate satisfactorily on the lower output voltage near the "discharged" point. Much gear intended for "mobile" use may be designed for an average of 13.6 V and a peak of perhaps 15 V, but will not operate well below 12 V. For full use of battery charge, the gear should operate well (if not at full power) on as little as 10.5 V with a nominal 12 to 13.6-V rating.

Somewhat the same condition may be seen in the replacement of carbon-zinc cells by nickel-cadmium storage cells. Eight of the former will give 12 V, while 10 of the same size nickel-cadmium units are required for the same voltage. If a 10-cell battery holder is used, the equipment should be designed for 15 V in case the carbon-zinc units are plugged in.

Deep-cycle and nickel-cadmium storage batteries will tolerate a light continual charge (trickle). The sealed nickel-cadmium types tolerate a near-full charging rate continuously.

### Discharge Planning

Transceivers usually drain a battery at two or three rates: one for receiving, one for transmit standby and one for key-down or average voice transmit. Considering just the first and last of these (assuming the transmit standby equal to receive), average

two-way CW communication would require the low rate  $\frac{3}{4}$  of the time and the high rate  $\frac{1}{4}$  of the time. The ratio may vary somewhat with voice. The user may calculate the percentage of battery charge used in an hour by the combination (sum) of rates. If, for example, 20% of the battery capacity is used, the battery will provide five hours of communications per charge. In most actual traffic and DX-chasing situations the time spent listening should be much greater than that spent transmitting.

### Caring for Storage Batteries

In addition to the precautions given above, the following are recommended. (Your manufacturer's advice will probably be more applicable.)

Gas escaping from storage batteries may be explosive. Keep flame away.

Dry-charged storage batteries should be given electrolyte and allowed to soak for at least half an hour. They then should be charged at perhaps a 15 A rate for 15 minutes or so. The capacity of the battery will build up slightly for the first few cycles of charge and discharge, and then have fairly constant capacity for many cycles. Slow capacity decrease may then be noticed.

No battery should be subjected to unnecessary heat, vibration or physical shock. The battery should be kept clean. Frequent inspection for leaks is a good idea. Leaking or spraying electrolyte should be cleaned from the battery and surroundings. The electrolyte is chemically active and electrically conductive, and may ruin electrical equipment. Acid may be neutralized with sodium bicarbonate (baking soda), and alkalis may be neutralized with a weak acid such as vinegar. Both neutralizers will dissolve in water, and should be quickly washed off. Do not let any of the neutralizer enter the battery.

Keep a record of the battery usage, and include the last output voltage and (for lead-acid storage batteries) the hydrometer reading. This allows prediction of useful charge remaining, and the recharging or procuring of extra batteries, thus minimizing failure of battery power during an excursion or emergency.

### Charging Rechargeable Batteries

The rated full charge of a battery, C, is expressed in ampere-hours. No battery is perfect, so more charge than this must be offered to the battery for a full-charge. If, for instance, the charge rate is 0.1 C (the 10-hour rate), 12 or more hours may be needed for the charge.

Basically nickel-cadmium batteries differ from the lead-acid types in the methods of charging. It is important to note these differences, since improper charging can drastically shorten the life of a battery.

Nickel-cadmium cells have a flat voltage-vs.-charge characteristic until full charge is reached; at this point the charge voltage rises abruptly. With further charging, the

electrolyte begins to break down and oxygen gas is generated at the positive (nickel) electrode and hydrogen at the negative (cadmium) electrode.

Since the cell should be made capable of accepting an overcharge, battery manufacturers typically prevent the generation of hydrogen by increasing the capacity of the cadmium electrode. This allows the oxygen formed at the positive electrode to reach the metallic cadmium of the negative electrode and reoxidize it. During overcharge, therefore, the cell is in equilibrium. The positive electrode is fully charged and the negative electrode less than fully charged, so oxygen evolution and recombination "wastes" the charging power being supplied.

In order to ensure that all cells in a NiCd battery reach a fully charged condition, NiCd batteries should be charged by a constant current at about a 0.1 C current level. This level is about 50 mA for the AA-size cells used in most hand-held radios. This is the optimum rate for most NiCds since 0.1 C is high enough to provide a full charge, yet it is low enough to prevent overcharge damage and provide good charge efficiency.

Although fast-charge-rate (3 to 5 hours typically) chargers are available for hand-held transceivers, they should be used with care. The current delivered by these units is capable of causing the generation of large quantities of oxygen in a fully-charged cell. If the generation rate is greater than the oxygen recombination rate, pressure will build in the cell, forcing the vent to open and the oxygen to escape. This can eventually cause drying of the electrolyte, and then cell failure. The cell temperature can also rise, which can shorten cell life. To prevent overcharge from occurring, fast-rate chargers should have automatic charge-limiting circuitry which will switch or taper the changing current to a safe rate as the battery reaches a fully-charged state.

By contrast, the gelled-electrolyte lead-acid battery cannot tolerate overcharging, even at very low charge rates. For this reason, constant current or trickle charging should not be used for charging gel cells unless the battery voltage is monitored and charging is terminated when full charge is reached. Voltage-limited charging is best for these batteries. The proper charger would charge the battery at a safe current (C/10 or C/20) until a per-cell voltage of about 2.3 volts is reached (13.8 V for a 12-V battery). At this point, the charge current will taper to only enough to maintain the full-charge voltage. This makes the gel cell the optimum choice for "floating" across a regulated 13.8 volt power system to provide battery backup in the event of power failure.

Deep-cycle lead-acid cells are best charged at a slow rate, while automotive and some nickel-cadmium types may safely be given quick charges. This depends on the amount of heat generated within each

Fig. 47 — Solar-electric arrays are excellent for short- or long-term field and emergency use to power amateur stations. A 14-volt, 1.5-A solar panel and two automobile batteries in parallel can provide many after-dark hours of operation with typical 100-watt HF-band transceivers of the solid-state variety.

cell, and cell venting to prevent pressure build-up. Some batteries have built-in temperature sensing, used to stop or reduce charging before the heat rise becomes a danger. Quick and fast charges do not usually allow gas recombination, so some of the battery water will escape in the form of gas. If the water level falls below a certain point, acid hydrometer readings are no longer reliable. If the water level falls to plate level, permanent battery damage may result.

Overcharging in moderation causes little loss of battery life. However, continuous overcharge may generate a voltage depres-

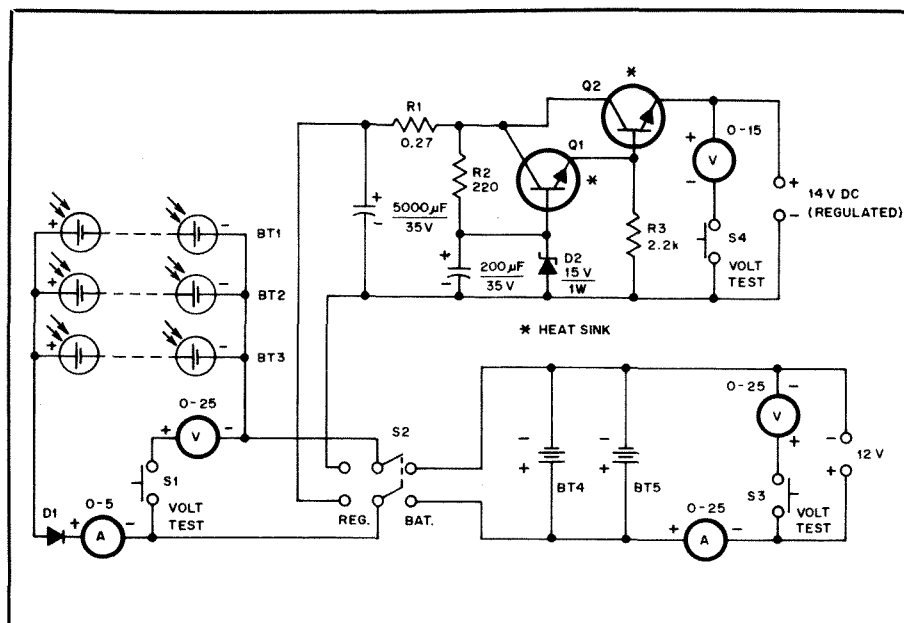

Fig. 48 — Schematic diagram of a solar power supply. Note that the battery-charging circuit does not employ a regulator or switch to shut off charging current once the storage battery reaches full charge state. Because the output of the solar panels is, at most, 1½ A and the storage batteries are full-size automobile batteries, the danger of damage from overcharging is not great. Anyone contemplating higher current solar batteries or smaller storage batteries should give serious consideration to a regulator and/or an automatic cutoff switch for the charging circuit. (See Fig. 49.)

sion when the cells are later discharged. For best results, charging of NiCd cells should be terminated after 15 hours at the slow rate. Better yet, circuitry may be included in the charger to stop charging, or reduce the current to about 0.02 C when the 1.43-V-per-cell terminal voltage is reached. For lead-acid batteries, a timer may be used to run the charger to make up for the recorded discharge, plus perhaps 20%. Some chargers will switch over automatically to an acceptable standby charge.

### SOLAR-ELECTRIC POWER

Although solar-electric arrays are quite expensive when purchased new, surplus individual cells and groups of cells (arrays) can be bought inexpensively on occasion. Photons from the sun strike the PN junctions of the cells to generate 0.5 volt per cell (see Chapter 4). The current rating of an individual cell is dependent upon the diameter of the cell. Typical production units deliver 100 mA, 600 mA, 1 A or

1.5 A. Cells with higher current ratings are manufactured, but are quite costly.

A solar-electric panel generally contains 36 cells wired in series. This provides approximately 18 volts dc under no-load conditions at peak sunlight. The current capability of the panel is determined by the diameter of the cells. Greater amounts of current output can be had by paralleling like panels. That is, two 1.5-A panels can be operated in parallel to deliver 3 amperes of current, and so on.

The usual operating system has the array output routed through a regulator to a storage battery. The regulator prevents overcharging of the battery. The station equipment takes its power from the battery. Most automotive 12-volt batteries are suitable for use with solar-electric panels. NiCd batteries are also satisfactory. Fig. 47 shows a solar array in a frame. The cells are wired in series.

Fig. 48 shows a solar-electric system suitable for low- or high-power operation.

If the current drain is less than the capacity of the solar bank (1.5 A in this case), the load can be powered from the solar cells through the regulator circuit. For heavier loads, the current is taken from the storage batteries, which are charged by the solar array. The circuit of Fig. 48 was designed by John Akiyama, W6PQZ, and was described by John Halliday, W5PIZ in August 1980 *QST*. In the same issue, Doug Blakeslee, N1RM, described an electronic switch to automatically disconnect storage batteries from a solar system when full charge (13.5 V) is reached. The circuit is shown in Fig. 49. U1, D4 and D5 establish a 6.2-V reference for comparator U2. A voltage divider composed of R1, R3 and R7 scales the battery voltage down to the reference value, while R4 provides hysteresis to prevent oscillation. When the battery potential exceeds the comparator threshold, U2 goes high, turning off Q1 and Q2. The LED, D6, indicates that the battery is being charged.

# Audio and Video

Of the five senses we humans possess — sight, smell, taste, hearing and feeling — three are used for communication. We communicate visually, through actions and through body language such as facial expressions. We communicate aurally, through speech. On occasion we may communicate through feeling by touching; a tap on the shoulder, for example. Aural and visual communications can be transmitted electronically, and are therefore pertinent to Amateur Radio. This chapter deals with the fundamentals involved.

### SPEECH

Human speech consists predominantly of two types of sounds — voiced and unvoiced. Voiced sounds originate when air passes from the speaker's lungs through the larynx (voice box), a passage in the human throat with the opening obstructed by vocal

cords. As air travels past these cords they vibrate, causing puffs of air to escape into the aural cavity, which consists of the throat, nasal cavity and mouth. Studies indicate that the acoustic waveform produced by the vocal cords has many harmonics of the fundamental vibration. Because of the irregular shape of the aural cavity, the spectral-amplitude distribution of the harmonics tends to show peaks at distinct points. As speech is produced, changes occur in the aural cavity shape, thus changing the spectral location of these peaks.

Fig. 1 shows a spectrogram or voice print of the utterance, "digital communications." The darkness of the bands indicates amplitude or voice strength. The fine structure of amplitude peaks very close together in the horizontal dimension is a measurement of vocal-cord vibration frequency or fundamental.

Notice the rather strong amplitude con-

centrations below 4000 Hz. These are the spectral peaks referred to above. They are called *formants*. The first three formants are shown in Fig. 1 at the beginning of the utterance. Fig. 1 also indicates a range of frequencies between the first and second formants, from approximately 600 to 1500 Hz, where little energy is present. This is identified in the figure as a spectral gap.

Unvoiced sounds in speech occur when there is no vocal track excitation. They are caused by the speaker using his or her tongue, lips and teeth to cause clicks, hisses and popping sounds. These sounds, or evidence of their occurrence by formant extensions into or from an unvoiced sound, are very important in the intelligibility of speech. The spectral amplitude distribution of unvoiced sounds is generally above 1500 Hz and is "noise-like" in that very little periodic structure is present.

One other important aspect of speech is

Fig. 1 — A speech spectrogram of the utterance, "digital communications." The vertical axis represents frequency (80-8000 Hz) and the horizontal axis represents time (0-1.5 seconds).

Fig. 2 — Long-time audio spectrum of speech. The horizontal scale is 1000 Hz per division or 0 to 5000 Hz. The vertical scale is 10 dB per division.

the pause between acoustic sounds. Juncture pauses carry meaning and cannot be eliminated without impairing intelligibility. Some long pauses can, however, be shortened and thereby reduce message length. Briefly, then, speech is the continuous production of voiced and unvoiced sounds with appropriate pauses to add clarity and distinctness.

### Frequency and Amplitude Considerations

Measurements of the voices of different persons indicate that the first three formants, identified in Fig. 1, lie predominantly below 2500 Hz. Speech consisting of these three formants is of good quality both from an intelligibility and listenability standpoint. Sufficient information as to the existence of some unvoiced sounds appears to lie in this range also. For example, to produce *s* or hissing sounds the frequency range must extend to about 4000 Hz. This is not usually required for intelligibility, however, since contextual clues provide sufficient evidence for the listener to “hear” an *s*.

Fig. 2 shows a long-time amplitude spectrum of speech. Note the presence of the first three formants, appearing as peaks in the pattern. Note also that speech components above 2500 Hz (mid-scale on the horizontal axis) are 20 to 25 dB lower than those below 2500 Hz. From a frequency point of view, evidence from theory and practice indicates a bandwidth of 300 to 2500 Hz is adequate for good-quality speech. This is a bandwidth of 2.2 kHz.

From an amplitude standpoint, tests conducted with single coherent tone interference indicate that a dynamic range of 40 dB is quite adequate for good-quality speech. This is reinforced by the information displayed in Fig. 2. Many communications channels allow only 10 to 30 dB of signal-to-noise ratio, so equipment designed to preserve more than 40 dB of dynamic range is not warranted.

### SOUND WAVES

Sound waves travel through the air at the

speed of approximately 1190 feet per second. They propagate as pressure waves, or alternating condensations and rarefactions of the air. The amplitudes of the pressure changes that make up sound waves from human speech are quite small. Sound power is measured in microjoules, a metric unit. One microjoule equals 10 ergs. When a sentence of a few words is spoken by a typical voice, the potential energy in the resultant sound wave is approximately 30 or 40 microjoules. Compare this to the  $10^8$  microjoules per second required to power a 100-watt lamp. It has been calculated that it would take 500 people talking continuously for a year to produce enough energy to heat a cup of tea. Because of the extremely low level of human speech, sensitive microphones and speech amplifiers are required in equipment intended for radio communications.

Sound intensity levels are ordinarily expressed in decibels. The reference level in power units for these decibel figures, established by the American Standards Association, is  $10^{-16}$  watt per square centimeter. This equates approximately to 0.0002 dyne per square centimeter in pressure units, a figure that is more commonly used. (There is variation in the precise relationship between power and pressure units because of temperature and atmospheric pressure changes. However, agreement between the above values will be within 1 dB under most conditions.) The sound intensity level in decibels is calculated from the usual equation, 10 times the common logarithm of the power ratio, while using  $10^{-16}$  watt per square centimeter as the reference. This is the same relationship as 20 times the logarithm of the pressure ratio.

Instruments are available to read sound pressure levels. These are calibrated in decibels, and are called sound level meters. Typical sound levels are 35 dB in a hospital, 40 dB in a classroom, 45 dB in offices, and 50 dB in banks, stores and restaurants. Intensity levels in factories may be as high as 80 dB.

Human speech intensities vary from one talker to another, and also vary for the same talker depending on the environment and distance between the talker and the listener. The average intensity level for talkers, both men and women, is 66 dB. Softer talkers speaking in conversational tones were measured to be as low as 54 dB, while loud talkers were as high as 75 dB. When one whispers the level is about 26 dB, while a loud shout produces an intensity level of about 86 dB. Thus, the human voice has a dynamic range of approximately 60 dB. These figures are for intensity levels averaged over a period of time. In actual speech, the instantaneous power varies from zero during pauses and intervals between words to peak values as high as 100 times the average value. Men tend to speak with greater intensity levels than women. There are other differences, too.

The pitch of a woman's voice is about one octave higher than that of a man, and a woman's voice is richer in frequencies above 3000 Hz.

### HEARING

Pressure variations in the sound wave produce mechanical vibrations in the eardrum. These vibrations are transmitted to the inner ear, where nerve endings are excited. The ear consists of three parts: the outer ear, the middle ear and the inner ear. The outer ear is the external portion and the auditory canal. The middle ear consists of the ear drum and three small bones that are linked mechanically to the cochlea in the inner ear. In the cochlea are the nerves that give us the sense of hearing. The inner ear also contains parts that have no function in the mechanism of hearing, but do serve as an organ of balance or equilibrium.

Every person has a threshold of hearing, a level below which he or she cannot detect any sound, and that threshold level is quite dependent on frequency. If the sound is a single-frequency tone, as is commonly used for acuity measurements, an intermittent tone can be heard at levels 10 to 20 dB below that for a continuous tone. Frequencies of 20 Hz and 20 kHz represent the probable limits of human hearing, although not many persons can hear sounds at these extremes. A person with acute hearing has a threshold of approximately 20 dB in the mid-frequency range, 2 to 3 kHz.

As a person becomes older, hearing acuity decreases, particularly for the high frequencies. The loss below 1 kHz is usually less than 10 dB, but the losses with age run from 10 dB at 40 years to 40 dB at 60 years. (These decibel losses are referenced to normal hearing.) Hearing losses also occur with continued exposure to very loud sounds. The loss is usually permanent with continued exposure to intensities in excess of 85 dB. Men hear low frequencies better than women at comparable ages, and women hear high frequencies better, with the range from 1.5 to 2 kHz being heard about equally well.

### MICROPHONES

A microphone is the transducer that converts sound waves into electrical energy. All voice transmissions begin with a microphone. Mics, as they are commonly called, have a number of basic characteristics including distortion, frequency response, impedance, output level, mechanical design, and directional or noise-canceling ability.

Distortion in a microphone refers to a nonlinear response to sound pressure waves. Distortion is not usually a problem in mics of modern design, except the carbon type.

### Frequency Response

The frequency response of a mic is the bandwidth over which it responds to sound waves. In amateur transmissions, only the portion of the speech band from about 200

to 3500 Hz needs to be transmitted for good intelligibility. Mics usually have bandwidths greater than this, so the speech amplifiers in transmitters are often designed to limit the audio bandwidth to the minimum necessary.

A microphone should have a response that is as uniform as possible over the desired speech range, but this is the most difficult microphone characteristic to achieve. The inexpensive types often have peaks and valleys in their response as much as 20 dB above and below the nominal output level. This peaky response will increase the peak-to-average ratio of the speech waveform, which reduces the average level of audio power transmitted.

Microphones are generally omnidirectional, responding to sound from all directions, or unidirectional, picking up sound from one direction. If a microphone is to be used close to the operator's mouth, an omnidirectional microphone is ideal. If, however, speech is generated a foot or more from the microphone, a unidirectional microphone will reduce reverberation by a factor of 1.7:1. Some types of unidirectional microphones have a proximity effect in that low frequencies are accentuated when the microphone is too close to the mouth.

### Impedance

A microphone is a voltage generator that has an optimum load impedance. Mics are available in two broad categories of impedance, high and low. The high-Z mics are used within a short distance of the transmitter, as the connecting cable cannot be made very long without compensation or matching transformers. Shielding of the microphone cable is necessary to prevent hum and noise pickup. The actual impedance of a "high-Z" mic will vary with manufacturer and type, but values between 100 k $\Omega$  and 500 k $\Omega$  are typical.

Low-Z microphones are sold in three popular impedances, 50, 150 and 600 ohms. The 50-ohm types are used by the commercial communications services, while the 150- and 600-ohm mics are usually found in broadcast, telephone and public address applications. The amateur's choice of mic impedance is usually dictated by the requirements of the transmitter, unless an impedance-matching transformer is used.

### Output Level

Related to impedance, output level varies widely with different types of microphones. There are several systems of specifying microphone output level in use, so direct comparison of various manufacturers' specifications can lead to erroneous conclusions. In addition, the test level, the reference level and the load impedances used in the specification of high-Z and low-Z mics are different, so the two cannot be compared directly.

The popular rating for high-Z microphones is the output voltage, expressed in

Fig. 3 — Simplified center chamber of a noise-canceling microphone.

decibels below 1 volt, measured across an open circuit with 1 dyne per square centimeter test signal at 1000 Hz applied to the microphone. Low-Z mics use a different system with the rating in output power, expressed in decibels below 1 milliwatt, measured across a 600-ohm load and using a test tone of 10 dynes per square centimeter at 1000 Hz. Several other test procedures are in use, so direct comparison of manufacturers' specifications will be valid only if the same measurement standards have been used.

### Noise Cancellation

Noise cancellation is the ability to cancel or reject noise while not attenuating the desired voice signal. A noise-canceling mic can be used to advantage in a noisy environment. The principle of noise cancellation (perhaps more properly called noise attenuation, as it is impossible to get rid of all noise) is quite simple.

See Fig. 3. The noise originating at some distant point enters the mic through two ports and is applied to both sides of the diaphragm. If the sound pressure is equal on both sides, the diaphragm will not move and the mic has no output. Speech is allowed to enter through only one port; the diaphragm moves in response to this sound pressure and output is produced. The shape of the diaphragm, the material it is made from, and the mounting are all important design considerations. A problem area is the tendency of the diaphragm to "lock up" under heavy noise pressure, distorting the desired speech signal. Considerable progress has been made in this area, and a good design will take very heavy noise without producing appreciable speech distortion.

The measurement of a mic's ability to attenuate noise is not standard, and most microphones or elements are sold simply with the label, "noise canceling," with no information on how well the mic actually cancels background noise. A good mic should attenuate noise by at least 20 dB across the speech band.

In noise-canceling mics designed for hand-held operation, the mic element itself must be physically small and light. This means the two sampling ports cannot be spaced very far apart. If the voice is allowed to enter both ports, it too will be at-

tenuated. For this reason, noise-canceling mics are inherently close-talk devices. They should be held within 1/2 inch of the lips for best results.

## TYPES OF MICROPHONES

Microphones are available in many types. Those commonly available or popular for amateur use are discussed in the sections that follow.

### Carbon Microphones

The carbon microphone consists of a metal diaphragm placed against a cup of loosely packed carbon granules. As the diaphragm is actuated by the sound pressure, it alternately compresses and decompresses the granules. When current is flowing through the element, a variable direct current corresponds to the movement of the diaphragm. The carbon mic is used almost universally by the telephone company, and until quite recently was quite popular with the military. Carbon elements are low impedance (usually between 30 and 80 ohms), and have very high output — 0.2 V or more, depending on the dc voltage across the element. They differ from most other popular types in that the transmitter (or some other source) must provide an operating voltage for the element. Practically, the voltage requirement limits the use of the element to transmitters designed for carbon mics.

The carbon mic has two principal disadvantages, a high level of distortion compared to other types and a problem when the element is exposed to moisture for long periods. Moisture in the element will pack the carbon granules together, reducing the output and increasing distortion. In some instances the element stops working altogether. The mic can sometimes be restored by heating it for several hours in the oven or with a sun lamp, and then tapping it lightly to loosen the granules.

### Piezoelectric Microphones

Piezoelectric microphones make use of the phenomenon by which certain materials produce a voltage by mechanical stress or distortion of the material. A diaphragm is coupled to a small bar of material such as Rochelle salt or ceramic made of barium titanate or lead zirconium titanate. The diaphragm motion is thus translated into electrical energy. These microphones are of high impedance. The Rochelle salt or crystal mic is of a fragile nature, and is susceptible to high temperatures, high humidity and extreme dryness. For this reason it is not suitable for mobile or portable work. A crystal mic has high output and a wide frequency response.

The ceramic type is impervious to temperature and humidity. This type has become very popular with manufacturers who supply mics with their amateur and CB transceivers. The reason is that the ceramics sell for low prices when mass produced. The impedance is high, and the output of

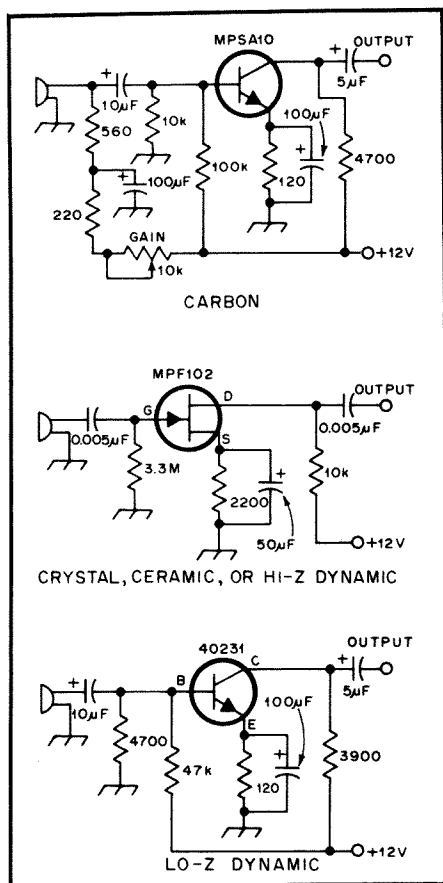

Fig. 4 — Speech circuits for use with standard-type microphones. Typical parts values are shown.

a modern ceramic microphone is generally enough to drive most popular rigs. However, a ceramic mic is a low-output device, and operation can be marginal with a transmitter that is lacking gain in the speech amplifier. An interesting characteristic of the ceramic microphone is that if it is terminated in a lower-than-optimum resistance (optimum being 100 k $\Omega$  to 250 k $\Omega$ ), the low-frequency output is attenuated — a simple way to eliminate the unwanted frequencies below 200 Hz. This frequency characteristic is also true of microphones made with Rochelle salts, another piezoelectric material.

Many of the inexpensive ceramic mics show the effects of mass production — excessive peaks in their frequency response. Manufacturers rate the nominal frequency response for these mics, but never mention the limits of deviation from the nominal output level. It is generally true that the cost of materials for all types of microphones is quite low unless put into a very fancy housing. The yield, testing, rework and retesting that a manufacturer goes through to ensure that a microphone meets a specified frequency response within specified limits is what adds up to the price of a “good” microphone.

#### Dynamic Microphones

The dynamic microphone resembles a

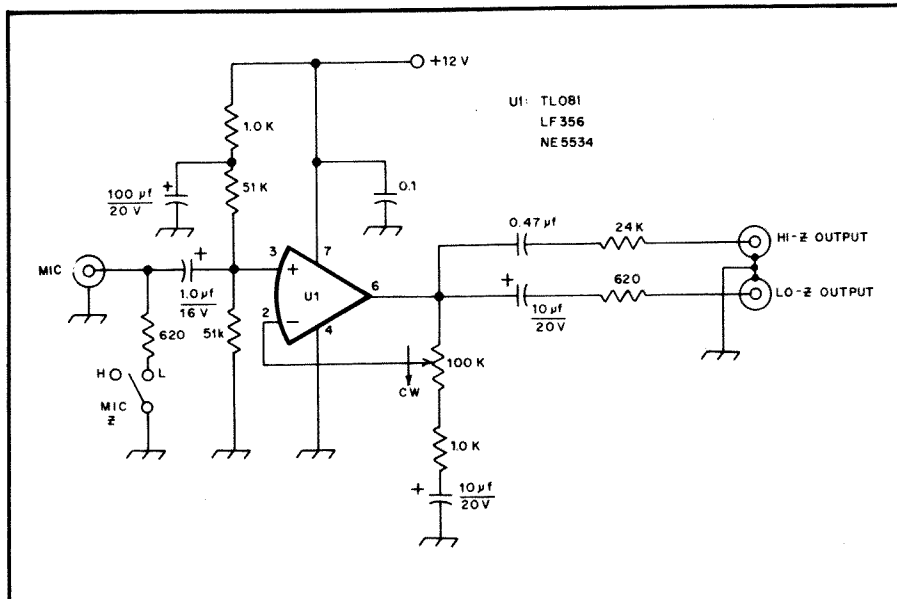

Fig. 5 — A speech amplifier suitable for microphone or interstage use. The input and output impedances can be tailored to match a wide range of loads. Maximum gain of this circuit is 40 dB.

dynamic loudspeaker. A lightweight coil, usually made of aluminum wire, is attached to a diaphragm. This coil is suspended in a magnetic field. When sound pressure impinges on the diaphragm, it moves the coil through the magnetic field, generating an alternating voltage. Dynamic mics are one of the most popular types for radio service. Dynamic elements are low impedance; matching transformers are built in if a high-Z output is desired.

Dynamics range all the way in price until they rival the cost of a communications receiver. The very expensive types are generally intended for recording and broadcast work. The dynamic element can be made noise canceling or directional. The mounting of the diaphragm is such that sound can easily be applied to both the front and the rear of the diaphragm to produce a desired pattern or effect. Because of its excellent speech quality and reliability, the military services have been changing over to this type of mic for use on field radio sets.

#### Electret Microphones

The electret microphone has recently appeared as a feasible alternative to the carbon, piezoelectric or dynamic microphone. An electret is an insulator that has a quasi-permanent static electric charge trapped in or on it. The electret operates in a condenser fashion, using a set of biased plates. Motion caused by air pressure variations creates a changing capacitance and an accompanying change in voltage. The electret acts as the plates would, and being charged, it requires no bias voltage. A low voltage provided by a battery used for an FET impedance converter is the only power required to produce an audio signal.

Electrets traditionally have been suscep-

tible to damage from high temperatures and high humidity. New materials and different charging techniques have lowered the chances of damage, however. Only in extreme conditions (such as 120 °F at 49% humidity) are problems present. The output level of a typical electret is higher than that of a standard dynamic microphone.

#### SPEECH AMPLIFIERS

The purpose of a speech amplifier is to raise the level of audio output from a microphone to that required by the modulator of a transmitter. In SSB and FM transmitters the modulation process takes place at low levels, so only a few volts of audio is necessary. One or two simple voltage-amplifier stages will suffice. AM transmitters often use high-level plate modulation requiring considerable audio power, compared to SSB and FM. The microphone-input and audio voltage-amplifier circuits are similar in all three types of phone transmitters, however.

When designing speech equipment it is necessary to know (1) the amount of audio power the modulation system must furnish, and (2) the output voltage developed by the microphone when it is spoken into from a normal distance with ordinary loudness. It then becomes possible to choose the number and type of amplifier stages needed to generate the required audio power without overloading or undue distortion anywhere in the system.

The circuit immediately following the audio input establishes the signal-to-noise ratio of the transmitter. General-purpose ICs such as 741 op amps are widely used in speech amplifiers, but they are fairly noisy, so it is best to precede them with a lower noise discrete device (FET or bipolar transistor). The circuits

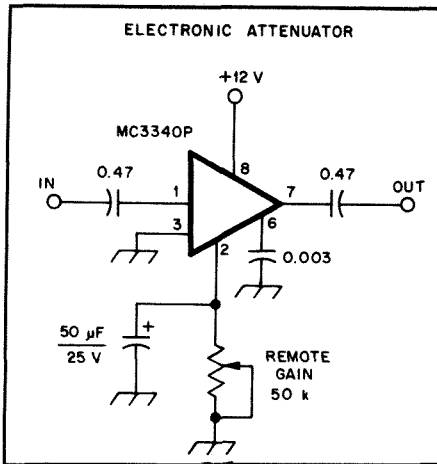

Fig. 6 — A dc voltage controls the gain of this IC, eliminating the need for shielded leads to the gain control.

in Fig. 4 fulfill this requirement.

### Voltage Amplifiers

The important characteristics of a voltage amplifier are its voltage gain, maximum undistorted output voltage and its frequency response. The voltage gain is the voltage-amplification ratio of the stage. The output voltage is the maximum AF voltage that can be obtained from the stage without distortion. The amplifier frequency response should be adequate for voice reproduction; this requirement is easily satisfied.

The voltage gain and maximum undistorted output voltage depend on the operating conditions of the amplifier. The output voltage is in terms of *peak* voltage, rather than RMS; this makes the rating independent of the waveform. Exceeding the peak value causes the waveform to distort, so it is more useful to consider only peak values in working with amplifiers.

A circuit suitable for use as a microphone preamplifier or the major gain block of a speech system is shown in Fig. 5. The response rolls off below 200 Hz to reduce hum pickup. Ordinary 741 op amps can be used in stages following the preamp, provided the voltage gain is held to about 20 (26 dB).

### Gain Control

A means for varying the overall gain of the amplifier is necessary for keeping the final output at the proper level for modulating the transmitter. The common method of controlling the gain is to adjust the value of ac voltage applied to the input of one of the amplifiers by means of a voltage divider or potentiometer.

The gain-control potentiometer should be near the input end of the amplifier, at a point where the signal voltage level is so low there is no danger that the stages ahead of the gain control will be overloaded by the full microphone output. In a high-gain amplifier it is best to operate the first stage

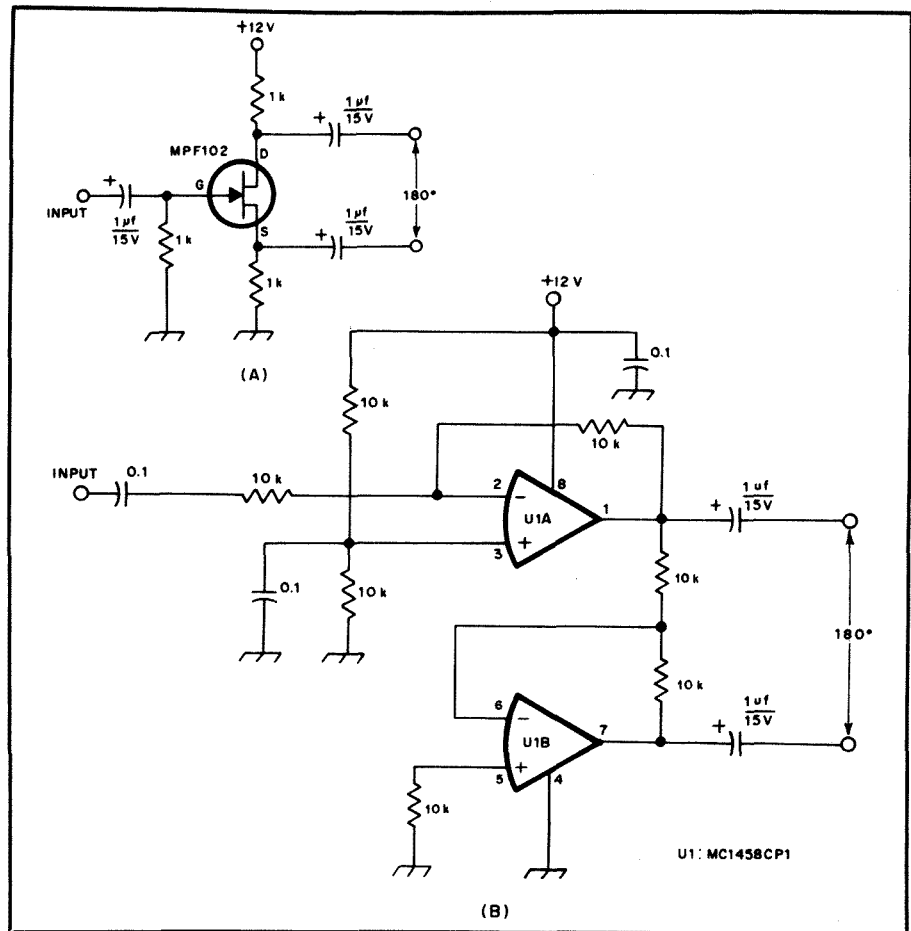

Fig. 7 — Phase splitter circuits using (A) a JFET and (B) a dual operational amplifier.

at maximum gain, since this gives the best signal-to-hum ratio. The control is usually placed in the input circuit of the second stage.

Remote gain control can be accomplished with an electronic attenuator IC, such as the Motorola MC3340P. A dc voltage varies the gain of the IC from +6 to -85 dB, eliminating the need for shielded leads to a remotely located volume control. A typical circuit is shown in Fig. 6.

### Phase Inversion

Some balanced modulators and phase shifters require push-pull audio input. The obvious way to obtain push-pull output from a single-ended stage is to use a transformer with a center-tapped secondary. Phase-inverter or phase-splitter circuits can accomplish the same task electronically. A differential amplifier can be used to convert a single-ended input to a push-pull output. Two additional phase-splitter circuits are shown in Fig. 7.

### Speech-Amplifier Construction

Once a suitable circuit has been selected for a speech amplifier, the construction problem resolves itself into avoiding two difficulties — excessive hum and unwanted feedback. For reasonably humless opera-

tion, the hum voltage should not exceed about one percent of the maximum audio output voltage — that is, the hum and noise should be at least 40 dB below the output level.

Unwanted feedback, if negative, will reduce the gain below the calculated value. If positive, feedback is likely to cause self-oscillation or howls. Feedback can be minimized by isolating each stage with decoupling resistors and capacitors, by avoiding layouts that bring the first and last stages near each other, and by shielding of "hot" points in the circuit, such as high-impedance leads in low-level stages.

If circuit-board construction is used, high-impedance leads should be kept as short as possible. All ground returns should be made to a common point. A good ground between the circuit board and the metal chassis is necessary. Complete shielding from RF energy is always required for low-level solid-state audio circuits. The microphone input should be decoupled for RF with a filter, as shown in Fig. 8. At A, an RF choke with a high impedance over the frequency range of the transmitter is used. For high-impedance inputs, a resistor may be used in place of the choke, shown in Fig. 8B.

When using paper capacitors as by-

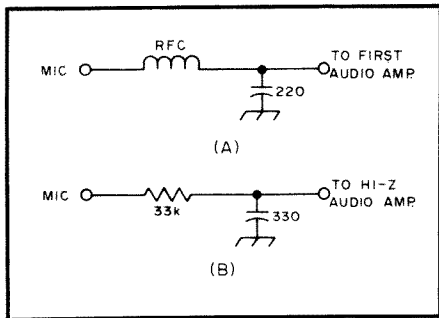

Fig. 8 — RF filters using LC components, A, and RC components, B. These filters are used to prevent feedback caused by RF pickup on the microphone lead.

passes, be sure the terminal marked “outside foil,” often indicated with a black band, is connected to ground. This utilizes the outside foil of the capacitor as a shield around the “hot” foil. When paper or Mylar capacitors are used for coupling between stages, always connect the outside foil terminal to the side of the circuit having the lower impedance to ground.

#### Driver and Output Stages

Commonly used balanced modulators and transmitting mixers have power outputs too low for consistently effective communications. Most modern grounded-grid linear amplifiers require 30 to 100 watts of exciter output power to drive them to their rated power output. An exciter output amplifier serves to boost the output power to a useful level while providing additional selectivity to reject spurious mixing products.

Two stages are usually required to obtain the necessary power. The stage preceding the output amplifier is called the driver. Some tubes that work well as drivers are the 6CL6, 12BY7, 6EH7 and 6GK6. Since all of these tubes are capable of high gain, instability is sometimes encountered in their use. Parasitic suppression should be included as a matter of course. Some form of neutralization is recommended. Driver stages should be operated in Class A or AB1 to minimize distortion. The higher quiescent dissipation can be handled easily at these power levels. VMOS power FETs are also well suited to SSB driver circuits.

#### SPEECH PROCESSING

Four basic systems, or a combination thereof, can be used to reduce the peak-to-average ratio, and thus raise the average power level of an SSB signal. They are compression or clipping of the AF wave before it reaches the balanced modulator, and compression or clipping of the RF waveform after the SSB signal has been generated. One form of RF compression, commonly called automatic level control or ALC, is used almost universally in amateur SSB transmitters. Audio processing is also

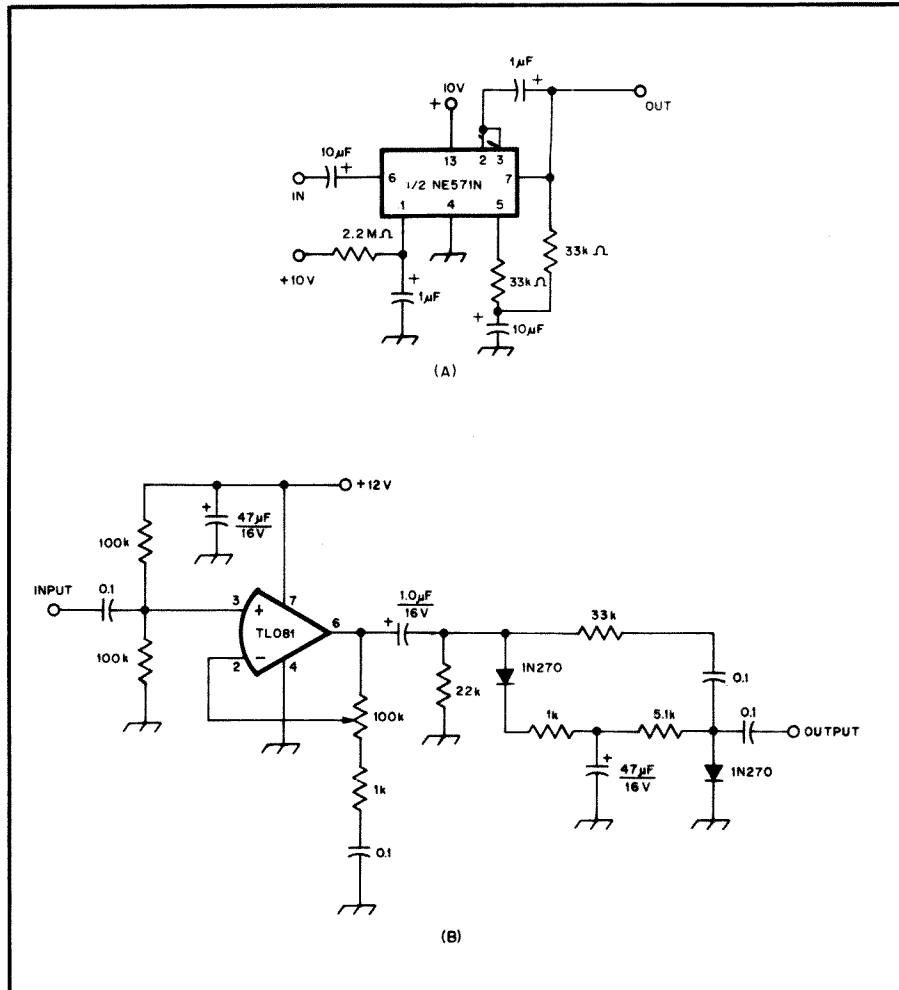

Fig. 9 — Typical solid-state compressor circuits. The circuit at A works on the AGC principle, while that at B is a forward-acting compressor.

used to increase the level of audio power contained in the sidebands of an AM transmitter and to maintain constant deviation in an FM transmitter. Both compression and clipping are used in AM systems, while most FM transmitters employ only clipping.

#### Volume Compression

Although it is obviously desirable to keep the voice level as high as possible, it is difficult to maintain constant voice intensity when speaking into the microphone. To overcome this variable output level, it is possible to use automatic gain control that follows the *average* (not instantaneous) variations in speech amplitude. This can be done by rectifying and filtering some of the audio output and applying the resultant dc to a control electrode in an early stage in the amplifier.

The circuit of Fig. 9A works on this AGC principle. One section of a Signetics NE571N IC is used. The other section can be connected as an expander to restore the dynamic range of received signals that have been compressed in transmission. Operational transconductance amplifier ICs such

as the CA3080 are also well suited for speech-compression service.

When an audio AGC circuit derives control voltage from the output signal, the system is a closed loop. If short attack time is necessary, the rectifier-filter bandwidth must be opened up to allow syllabic modulation of the control voltage. This allows some of the voice-frequency signal to enter the control terminal, causing distortion and instability. Because the syllabic frequency and speech-tone frequencies have relatively small separation, the simpler feedback AGC systems compromise fidelity for fast response.

Problems with loop dynamics in audio AGC systems can be sidestepped by eliminating the loop and using a forward-acting system. The control voltage is derived from the *input* of the amplifier, rather than from the output. Eliminating the feedback loop allows unconditional stability, but the trade-off between response time and fidelity remains. Care must be taken to avoid excessive gain between the signal input and control voltage output. Otherwise, the transfer characteristic can reverse; that is, an increase in input level can cause a

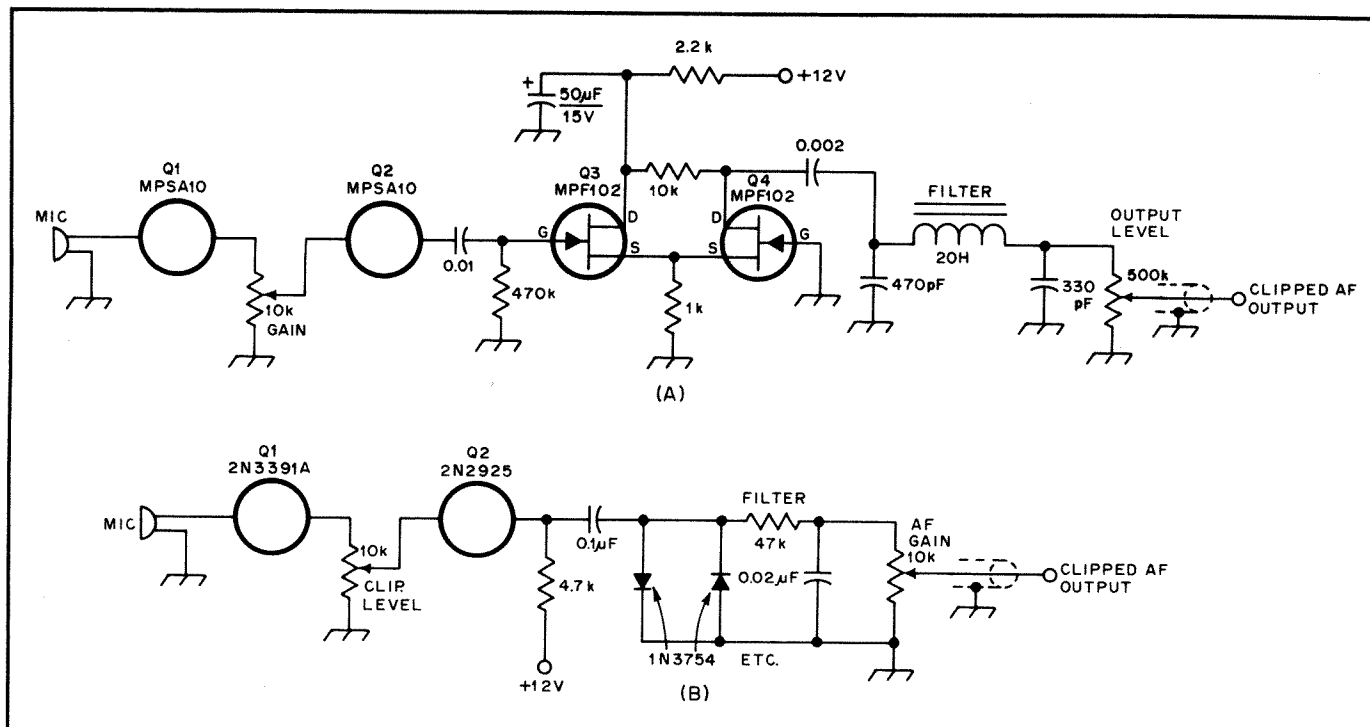

Fig. 10 — This diagram illustrates the use of JFETs or silicon diodes to clip positive and negative voice peaks.

decrease in output. A simple forward-acting compressor is shown in Fig. 9B.

To test or adjust a speech compressor, one would apply a single steady tone to the input and measure the input and output signal levels over the dynamic range of the instrument. The single-tone test may indicate gross distortion, but one cannot judge the speech performance by this result. Provided the release time is longer than the time between syllables, the compressor will generate distortion only during brief signal peaks.

### Speech Clipping and Filtering

In speech waveforms the average power content is considerably less than in a sine wave of the same peak amplitude. If the high amplitude peaks are clipped off, the remaining waveform will have a considerably higher ratio of average power to peak amplitude. Although clipping distorts the waveform and the result therefore does not sound exactly like the original, it is possible to obtain a worthwhile increase in audio power without sacrificing intelligibility. Once the system is properly adjusted it will be impossible to overdrive the modulator stage of the transmitter because the maximum output amplitude is fixed.

By itself, clipping generates high-order harmonics and therefore will cause splatter. To prevent this, the audio frequencies above those needed for intelligible speech must be filtered out after clipping and before modulation. The filter required for this purpose should have relatively little attenuation below about 2500 Hz, but high attenuation for all frequencies above 3000 Hz.

There is a loss in naturalness with "deep" clipping, even though the voice is highly intelligible. With moderate clipping levels (6 to 12 dB) there is almost no change in "quality" but the voice power is increased considerably.

Before drastic clipping can be used, the speech signal must be amplified several times more than is necessary for normal modulation. Also the hum and noise must be much lower than the tolerable level in ordinary amplification, because the noise in the output of the amplifier increases in proportion to the gain.

In the circuit of Fig. 10B a simple diode clipper is shown following a two-transistor preamplifier section. The 1N3754s conduct at approximately 0.7 volt of audio and provide positive- and negative-peak clipping of the speech waveform. A 47-kΩ resistor and a 0.02-μF capacitor follow the clipper to form a simple RC filter for attenuating the high-frequency components generated by the clipping action, as discussed earlier. Any silicon diodes may be used in place of the 1N3754s. Germanium diodes (type 1N34A) can also be used, but will clip at a slightly lower peak audio level.

### SSB Speech Processing

Compression and clipping are related, as both have fast attack times. And when the compressor release is made quite short, the effect on the waveform approaches that of clipping. Speech processing is most effective when accomplished at radio frequencies, although a combination of AF clipping and compression can produce worthwhile results. The advantage of an out-board audio speech processor is that no in-

ternal modifications are necessary to the SSB transmitter with which it will be used.

To understand the effect of SSB speech processing, consider that basic RF waveforms without processing have high peaks but low average power. With proper processing, the amount of average power is raised considerably. Fig. 11 shows a comparison of received signal-to-noise ratio with different forms of signal processing. An advantage of several decibels for RF clipping (for 20 dB of processing) is shown over any other type of processing.

Investigations by W6JES, reported in January 1969 *QST*, showed that, for a transmitted signal using 15 dB of audio clipping from a remote receiver, the intelligibility threshold was improved nearly 4 dB over a signal with no clipping. Increasing the AF clipping level to 25 dB gave an additional 1.5 dB improvement in intelligibility. Audio compression was found to be valuable for maintaining relatively con-

Fig. 11 — The improvement in received signal-to-noise ratio obtained by the simple forms of signal processing.

Fig. 12 — Two-tone envelope patterns with various degrees of RF clipping. All envelope patterns are formed using tones of 600 and 1000 Hz. At A, clipping threshold; B, 5 dB of clipping; C, 10 dB of clipping; D, 15 dB of clipping.

stant average-volume speech, but such a compressor added little to the intelligibility threshold at the receiver — only about 1 to 2 dB.

Evaluation of RF clipping from the receive side with constant-level speech, and filtering to restore the original bandwidth, resulted in an improved intelligibility threshold of 4.5 dB with 10 dB of clipping. Raising the clipping level to 18 dB gave an additional 4 dB improvement at the receiver, or 8.5 dB total increase. The improvement of the intelligibility of a weak SSB signal at a distant receiver can thus be substantially improved by RF clipping. The effect of such clipping on a two-tone test pattern is shown in Fig. 12.

Automatic level control, although a form of RF speech processing, has found its primary application in maintaining the

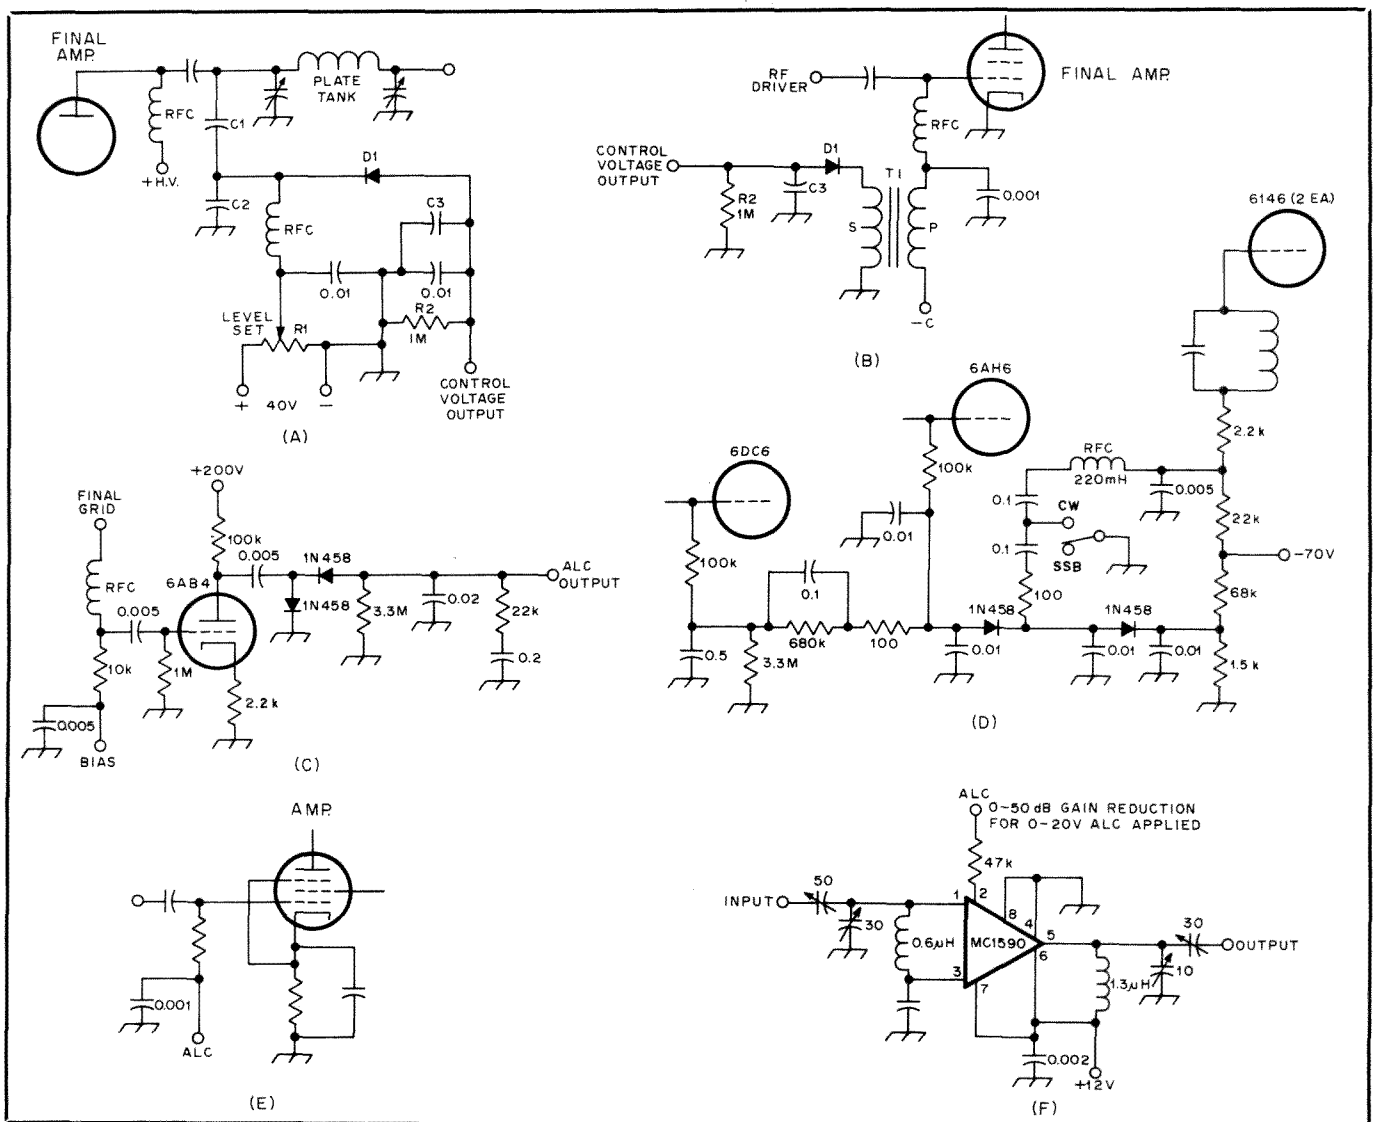

Fig. 13 — At A, control voltage obtained by sampling the RF output voltage of the final amplifier. The diode back bias, 40 volts or so maximum, may be taken from any convenient positive voltage source in the transmitter. R may be a linear control having a maximum resistance on the order of 50 k $\Omega$ . D1 may be a 1N34A or similar germanium diode.

At B, control voltage obtained from the grid circuit of a Class AB1 tetode amplifier. T1 is an interstage audio transformer having a turns ratio, secondary to primary, of 2 or 3 to 1. An inexpensive transformer may be used, since the primary and secondary currents are negligible. D1 may be a 1N34A or similar type. Time constant R2-C3 is discussed in the text.

At C, control voltage is obtained from the grid of a Class AB1 tetode amplifier and amplified by a triode audio stage.

At D, ALC system used in the Collins 32S-3 transmitter. At E, applying control voltage to the tube or, at F, to the linear IC-controlled amplifier.

peak RF output of an SSB transmitter at a relatively constant level, desirably below the point at which the final amplifier is overdriven during peaks in the audio input. These typical ALC systems, shown in Fig. 13, by the nature of their design time constants offer a limited increase in the ratio of transmitted average power to peak envelope power. A value in the region of 2 to 5 dB is typical. An ALC circuit with shorter time constants will function as an RF syllabic compressor, producing up to 6 dB improvement in the intelligibility threshold at a distant receiver. The Collins Radio Company used an ALC system with dual time constants (Fig. 13D) in their S/Line transmitters, and this has proved to be quite effective.

Heat is an extremely important consideration in the use of any speech processor that increases the ratio of average to peak power. Many transmitters, in particular those using television sweep tubes, simply are not built to withstand the effects of increased average input, either in the final-amplifier tube(s) or in the power supply. If heating in the final tube is the limiting factor, adding a cooling fan may be a satisfactory answer.

### Compondoring

Compressing the audio signal prior to modulation for more efficient use of the transmitter power has been widely used by amateurs. However, by compressing only the amplitude peaks, background noise increases relative to the peaks. A significant advantage can be obtained by expanding the compressed audio at the receiver. The term "compondor" is a fusion of the terms "compressor" and "expandor." The positive effects of compounding are illustrated in Fig. 14. A short segment of the speech time waveform is shown in Fig. 14A. When compressed and transmitted, this waveform becomes noisy because of compression, and also from the added circuit and radio channel noise. This is shown in Fig. 14B. Notice the increased noise between the two passages of speech. After the waveform is processed by an amplitude expander (the receiving portion of an amplitude compandor), the waveform appears as shown in Fig. 14C. The noise during the quiet passage has been reduced relative to the high-level passages. Although the S/N ratio during the loud passage is not as good as the input waveform, the ratio for the overall passage is much better than it would be without expansion. Noise during loud passages is not nearly as objectionable as noise between passages of speech.

Using a two-to-one amplitude compandor\* (Signetics NE571N), tests performed for the FCC indicated a measurable 12- to 15-dB improvement with a full

amplitude compandor (compression on transmit and expansion on receive). When only compression was used, significant S/N ratio reduction resulted, even though a higher average transmitter power was being used.

An amplitude expander circuit is shown in Fig. 15. It is important to realize that the amplitude compandor will improve the S/N ratio, but only when sufficient signal is present for use as a reference. Thus, it has a thresholding effect. As long as the received signal is a few decibels above the noise, the expander can expand on the basis of the reference to provide a communications channel with a cleaner signal over a wider dynamic range. However, when the signal level drops into the noise, the expander will not operate properly. The S/N improvement is limited, but the improvement over the useful range is worthwhile. If we consider that a certain S/N ratio and corresponding voice quality were required, use of an amplitude compandor would allow the achievement of this goal with less transmitter power. In this respect the amplitude compandor can achieve the same quality S/N ratio with 12-15 dB less transmitted power. This is a significant power savings and can have a definite impact on the quality of communications per watt of transmitter power.

### Amplitude-Companded Single Sideband

Work has been taking place to develop an amplitude-companded single-sideband system (ACSSB) in the land-mobile communications industry. The purpose is to reduce the spectrum requirements per channel from that presently required for FM. Ordinary SSB operation was not found to be satisfactory for operators who were accustomed to noise-free FM and who were not trained communicators. The "clarifier" or receiver incremental tuning control was a nuisance, as was signal fading that never occurred on FM. So to get the spectrum savings of SSB over FM, the engineers have come up with a system that gives the land mobile users everything they are accustomed to with FM, including signaling.

A conventional SSB transmission has a suppressed carrier. In order to demodulate the signal at the receiver, the missing carrier must be replaced. At the higher frequencies this becomes difficult. In ACSSB, a pilot tone is added to the audio, sufficiently separated in frequency and filtered so the two do not interfere. Although there is some variation among manufacturers, the pilot tone is usually 3 or 3.1 kHz. The pilot power level is about 10 dB below the voice peak power. Thus, with no voice modulation the transmitter has an output power of approximately 1/10th that when there is voice modulation.

At the receiver, the pilot tone is compared with an internal reference oscillator in a phase-locked loop circuit. The difference voltage thus produced is used to

Fig. 14 — Speech waveforms for the amplitude compandor, showing amplitude (vertical axis) vs. time, *t*. At A is the input waveform, at B the compressed waveform with additional circuit noise as might be received, and at C the expanded waveform. Note the improvement in signal-to-noise ratio upon expansion after reception.

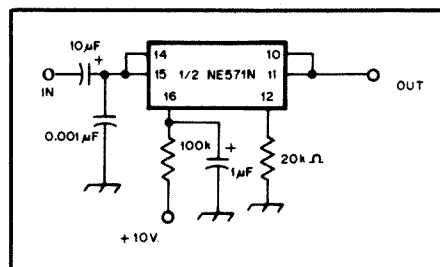

Fig. 15 — Amplitude expander circuit.

shift the receiver local oscillator until the frequency error is eliminated. The time constant of the phase-locked loop is short enough to be ignored by the user and to be compatible with tone decoders used for signal purposes.

The compandor thresholding effect provides an operator with a sensation similar to the capture effect in FM. Thus, when the signal strengths are high, FM and ACSSB give comparable results with noticeably less flutter on ACSSB than on FM.

ACSSB is a means of packing about four times more voice transmissions in a given band than FM. The pilot tones and compandoring compensate for some inherent SSB shortcomings, but with additional complexity. This appears to be an area for Amateur Radio experimentation.

### MORSE CODE

Previous sections have been concerned

\*A two-to-one amplitude compandor yields a compression of 1 dB out for every 2 dB in and an expansion of 2 dB out for every 1 dB in.

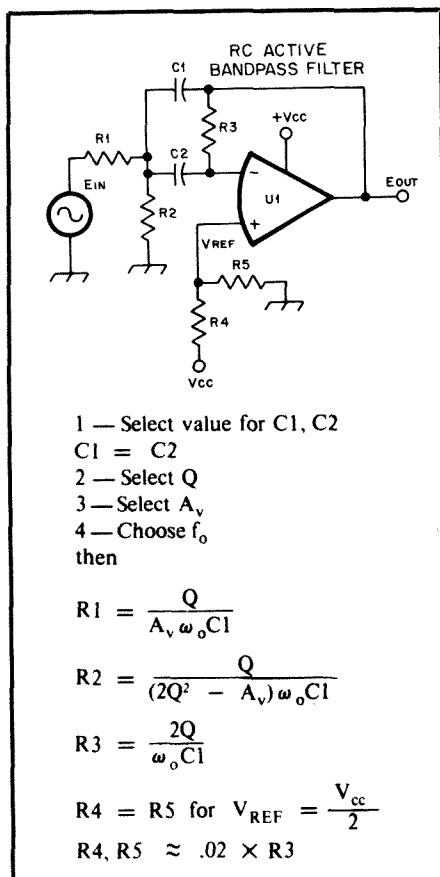

Fig. 16 — Basic circuit for an RC active band-pass filter. One pole is shown along with the fundamental equations for finding the resistance values needed.

primarily with voice communications, but Morse code is equally important in Amateur Radio. With computers or other logic circuits, Morse code can be copied by machine to present a visual display of the text being received, but by far the majority of operators copy code "by ear." To do this, of course, it is necessary to *hear* the received code.

Most operators prefer to receive code signals in a frequency range from 500 to 800 Hz. The ear is better able to distinguish two tones of fixed frequency separation at low pitch rather than at higher pitches. In other words, if an undesired signal is present at a frequency 200 Hz removed from a desired signal, the ear can better distinguish the desired signal if the tones are 500 Hz and 700 Hz, instead of 1100 and 1300 Hz. Thus, the ear is its own form of selective filter. For this reason, some operators prefer to adjust the receiver tuning for lower pitches yet, in the order of 200 to 300 Hz for the desired signal.

Morse code signals occupy significantly less bandwidth than do voice signals. Therefore, a much narrower filter may be used for code reception than is possible for receiving voice transmissions. Decreasing the received bandwidth improves the signal-to-noise ratio under a given set of conditions, as well as improving the selectivity.

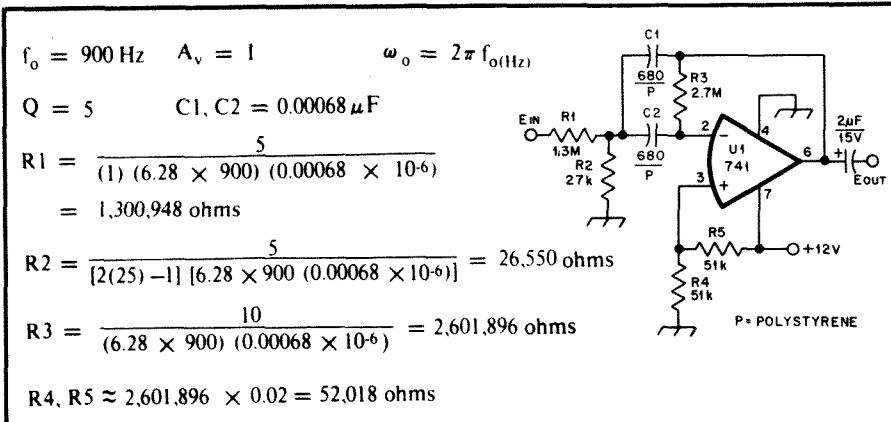

Fig. 17 — A design example based on the circuit of Fig. 16.

If a receiver lacks IF selectivity, an out-board filter may be used ahead of the speaker or headphones.

### Op Amps as Audio Filters

One of the more common uses to which operational amplifiers (op amps) are put can be seen in the RC active audio-filter field. Op amps have the distinct advantage of providing gain and variable parameters when used as audio filters. Passive filters that contain L and C elements are generally committed to some fixed frequency, and they exhibit an insertion loss. Finally, op amps contribute to the attainment of miniaturization that is seldom possible with bulky inductors in a passive type of audio filter.

Although RC active filters can be built with bipolar transistors, the modern approach is to use operational amplifiers. The use of an op-amp IC, such as a type 741, results in a compact filter pole that will provide stable operation. Only five connections are made to the IC, and the gain of the filter section, plus the frequency characteristic, is determined by the choice of components external to the IC.

Although there are numerous applications for RC active filters, their principal use in amateur work is that of establishing selectivity at audio frequencies. One or two poles may be used as a band-pass or low-pass section for improving the passband characteristics during SSB or AM reception. Up to four filter poles are frequently used to acquire selectivity for CW or RTTY reception. The greater the number of poles, up to a practical limit, the sharper the skirt response of the filter. Not only does a well-designed RC filter help to reduce QRM, but it improves the signal-to-noise ratio in some receiving systems.

Considerable design data is found in the National Semiconductor Corp. application note. A thorough treatment of Norton amplifiers is given, centering on the LM3900 current-differencing type of op amp. Design information is included for high-, low- and band-pass types of RC active audio filters. The simplified design data

presented here are based on the technique used in AN72-15.

Fig. 16 shows a single band-pass filter pole and gives the equations for obtaining the desired values for the resistors if the gain, Q,  $f_o$  and C1-C2 values are chosen. C1 and C2 are equal in value and should be high-Q, temperature-stable components. Polystyrene capacitors are excellent for use in this part of the circuit. Disc-ceramic capacitors *are not recommended*. R4 and R5 are equal in value and are used to establish the op-amp reference voltage. This is  $V_{cc}/2$ .

C1 and C2 should be standard values of capacitance. The filter design is less complicated when C1 and C2 serve as the starting point for the equations. Otherwise some awkward values for C1 and C2 might result. The resistance values can be "fudged" to the nearest standard value after the equations have been worked. The important consideration is that matched values must be used when more than one filter pole is employed. For most amateur work it will be satisfactory to use five percent,  $\frac{1}{2}$ -watt, composition resistors. If the resistor and capacitor values are not held reasonably tight in tolerance for a multipole filter, the  $f_o$  for each pole may be different, however slight. The result is a wide nose for the response, or even some objectionable passband ripple.

Fig. 17 illustrates the design of a single-pole band-pass filter. An arbitrary  $f_o$  of 900 Hz has been specified, but for CW reception the operator may prefer something much lower — 200 to 700 Hz. An  $A_v$  (gain) of 1 (unity) and a Q of 5 are stated. Both the gain and the Q can be increased for a single-section filter if desired, but for a multisection RC active filter it is best to restrict the gain to 1 or 2 and use a maximum Q of 5. This will help prevent unwanted filter "ringing" and audio instability.

C1 and C2 are 680-pF polystyrene capacitors. Other standard values can be used from, say, 500 to 2000 pF. The limiting factor will be the resultant resistor values. For certain design parameters and

C1-C2 values, unwieldy resistance values may result from the equations. If this happens, select a new value for C1 and C2.

The resistance values assigned to R1 through R5, inclusive, are the nearest standard values to those obtained from the equations. The principal effect from this is a slight alteration of  $f_o$  and  $A_v$ .

In a practical application the RC active filter should be inserted in the low-level audio stages. This will prevent overloading the filter during the reception of strong signals. The receiver AF gain control should be used between the audio preamplifier and the input of the RC active filter for best results. If audio-derived AGC is used in the receiver, the RC active filter will give best performance when it is contained within the AGC loop. Information on other types of active filters is given by Bloom in July 1980 *QST*.

## LOUDSPEAKERS AND HEADPHONES

The counterpart for the microphone at the transmitter is the loudspeaker or headphones at the receiver. These devices are transducers that convert electrical energy into vibrations of a diaphragm, thereby setting up sound waves.

Dynamic loudspeakers, or simply speakers, use a diaphragm of heavy paper or other thin material. This diaphragm is

formed in the shape of a shallow cone, with its rim attached to the speaker frame. At the apex of the cone is a small core on which a coil of fine wire is wound. The core and the coil are free to move, and are suspended in the field of a permanent magnet. When a direct current is passed through the coil, the apex of the cone or diaphragm is deflected in one direction. When the current is removed, the diaphragm returns to its resting position. A direct current of the opposite polarity will deflect the diaphragm in the opposite direction. An alternating current causes the diaphragm to move back and forth at the frequency of the current and thereby set up sound waves, assuming the frequency is not too high for the diaphragm to follow.

Speakers are available from an inch or less to many inches in diameter. The larger speakers are more efficient at reproducing lower frequencies. For the best audio quality, a speaker should be mounted in a cabinet or some form of baffle. Even a good quality speaker, if operated in open air, will have a "tinny" sound — reproducing only intermediate frequencies. Low frequencies will be conspicuously absent. A baffle or cabinet serves to reinforce or enhance the low frequencies. Small speakers mounted at the bottom of a small chassis leave something to be desired also

when it comes to audio fidelity.

Commonly available loudspeakers are designed with an impedance in the range of 4 to 16  $\Omega$ . Another impedance range available is 45  $\Omega$ ; speakers in this range are often used in intercommunication stations. In this application the speaker doubles as a microphone for talking — sound pressure waves move the diaphragm and the attached coil in the magnetic field, thereby inducing a voltage into the coil.

Headphones operate on the same general principle as dynamic speakers. In fact, some high-quality headsets for hi-fi or stereo listening use small dynamic speakers. A thin, flat, metal diaphragm is used in most headsets. In operation the diaphragm is set in motion by a varying magnetic field caused by current flowing through the headset coils, which are wound on a magnetic core. Headphone impedances of 4 to 8  $\Omega$  are the most popular because a reasonable amount of power can be coupled to the phones with relatively low audio voltages. Headphones are also available in an impedance range of 500 to 600  $\Omega$ , and in the 2000- $\Omega$  range. Those in the 2000- $\Omega$  range are referred to as high-impedance headphones. They may be operated with relatively low currents, but do require a higher voltage amplitude than phones of lower impedance.

## Video

For the sighted, much human communication is visual. In personal communication we watch faces, hands and bodies for visual cues and clues. Your grandparents used to listen to the radio — today the family watches television. Several hours a day is average. Visual communication is a part of Amateur Radio.

*QST* began carrying articles on TV in 1925. Those early experiments used crude mechanical methods. Nevertheless, radio amateurs were transmitting pictures. As early as 1928 a *QST* author pointed out the possibility of electronic television. The days

of the motor-driven scanning disc were numbered. Introduction of the moderately priced iconoscope in 1940 made electronic television a practical reality for the amateur. By 1960, amateurs were transmitting color-TV signals.

### Vision

Light is physical energy in the form of electromagnetic radiation. The visible light range falls between microwaves and X rays, as shown in Fig. 18. The human eye is sensitive to only a relatively narrow band of electromagnetic radiation. That band falls between the wavelengths of 400 and 720 nanometers, approximately.

Solar radiation contains all the visible wavelengths. Other light sources have different wavelength distributions. Incandescent sources tend to have more orange or yellow light; fluorescent light tends to be more bluish.

Physical objects selectively absorb light energy. Reflected light, therefore, has a different energy distribution than that of the original light. It is that difference that makes vision possible. Differences in reflected light account for the perception of brightness, texture and color.

Light enters the eye, and is focused by the lens onto the retina. The amount of light entering the eye is controlled by the

iris. See Fig. 19. Two types of light sensors make up the retina — rods and cones.

Rods are sensitive only to black, white and shades of gray. Cones allow us to perceive color. Rods are more sensitive than cones — that is they work at lower light levels. That is why we can see color in the sky at twilight or dawn, but we can only perceive black, white and gray for the objects on the ground about us. The rela-

Fig. 18 — The electromagnetic spectrum from VHF to gamma rays.

Fig. 19 — Cross-sectional view of the human eye. The retina contains rods and cones (see text). There are neither rods nor cones in the blind spot — that is where the optic nerve enters the eye.

Fig. 20 — Relative sensitivity of the human eye to light at various wavelengths.

Fig. 21 — The three primary colors are red, green and blue. The primaries combine, two at a time, to form the secondary colors, yellow, cyan and magenta. White is a combination of red, green and blue.

Fig. 22 — A picture can be described by dividing it into parts and then describing the parts.

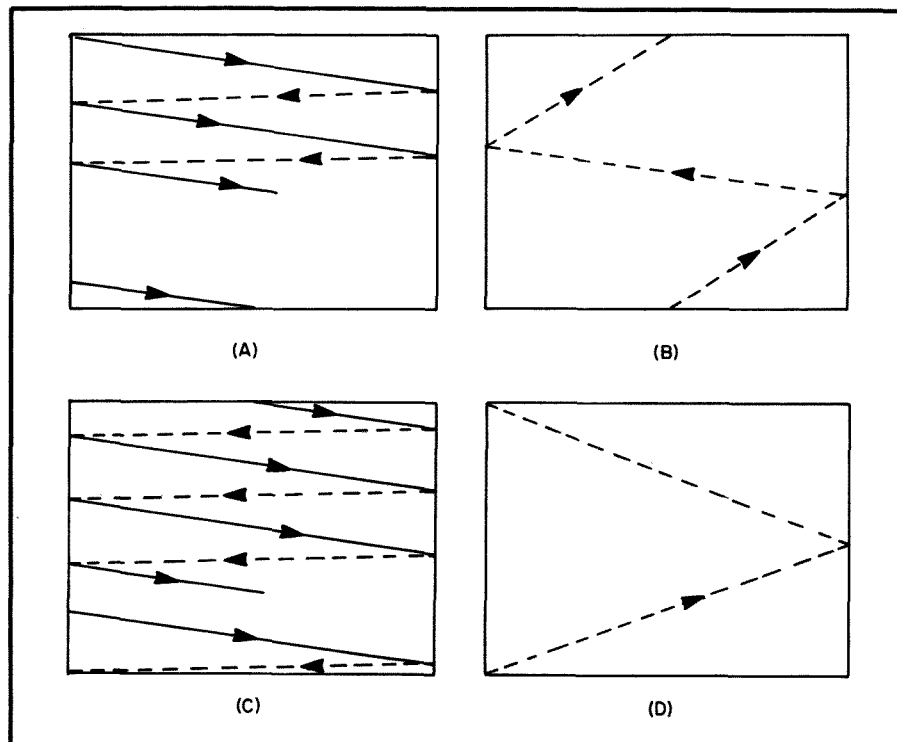

Fig. 23 — Interlaced scanning as used in TV. In field one, 262½ lines are scanned (A). At the end of field one, the electron scanning beam is returned to the top of the picture area (B). Scanning lines in field two (C) fall between the lines of field one. At the end of field two, the scanning beam is again returned to the top where scanning continues with field one (D).

tive sensitivity of the human eye to light varies with wavelength. See Fig. 20.

## Color

Impulses from the rods and cones in the retina travel along the optic nerve to the central nervous system. There the impulses are “seen” as light and color. Any number of different energy distribution combinations may be perceived as the same color. The eyes do not sort out wavelengths like a prism. Cones are of three “kinds”; each kind being more sensitive to light in a particular portion of the visible spectrum. The areas of sensitivity are known as red, blue and green light. Color is not a property of the electromagnetic energy that we call light. Rather, color is a psychological experience and a perceptual response to that energy.

It is possible to reproduce any color by combining in proper proportions three primary colors. The primaries are red, green and blue, as shown in Fig. 21. Combinations of equal amounts of two of the primaries form the secondary colors: yellow, cyan and magenta. White is a combination of all three primaries in the proper proportions.

Combining light is an additive process. A green light and a red light falling on a white wall make a yellow glow. This should not be confused with paints or pigments — they combine in a subtractive process.

This trichromatic system of color perception makes the transmission of color TV pictures possible. Light from the scene being transmitted is separated into red, green and blue components. These are transmitted to the receiver where they are simultaneously displayed on a screen. Through the eye and the central nervous system, the color picture is “reassembled” by the viewer.

## Flicker

A flickering light can appear to be continuous. When light reaches the eye for a brief instant, the eye responds, sending the information to the brain. However, when the light stops, the eye continues to send to the brain for an additional fraction of a second. If you have ever experimented with a strobe light or viewed a motion picture, you should know that light does not have to be continuous for the eye to perceive it as such. The fact that the eye “retains” an image for a fraction of a second after it has gone makes television possible. This retention of an image is called persistence. For high-intensity light, a rate of 50 to 60 flashes per second results in no visible flicker.

## PICTURE TRANSMISSION

If you wish to transmit a picture to another location, it is neither practical nor necessary to send all the information in that picture all at one time. Television and facsimile transmission systems send pictures “a piece at a time.” In Fig. 22 an area has

been divided into a mosaic of 12 squares. If the total area contained a picture, the scene could be described by detailing the contents of the individual squares in sequence (such as A through L). That is the concept behind television. Television (and facsimile) systems "divide" a picture in many more than 12 portions. In a workable system, each portion would be so small that it would contain only a single value of brightness (and color). Each tiny portion becomes a picture element or pixel, as it is commonly called.

The number of horizontal lines and the number of "pieces" along a line varies. There are three standards used worldwide for television broadcasting. Amateurs may use commercial transmission standards for TV. They are not limited to commercial standards, however. Amateurs use slow-scan TV and many experiment with other standards and systems. See Chapter 20 for information on Amateur TV and facsimile transmission.

This chapter will cover the theory of television. Discussion details are based on U.S. commercial standards — fast-scan TV (FSTV).

### The Scanning Process

Scanning is the way a picture is divided sequentially into pieces for transmission or presentation (viewing). A total of 525 scan lines comprise a frame (complete picture) in the U.S. television system. Thirty frames are generated each second. Each frame consists of two fields, each field containing 262½ lines. Sixty fields are generated each second. Scan lines from one field fall between (interlace) lines from the other field. The scanned area is called the television raster.

Fig. 23 illustrates the principle involved in scanning an electron beam (in the pickup or receiving device) across and down to produce the television raster. Scanning of field one begins in the upper left of the picture area. The electron beam is swept across the picture to the right side. At the end of the line, the beam is "turned off" or blanked and returned to the left side where the process repeats. In the meantime, the beam has also been moved slightly downward. At the end of 262½ horizontal scans (lines), the beam is blanked and rapidly returned to the top of the picture area. At that point, scanning of field two begins. Notice that this time the beam starts scanning from the top in the middle of the picture. For that reason, the scanning lines of field two will fall half way between the lines of field one. At the end of 262½ lines the beam is rapidly returned to the top of the picture again. Scanning continues — this time field one of the next frame.

Because the picture area is scanned top to bottom 60 times each second, there is no flicker. Because the entire picture area is scanned only 30 times each second, bandwidth is reduced.

It should be obvious that the horizontal

Fig. 24 — Electron beam deflection in TV cameras and receivers is usually accomplished by using two sets of coils. This is called electromagnetic deflection.

Fig. 25 — Current waveform used in electromagnetic deflection coils for deflection of the electron scanning beam.

Fig. 26 — Cross-sectional view of a vidicon.

and vertical oscillators that control the electron beam movement must be "locked together" for the two fields to interlace properly. If the frequencies of these oscillators are not locked, proper interlace will be lost and vertical resolution or detail will be degraded.

### Deflection

In most TV applications, the electron beam is scanned (deflected) by means of two pairs of coils. Because the deflection of the electron beam is accomplished magnetically, coils for horizontal deflection are located above and below the beam. Vertical deflection coils are located on either side of the beam. See Fig. 24.

The electron beam is deflected as a result of a "sawtooth" current passing through the deflection coils (Fig. 25). The frequency of the horizontal sawtooth current is 15,750 Hz. A similar waveform with a frequency of 60 Hz causes vertical deflection. The electron beam is turned off during beam retrace time by a process called blanking. Blanking is only associated with the electron beam and does not affect the deflection coil current or the resulting magnetic fields.

### THE TELEVISION CAMERA

Most modern TV cameras use vidicon tubes or vidicon derivatives. It is in the vidicon that optical energy is converted into a video (electrical) signal. The construction of a typical vidicon can be seen in Fig. 26.

Details, such as tube size, number of grids and the type of focus and deflection used, vary among the different types.

The cathode is the source of the electrons that form the electron beam. Grid 1 is a tubular element mounted concentric to the beam that controls the quantity of beam electrons, or the beam intensity. Grid 2, another tubular element, accelerates the beam electrons toward the target. Grid 3 operates in conjunction with an external focus coil to concentrate the beam into a focused electron stream at the target. Grid 4 is a screen mesh that is used to decelerate beam electrons and ensure that the beam strikes the target perpendicularly. Grid 4 also collects any excess beam electrons that are not attracted to the target.

The photosensitive element is made up of layers that are bonded to the faceplate glass of the tube. The layer directly adjacent to the faceplate glass is a transparent coating that is a conducting material. This coating is the signal electrode of the vidicon. Deposited on top of this layer are two more layers, the three forming the vidicon target. Adjacent to the first layer is a photoresistive layer that is backed by a conductive mosaic. A positive voltage is applied to the target to attract the beam electrons.

The target acts as a "leaky capacitor" at each point where the electron beam strikes the target. In other words the target can be viewed as a large number of small capacitors side by side distributed over its

Fig. 27 — Vidicon operation depicted. See text.

surface. On one side the capacitors are all joined together with a common connection for the output signal; on the other side the capacitors are left floating where they are exposed to the electron beam. The dielectric of these capacitors is the photoresistive layer of the target. Resistance of the middle layer is reduced in proportion to the intensity of light falling on it. This creates, in effect, a "leaky" capacitance with the amount of leakage proportional to the light falling on the target.

Target operation is depicted in Fig. 27. The light image consists of a series of black, gray and white areas. Where the image is black, the resistance of the photoresistive layer is very high. Where the image is white, the resistance is low. In the white areas, the

positive potential on the target attracts many electrons from the photoconductive mosaic — that leaves an area with a high positive potential. That is shown in Fig. 27 by a large plus sign on the photoconductive mosaic. In the gray area fewer electrons are attracted across the "leaky capacitor." That leaves a less positively charged area than for white. In the black portion, the charge is essentially zero.

Any given element of the target is scanned by the electron beam once for each frame (two fields) or every 33 ms. The charge on the floating side of the target is neutralized each time the beam scans it. As electrons are added to the back of the target, other electrons are drawn off through the target connection. This causes

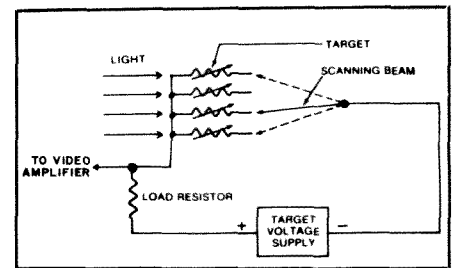

Fig. 28 — Vidicon equivalent circuit.

varying amounts of current to flow through the target connection as the scanning beam sweeps the picture area. The amount of current flow is proportional to the amount of light in a given area. In the black areas no change in resistance occurs and the actual resistance is the static resistance of the photoresistive material (Fig. 28). Some current will flow, however, and this is called the dark current of the vidicon.

Electrons flowing from the target through the load resistor create the signal voltage or video signal that corresponds to the optical image on the face of the vidicon. The signal polarity across the load resistor is positive going for low light areas and negative going for the high light areas as shown in Fig. 29. A properly adjusted vidicon will produce approximately  $0.3 \mu\text{A}$  in the high light areas and as little as  $0.02 \mu\text{A}$  (dark current) in the low light areas. The difference between the dark current and the maximum current is the useful signal current.

Blanking pulses are applied to the vidicon cathode to turn off the electron beam during retrace time of the scanning beam. Usually the pulse shape at the output of the vidicon is not as clean as shown in Fig. 29. The signal requires processing.

Good signal-to-noise ratio is a function of several factors. Two factors you can control are plenty of light and only enough beam current to discharge the white highlights.

It is wise to keep scene contrast to a minimum. In other words, keep the lighting flat for best results. About 100 foot candles should be enough illumination. Too little light results in noisy video. Too much light

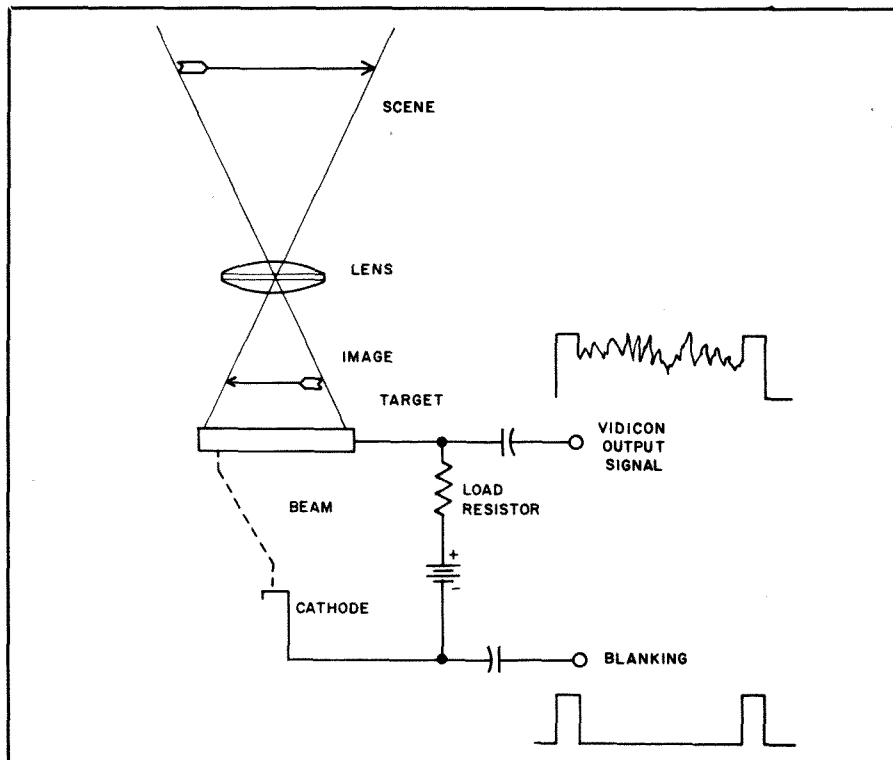

Fig. 29 — The vidicon output is a combination of video and blanking. See text.

Fig. 30 — Waveform showing horizontal sync pulses.

Fig. 31 — Vertical sync. Field 1 is shown at A, field 2 at B.

**Table 1**  
**Standard Video Levels**

	IEEE Units	%PEV	%PEP
Zero carrier	120	0	0
White	100	12.5	1.6
Black	7.5	70	50
Blanking	0	75	56
Sync tip	-40	100	100

runs up the electrical bill and can be uncomfortable — even with air conditioning.

### Synchronizing Pulses

To ensure a stable picture at the receiver, the scanning process at the transmitting and receiving ends must be synchronized. Fig. 30 shows the pulses used to control the horizontal scan. They are called horizontal sync pulses, and occur once per line — a frequency of 15,750 Hz. Horizontal sync pulses occur during the horizontal blanking interval.

Vertical scanning is controlled by vertical sync pulses, which can be seen in Fig. 31. The vertical sync pulse is preceded and followed by six equalizing pulses. The vertical sync pulse has a duration of three line times and is slotted or serrated at the end of each half-line time. Blanking turns off the electron beam during vertical retrace and sync.

The equalizing pulses are twice the frequency and approximately half the duration of horizontal sync pulses (2 equalizing pulses per line). The equalizing pulses

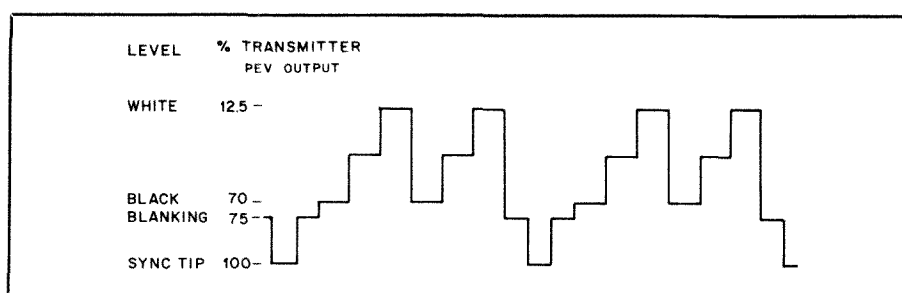

Fig. 32 — Composite video waveform. For transmission, sync is positive and white is negative.

Fig. 33 — Field of view nomograph.

ensure that there is always a pulse to lock the horizontal sweep to at the beginning of each line. Line 1 of field 1 begins at the first equalizing pulse and vertical sync starts at line 4. In field 2, line 1 begins at the second equalizing pulse and vertical sync starts at line 3½. This creates the ½-line offset that generates the interlaced scanning pattern shown in Fig. 23.

### Composite Video

Video, as it comes from the camera shown in Fig. 29 is not suitable for transmission. Horizontal and vertical sync must be added first. The composite video signal contains video, blanking and sync. See

Table 1. Fig. 32 shows these three elements combined for two horizontal lines of the visual image of Fig. 27.

Compact, hand-held cameras today require only power and light to generate a composite video signal. Some older cameras and most TV studio cameras require horizontal and vertical sync signals from an external source. Those signals can be provided by a sync generator.

### Camera Optics

The camera lens is used primarily to focus the scene image on the face of the pickup tube. The two basic characteristics of lenses are focal length (FL) and diameter

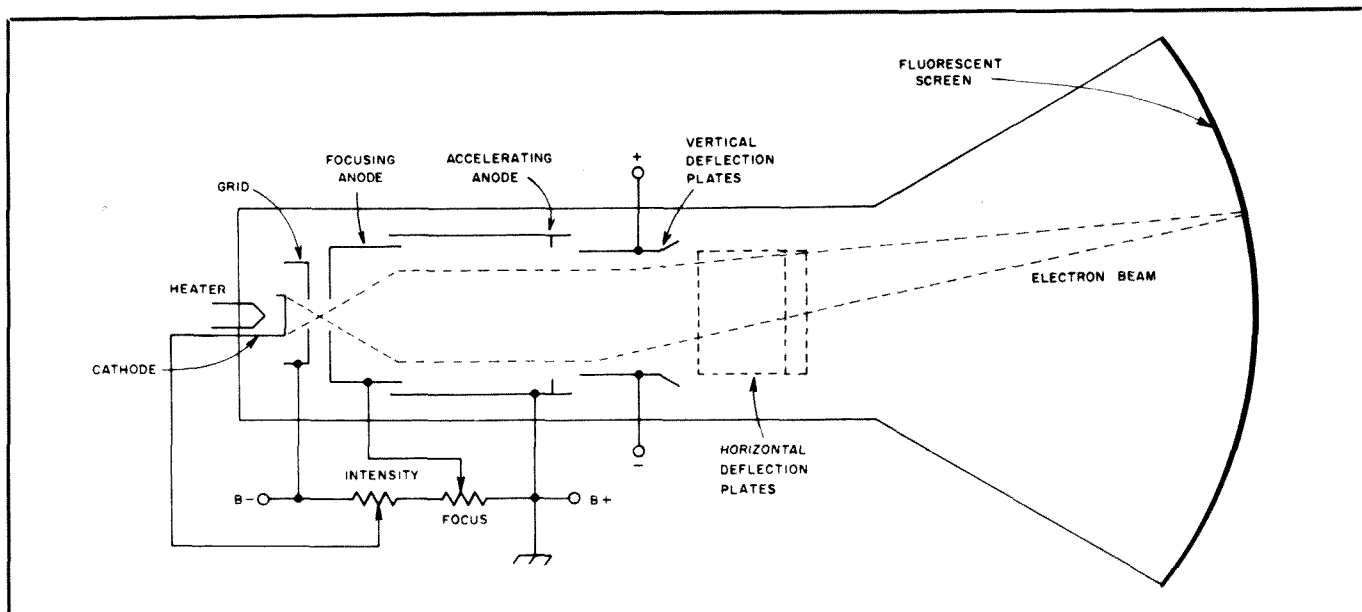

Fig. 34 — Cathode ray tube using electrostatic deflection and focusing.

of the lens opening (related to f-stop).

Lens FL is the distance from the optical center of the lens to the point behind the lens where the image comes into focus. For example, if an object at infinity comes into focus 1 inch behind a lens the FL is 1 in.

Focal length governs the magnification of the image and therefore the field of view of the lens. Long focal length lenses bring objects up closer and the field of view is less. The field of view of a lens used with a camera is related to the scanned area by the ratio:

$$FL/w = D/W \quad (\text{Eq. 1})$$

where

FL = focal length of the lens

w = width of the scanned area in the same units as FL

D = distance to the subject

W = width of the field in the same units as D

The image size of the scanned area of a typical vidicon is 0.375 in high  $\times$  0.50 in wide. If a 1-in lens is used, the width of the field of view would be:

$$W = D \times 0.5 \text{ in}/1 \text{ in}$$

If the subject were 5 ft away from the camera the field of view would be 2.5 ft wide (and 1.875 ft high).

This same equation can be used to determine the position of a given sized object to fill the screen. Example: Use Eq. 1 to determine how far from the camera with the 1-inch lens a 2-ft wide card should be placed to fill the screen. The answer is 4 ft.

By rearranging Eq. 1, you can determine the focal length of the lens required to view a scene of a given width at a given distance. For example, if you wish to view a scene 10 ft wide at a distance of 10 feet the lens must have a FL of 0.5 in.

$$FL = w \times D/W = 0.5 \times 10/10 = 0.5$$

Fig. 33 is a nomograph that can be used to determine these relationships easily.

#### F Stops

The lens iris of a TV camera operates like the iris of the human eye. If you suddenly look into a bright light, the iris of your eye closes down to admit less light. Since camera tubes operate over a limited light level range, the camera lens iris must be used to control the amount of light striking the pickup tube.

The f stop of a lens is a function of the FL and lens diameter with the iris wide open:

$$f = FL/d \quad (\text{Eq. 2})$$

where

f = f-stop number

FL = focal length of the lens

d = diameter of the iris opening in the same units as FL

Use Eq. 2 to prove that a lens with an 1-in FL and an iris opening of 0.66 in has an f-stop number of 1.5. Lenses are referred to as "fast lenses" or "slow lenses." These are expressions that refer to lens performance based on f-stop number. As the f-stop number of a lens increases, the opening size decreases and less light passes through the lens. The amount of light passing through the lens is inversely proportional to the square of the f-stop numbers. For example, the amount of light passing through an f/1.5 lens compared to an f/3 lens is:

$$(f - 3/f - 1.5)^2 = 4$$

The f/1.5 lens passes four times as much

Fig. 35 — Electromagnetic focus is shown at A and deflection at B. The drawings show the physical location of the windings.

# BLACK AND WHITE TV RECEIVER

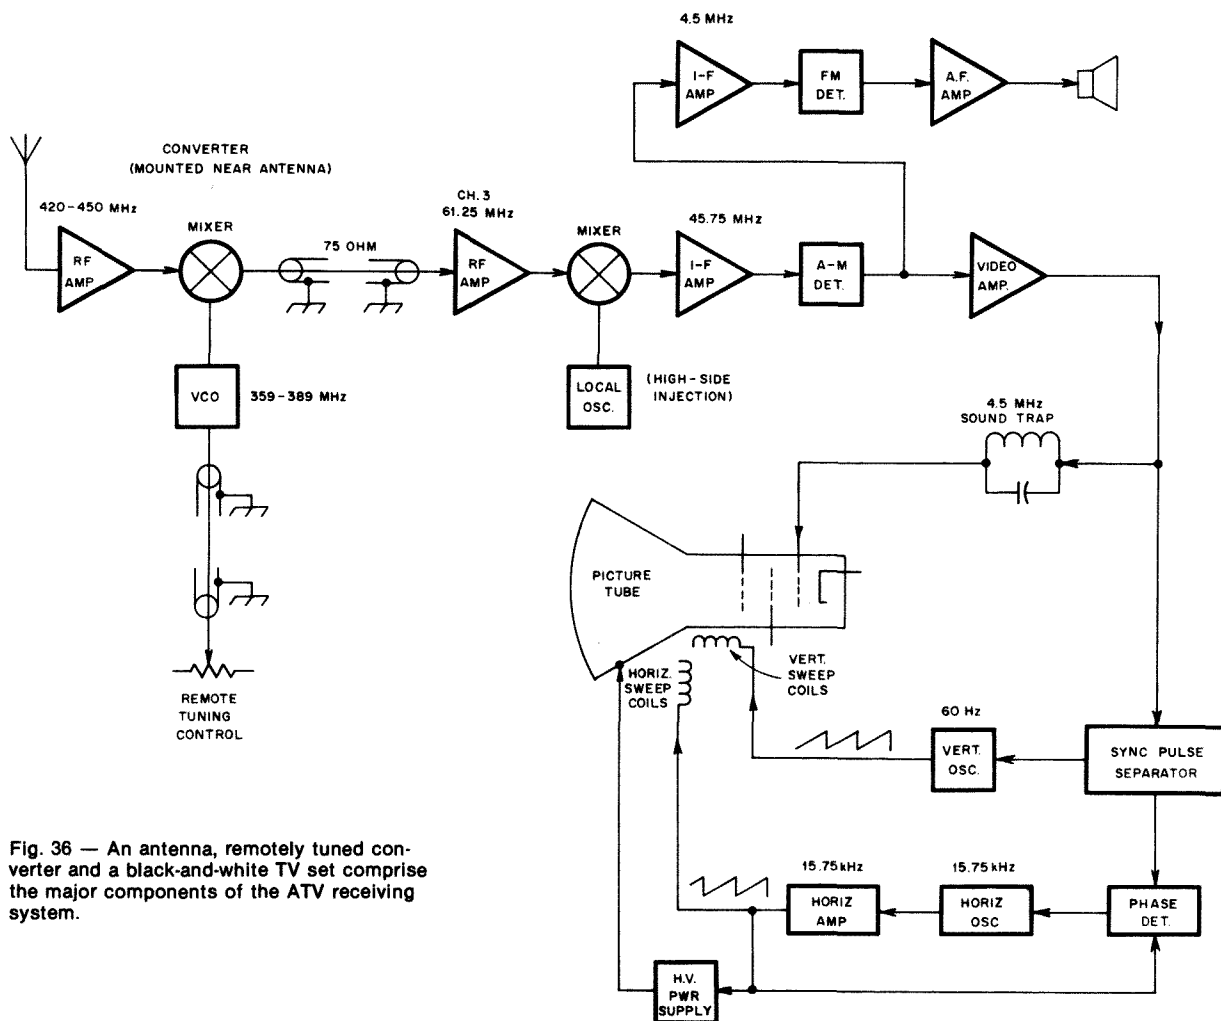

Fig. 36 — An antenna, remotely tuned converter and a black-and-white TV set comprise the major components of the ATV receiving system.

light as the  $f/3$  lens. To put it another way, when you set an  $f/1.5$  lens iris for  $f/3$ , light passing through the lens is reduced to one quarter of the original amount.

## Depth of Field

Depth of field describes how much of the scene, from front to rear, is in focus. The larger the  $f$ -stop number used with a lens the greater is the depth of field. Also, the shorter the focal length of a lens the more depth of field it has.

There is no substitute for a good lens — beware of bargains! In choosing a lens, many other qualities should be considered. A discussion of those qualities is beyond the scope of this *Handbook*.

## The TV Picture Tube

A picture or cathode-ray tube (CRT) similar to those used in oscilloscopes is shown in Fig. 34. The heater and cathode supply a stream of electrons that is controlled by the grid. Focus of the stream to a single point at the screen is realized by adjusting the voltage on the focusing anode. Voltage differences between the deflection plates control the deflection of

the electron stream. In Fig. 34 the top vertical deflection plate is positive with respect to the bottom plate. Therefore, the negatively charged electron stream is deflected upward. When the electrons strike the coating on the back of the screen there is a resulting fluorescence. Persistence and color of the fluorescence will depend on the material that coats the back of the screen.

Unlike an oscilloscope CRT, the modern TV picture tube uses electromagnetic deflection and focus. This is illustrated in Fig. 35. Notice that the top and bottom deflection coils are used to sweep the beam horizontally. That is because they are using the magnetic rather than the electric field for deflection.

Fig. 36 is a block diagram of an ATV receiving station. For best results the converter should be mounted near the antenna. Any TV set may be used after the converter. See Chapter 20 for more information on assembling and operating an ATV station.

## TV Sound

In a regular TV channel, the sound is transmitted on an FM carrier 4.5 MHz

higher than the picture carrier. A separate transmitter can be used to generate the sound carrier, but that requires a hard-to-build combiner or a second antenna. It is easy to frequency-modulate the visual carrier, but that requires special circuitry for receiving. An attractive alternative to these methods is to generate an FM sound sub-carrier at 4.5 MHz and combine that with the picture information at the video modulator input. Perhaps the easiest way for amateurs to transmit TV sound is to use an FM simplex channel on another band.

In many areas a 2-meter FM simplex channel is used for ATV coordination. This helps minimize interference. Another signal 50 dB weaker can cause noticeable interference to an ATV picture. When the ATV station is sending in-channel sound, the receiving station can transmit on the coordinating frequency; the result is full duplex sound — a most pleasant benefit. Most CQ calls for ATV are heard on the coordinating frequency.

## COLOR TV

A color TV camera typically splits light, by means of a prism, into the three primary

Fig. 37 — Modern single-gun color picture tube. Earlier color CRTs used three guns and a shadow mask. The advantage of the single gun type of tube is that it is easier to converge. Convergence occurs when the RGB electron beams illuminate the same aperture in the slotted grill at the same time. That ensures that the constituent parts of the color image are aligned with one another.

Fig. 38 — Details of horizontal sync and blanking for color TV.

Fig. 39 — Rise time is depicted at A, bandwidth at B. See text.

colors — red, green and blue (RGB). A separate tube is used to detect each primary. The RGB outputs are combined to give a luminance (brightness) signal, which is transmitted in the normal way. In addition, difference signals are used to phase-modulate a 3.58-MHz subcarrier (actually 3,579,545 Hz) with the color, or chroma, information.

A color TV receiver is similar to the set shown in Fig. 36. The major difference is in the video detection and display. A simple envelope detector will not do for color reception; the phase-encoded chroma information must be extracted from the 3.58-MHz subcarrier. RGB plus luminance signals are detected and are then used to control three separate electron beams (one per primary) in the picture tube. A typical color picture tube can be seen in Fig. 37.

Eight to 10 cycles of color subcarrier are sent after horizontal sync. See Fig. 38. These are the color-sync burst, or color burst, as it is commonly called. Color burst is used for a subcarrier phase reference in the receiver color detector circuitry synchronous demodulator. Also given in Fig. 38 are the names for the various portions of the horizontal sync and blanking waveform.

### Video Frequencies and Bandwidth

The lowest video frequency component is determined by the time rate of change of average luminance of the scene. For a picture that is uniform and unchanging, the lowest frequency component is zero — dc. It would be very difficult to pass a dc signal

**Table 2**  
**Relationship of Rise Time and Bandwidth**

Rise time ( $\mu$ s)	Bandwidth (MHz)
0.35	1
0.18	2
0.117	3
0.087	4
0.07	5
0.058	6
0.05	7
0.044	8
0.039	9
0.035	10

from the camera, through the transmitter and to the TV picture tube. The first blocking capacitor would spell and end to 0-Hz frequency response! Fortunately, that kind of response is not necessary.

A reference (dc) level can be set for each video scan line through a technique known as clamping. Clamping sets or holds a level at a reference point. Sync and blanking are present for each line of the video frame. The sync tip or the blanking level can be used to "clamp" or set a dc level at the beginning of each line time.

Maximum video frequency must be considered for three different points. First, the maximum frequency generated by the camera. Second, the maximum video frequency passed through the transmitter. Third, the maximum frequency present at the receiver picture tube.

The maximum camera frequency is determined by the size of the electron scanning beam and the bandwidth of the video amplifiers. Bandwidth limitation is based on the ability to reproduce an abrupt level change. Consider a black-to-white transition. It will take some finite amount of time for the level to shift from black to white. The time it takes for levels to shift between the 10 and 90 percent points in the level shift is called the rise time. See Fig. 39A. The bandwidth required to make that shift is depicted in Fig. 39B. The relationship of bandwidth and rise time is:

$$BW = 0.35/T \quad (\text{Eq. 3})$$

where

BW = bandwidth in hertz

T = rise time in seconds

The relationship between rise time and bandwidth for some specific values is given in Table 2.

Fig. 40 — Video energy tends to "bunch" at the fundamental and harmonic frequencies of horizontal and video sync.

Fig. 41 — With the proper selection of sync and chrominance-subcarrier frequencies, chrominance and luminance information "bunches" fall between each other.

Video cameras typically have a bandwidth of 8 MHz or so. Simple black-and-white cameras may have less, and sophisticated color cameras have more.

The maximum video passed through a transmitter is usually limited by the transmitter circuitry. Broadcast TV transmitters are carefully designed and adjusted to pass video frequencies according to strict standards. Amateurs do not have the same restraints. A little over 4-MHz bandwidth is required to pass carrier and one sideband of a color-TV signal.

A number of factors determine the maximum video frequency to reach the TV receiver picture tube. IF bandwidth is usually the limiting factor. On-screen resolution of the CRT is also limited by the design and construction of the electron-

beam focus and deflection coils.

### TV Energy Distribution

The square-wave sync pulses are transmitted at maximum power level. For that reason, power distribution in the video passband is concentrated at the fundamental and harmonics of the horizontal scanning frequency. Surrounding these are sidebands related to the vertical scanning frequency and its harmonics. That distribution is depicted in Fig. 40.

For color TV, chrominance information must be added to the luminance information. Fig. 41 shows how this is done to minimize interference between the two signal components. The chrominance sub-carrier has a nonintegral relationship to the horizontal scanning frequency. The energy "bunches" from color and luminance fall between each other.

## Chapter 8

# Digital Basics

**D**igital electronics is an important aspect of Amateur Radio. Everything from simple digital circuits to sophisticated microcomputers has found application in modern Amateur Radio systems. Applications include digital communications, code conversion, signal processing, station control, frequency synthesis, amateur satellite telemetry, message handling, word processing and other information-handling operations.

The fundamental principle underlying digital electronics is that a device can have only a finite number of states. In *binary* digital systems there are two discrete states, represented in base-2 arithmetic by the numerals 0 and 1. Although binary digital systems are the most common, trinary (3 states), quaternary (4 states) and other digital systems exist. Digital systems, with their discrete states, are contrasted with analog systems, in which voltages or other quantities vary in a continuous manner. Fig. 1 compares a sine wave with a digital approximation of the same waveform. There are situations in which a designer is faced with a choice between digital technology and analog technology. Some problems are best solved by digital circuits, some by analog circuits, and others by circuits using both digital and analog components. To understand Amateur Radio equipment, you will need a good working knowledge of both analog and digital circuits. This chapter examines digital electronics from the simplest digital building blocks to the complex microcomputer.

### Binary Quantities

As stated above, most digital systems are binary. When discussing these systems, each binary digit, or *bit*, is represented by a 1 or a 0. The binary states described as 1 and 0 may represent on and off, a punched hole and the absence of a hole in paper tape or card, or a mark and space in a communications transmission. In most electronic digital logic systems, bits are represented by voltage levels. For example, in one common circuit family, 0 volts is a binary 0, and +5 volts is a binary 1. Because it is not always possible to achieve exact voltages in practical circuits, digital circuits consider the signal to be a 1 or 0

Fig. 1 — A sine wave and a digital approximation of that waveform. Note that the sine wave has continuously varying voltage and that the digital waveform is composed of discrete steps.

Fig. 2 — A typical digital logic signal is shown in A. B illustrates possible ranges of recognition for binary 1 and 0.

if the voltage comes within certain bounds, as shown in Fig. 2.

In electronic circuits, changes of state do not occur instantly. The time it takes to go from a 0 to a 1 state is called *rise time*. *Fall time* is the time it takes to change from a 1 to a 0. Fig. 3 shows how rise and fall times effect the shape of a binary signal, or *pulse*. Rise and fall times describe a signal at a specific point in a circuit. The

Fig. 3 — Shape of a typical digital pulse.

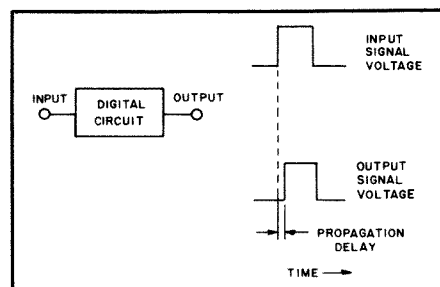

Fig. 4 — Propagation delay in a digital circuit.

distributed inductances and capacitances in a wire or PC-board trace cause rise and fall times to lengthen as a pulse gets farther from its source. Rise and fall times are typically in the microsecond or nanosecond range and vary with the logic family used.

Digital signals take a measurable amount of time to pass through a circuit. This phenomenon is called *propagation delay*, and results in an output signal being slightly delayed from an input signal, as shown in Fig. 4. Propagation delay is the result of transistor switching delays, reactive element charging times and the time needed for signals to travel through wires. In complex circuits, different propagation delays through different paths can cause problems when pulses must arrive somewhere at exactly the same time.

### COMBINATIONAL LOGIC

In binary digital circuits, a combination of binary inputs results in a specific binary output or combination of binary outputs. These circuits are used to implement everything from simple switches to

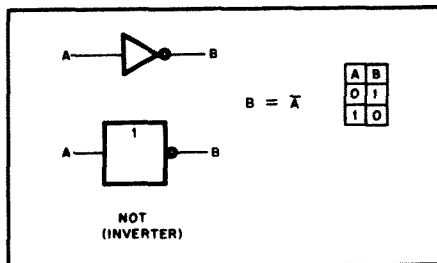

Fig. 5 — Inverter. The distinctive triangular symbol is the standard used in ARRL and other U.S. publications. The square symbol is used in some other countries.

Fig. 6 — Two-input AND gate.

Fig. 7 — Two-input OR gate.

Table 1

### Useful Properties and Theorems in Boolean Algebra

Commutative Property	$AB = BA$ $A + B = B + A$
Associative Property	$A(BC) = (AB)C$ $A + (B + C) = (A + B) + C$
Distributive Property	$A(B + C) = AB + AC$ $A + (BC) = A + B(A + C)$
Theorems	$A \cdot 0 = 0$ $A \cdot 1 = A$ $A \cdot A = A$ $A \cdot \bar{A} = 0$ $\bar{\bar{A}} = A$ $A + 0 = A$ $A + 1 = 1$ $A + A = A$ $A + \bar{A} = 1$

powerful computers. Some binary circuits are called *combinational logic networks*. The output of a combinational logic network is dependent only on its inputs, and its output changes immediately when its input changes. While there are more complex types of binary circuits, these circuits are usually composed of combina-

tional logic elements. To understand complex digital circuits, one must understand combinational logic.

## BOOLEAN ALGEBRA

Just as there are mathematical theories and equations used in designing analog circuits, there is a special branch of mathematics, *Boolean algebra*, that is used to describe and design binary digital circuits. In standard algebra there are several basic operations: addition, subtraction, multiplication and division. In Boolean algebra, the basic operations are *logical operations*: AND, OR and NOT. Boolean algebra is used to describe complex logical functions (often digital circuits) as combinations of these logical operators.

A logical function or operator can be defined by describing its output for all possible inputs. Such a list of inputs and outputs is called a *truth table*. In a truth table, a T represents a true or a 1 signal and an F represents a false or a 0 signal.

### Boolean Operators

Figs. 5 through 7 show the truth tables, circuit symbols and Boolean algebra symbols for the three basic Boolean operations, NOT, AND and OR. All combinational logic functions, no matter how complex, can be described in terms of these three operators.

#### NOT

The NOT operation is called inversion, negation or complement. The Boolean notation for NOT is a bar over a variable or expression. As can be seen from the truth table in Fig. 5, NOT 1 is 0 and NOT 0 is 1. The circuit that implements the NOT function is called an *inverter* or *inverting buffer*.

#### AND

The AND operation results in a 1 only when both of its operands are 1. That is, if the inputs are called A and B, the output is 1 only if A *and* B are 1. In Boolean notation, AND is represented by a middle dot ( $\cdot$ ) between the variables, or nothing between the variables. Both of these forms

Fig. 8 — Each gate in column A is equivalent to the gate opposite it in column B. The Boolean expressions in column C formally state the equivalences.

are shown in Fig. 6. The circuit that implements the AND function is called an *AND gate*. Gates are combinational logic elements with two or more inputs and one output state.

#### OR

The OR operation results in 1 if one or the other of its operands is 1 (Fig. 7). This also includes the case where both operands are 1; because of this, OR is sometimes called the *INCLUSIVE OR*. The Boolean notation for OR is  $+$  between the two operands. The circuit that implements the OR function is called an *OR gate*.

### Boolean Identities

Algebraic identities, such as  $A \times B = B \times A$ , help us solve complicated problems in mathematics. There are several identities in Boolean algebra that are useful for solving complex logic problems. These identities are shown in Table 1.

### DEMORGAN'S THEOREM

One of the Boolean identities deserves

Table 2

### DeMorgan's Theorem

- (A)  $\overline{A \cdot B} = \bar{A} + \bar{B}$   
 (B)  $\overline{A + B} = \bar{A} \cdot \bar{B}$

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
A	B	$\bar{A}$	$\bar{B}$	$A \cdot B$	$\overline{A \cdot B}$	$A + B$	$\overline{A + B}$	$\bar{A} \cdot \bar{B}$	$\bar{A} + \bar{B}$
0	0	1	1	0	1	0	1	1	1
0	1	1	0	0	1	1	0	0	1
1	0	0	1	0	1	1	0	0	1
1	1	0	0	1	0	1	0	0	0

(A) and (B) are statements of DeMorgan's Theorem. The truth table at (C) is proof of these statements; (A) is proven by the equivalence of columns 6 and 10; (B) is proven by the fact that columns 8 and 9 are the same.

Fig. 9 — Two-input XOR gate.

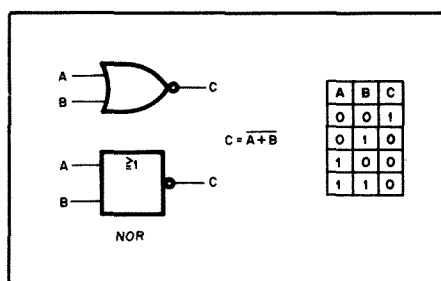

Fig. 10 — Two input NOR gate.

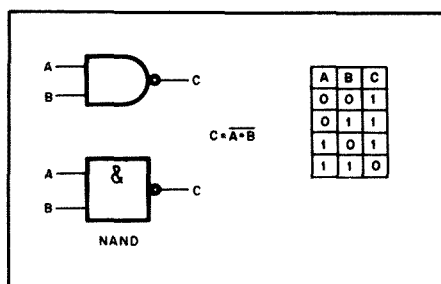

Fig. 11 — Two-input NAND gate.

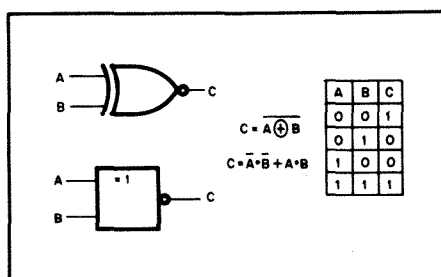

Fig. 12 — Two-input XNOR gate.

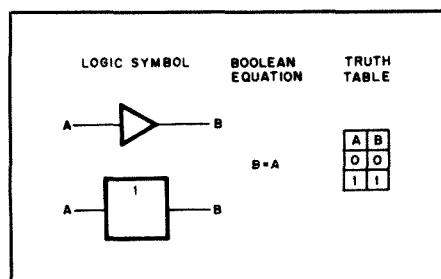

Fig. 13 — Noninverting buffer.

special attention. This identity is called DeMorgan's Theorem. DeMorgan's Theorem consists of two identities:  $A \cdot B = \overline{A + \overline{B}}$  and  $\overline{A + B} = \overline{A} \cdot \overline{B}$ . The truth table in Table 2 proves these identities. The important consequence of DeMorgan's Theorem is that any logical function can be implemented using either inverters and AND gates or inverters and OR gates. The theorem gives the circuit designer freedom, because it allows AND gates and inverters to be substituted for OR gates, and vice versa. The gate substitutions shown in Fig. 8 illustrate some uses of DeMorgan's Theorem. Such substitutions can lead to simplification of design or to more efficient use of available gates.

### Other Common Gates

While we have shown that any logical function can be implemented with only two logic elements (AND and NOT or OR and NOT), there are several other logic elements that are easily implemented and commonly available. Using these available gates (illustrated in Figs. 9 through 13) can simplify logic circuits.

#### EXCLUSIVE OR

In an EXCLUSIVE OR (XOR) gate, the output is 1 only if a single input is 1. If both inputs are 1 or both inputs are 0, the output is 0. The symbol  $\oplus$  in a Boolean expression represents the XOR operation.

#### NOR

NOR means NOT OR. A NOR gate is a circuit that produces a 0 at its output if any or all of its inputs are 1.

#### NAND

NAND is a contraction of NOT AND. A NAND gate has a 0 output only when all of its inputs are 1.

#### EXCLUSIVE NOR

The EXCLUSIVE NOR (XNOR) gate produces 0 output only if a single input is 1. Note that if both of the inputs are 1, there is a 1 on the output.

#### Noninverting Buffer

The *noninverting buffer* does not implement a Boolean function. Its output is simply equal to its input. While not useful for logical operations, a noninverting buffer has several uses: (a) providing sufficient current to drive a number of gates, (b) in-

terfacing between two logic families, (c) obtaining a desired pulse rise time and (d) providing a slight delay to make pulses arrive at the proper time.

### Polarity

In Boolean algebra, gates operate on the logical values 1 (true) and 0 (false). When implementing gates as electronic circuits, we need to assign voltage levels to 1 and 0. The intuitively acceptable convention is to use a higher voltage for 1 and a lower voltage for 0. This convention is called *positive logic*, and the standard logic symbols illustrated above are symbols for positive logic elements. In *negative logic*, the higher voltage represents 0 and the lower voltage represents 1. A negative logic input or output is represented by a small circle on the negative logic terminal. One can also think of these circles as representing inverted inputs or outputs. While logic polarity can be confusing, being able to think in both positive and negative logic sometimes makes circuit design easier.

### SEQUENTIAL LOGIC

The previous sections discussed combinational logic, which has its outputs *immediately* dependent on its *inputs only*. There is another class of logic called *sequential logic*. In sequential logic, a network's outputs are dependent not only on its current inputs, but also on its current outputs. This is a type of feedback and requires memory. The logic element that supplies memory is generally called a *flip-flop*.

A flip-flop (also known as a *bistable multivibrator* or an *Eccles-Jordan circuit*) is a binary sequential logic element with two stable states. One is the *set* state (1 state); the other is the *reset* state (0 state). The schematic symbol for a flip-flop is a rectangle with the letters FF. These letters may be omitted if there is no ambiguity.

Flip-flop inputs and outputs are normally identified by a single letter. A letter followed by a subscripted letter (such as  $D_C$ ), means that the input is dependent on the input of the subscripted letter (input  $D_C$  is dependent on input C). Flip-flop outputs are labelled Q and  $\overline{Q}$  (Table 3).

#### State Transition Tables

Conventional truth tables are difficult to apply to flip-flops, because flip-flop outputs depend on current outputs as well as on current inputs. Also, a certain input

Table 3  
Flip-Flop Out Designations

Output	Action	Restrictions
Q (Set)	Normal output	Only two output states are possible: $Q = 1, \overline{Q} = 0$ ; and $Q = 0, \overline{Q} = 1$ .
$\overline{Q}$ (Reset)	Inverted output	

#### Notes

- 1)  $\overline{Q}$  is the complement of Q.
- 2) The normal output is normally marked Q or unmarked.
- 3) The inverted output is normally marked  $\overline{Q}$ . If so, if there is a 1 state at Q, there will be a 0 state at  $\overline{Q}$ .

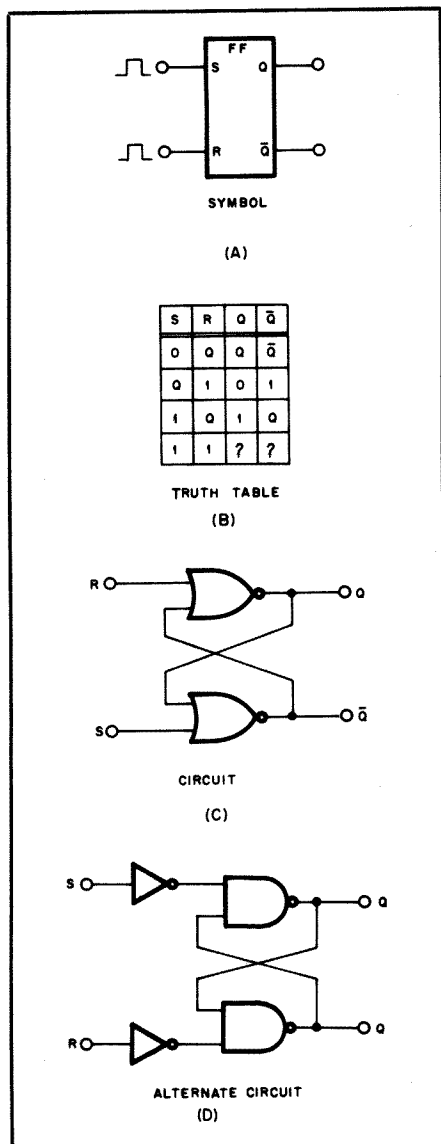

Fig. 14 — An unlocked R-S flip-flop. Where Q and  $\bar{Q}$  are shown in the truth table, the previous states are retained. A question mark (?) indicates that the output state is unpredictable. C shows an R-S flip-flop made from two NOR gates. Circuit D is another implementation using two NAND gates and two inverters.

condition may not have a unique output state. The simpler sequential circuits can be defined by state tables showing input and output states as they are now, and output states as they will be after the next input pulse. These tables are called *state transition tables*. State transition tables are used for designing sequential logic networks.

#### Unlocked R-S Flip-Flop

One of the simplest circuits for storing a bit of information is the R-S (or S-R) flip-flop. Its inputs are R (reset) and S (set). Fig. 14 shows how an R-S flip-flop can be made using combinational logic elements.

When S = 0 and R = 0 the output will stay the same as it was at the last input pulse. This is indicated by the letter Q in the truth table.

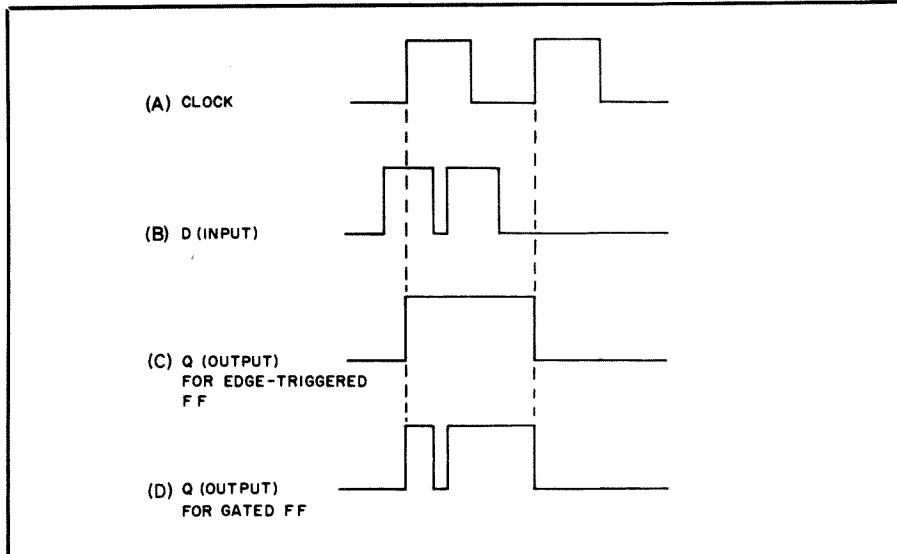

Fig. 15 — This figure illustrates the different outputs that may result when a D flip-flop is edge triggered (C) or gated (D). Notice that the short negative pulse on the input (B) is not reproduced by the edge-triggered flip-flop.

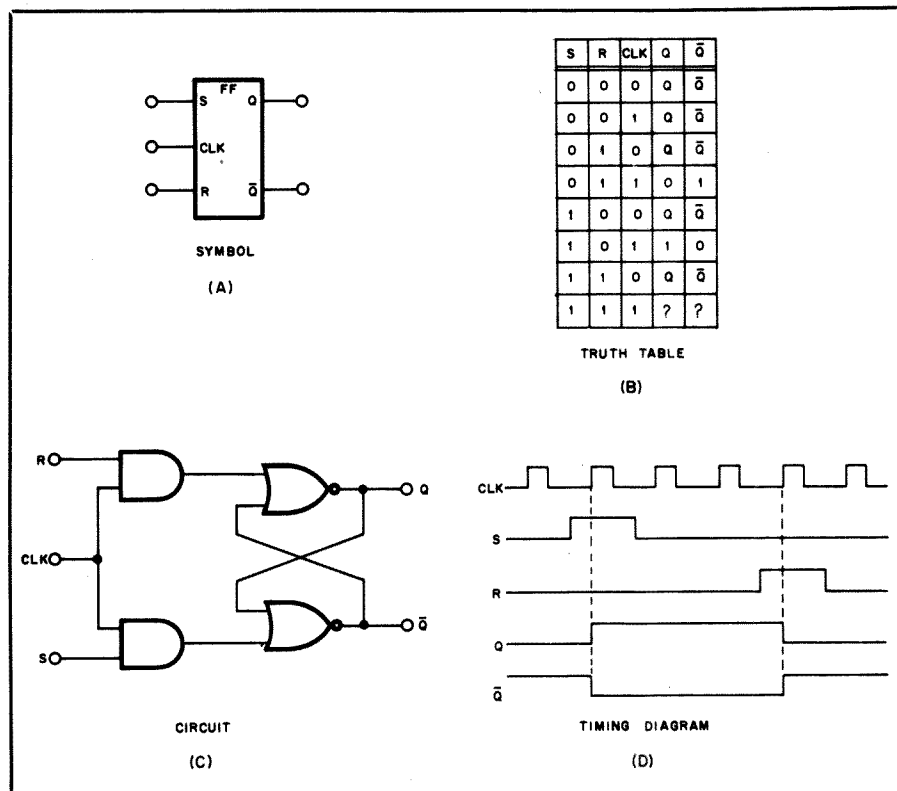

Fig. 16 — A gated R-S flip-flop. Where Q and  $\bar{Q}$  are shown in the table, the previous states are retained. A question mark (?) indicates an unpredictable output state.

If S = 1 and R = 0, Q will change to 1. If S = 0 and R = 1, Q will change to 0.

If both the R input and the S input are 1, the flip-flop output assumes an unpredictable state. This state varies from circuit to circuit, and may be Q =  $\bar{Q}$  = 1 or Q =  $\bar{Q}$  = 0. While Q =  $\bar{Q}$  is a logical impossibility, real flip-flops may present this output state. Avoid the R = S = 1 input, and make no assumptions about the

resulting output.

#### Synchronous Flip-Flops

The R-S flip-flop is an *asynchronous* device; its outputs change immediately to reflect changes on its inputs. *Synchronous* flip-flops change state (to reflect input conditions) only at specific times. These times are dictated by a *clock*, *toggle* or *gate* input.

Synchronizing inputs can take two

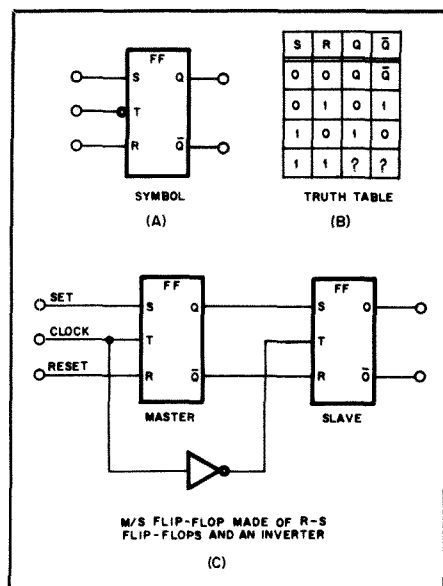

Fig. 17 — A master/slave flip-flop.

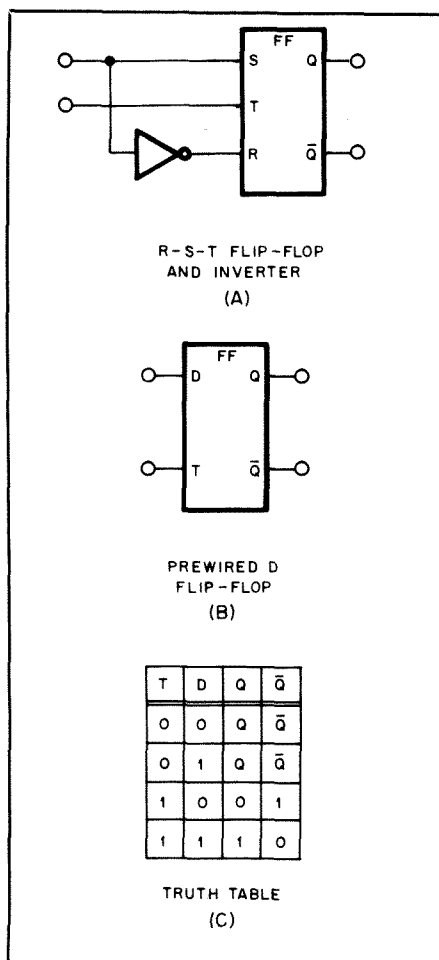

Fig. 18 — The D flip-flop. When  $T = 0$ ,  $Q$  and  $\bar{Q}$  states don't change. When  $T = 1$ , the output states change to reflect the input (D).

forms, *static* or *dynamic*. *Static, gated, or level triggered* inputs allow the flip-flop to change state whenever the clock input is at

Fig. 19 — The T flip-flop. The output frequency is half of the input frequency.

a specified level (1 or 0). Dynamic or *edge triggered* inputs allow the flip-flop to change state only when the clock *changes* level. Dynamic inputs that react to a transition from 0 to 1 are called *positive-edge triggered* inputs, and are indicated by a small isosceles triangle inside the flip-flop at the clock input. Inputs that are sensitive to the transition from 1 to 0 are *negative-edge triggered*, and are indicated by the triangle and a negation symbol (a small circle outside the flip-flop rectangle). It is important to remember that input levels affect gated flip-flops whenever the clock is in a specific state, while inputs affect edge triggered flip-flops only when the clock is in transition. Fig. 15 shows how the same input to a gated and an edge-triggered flip-flop results in two different outputs.

#### Gated R-S Flip-Flop

The gated R-S flip-flop, or *gated latch*, has R, S and clock inputs. It is also called the R-S-T flip-flop, the "T" indicating a *toggle* input. Although not often used, the R-S-T flip-flop is important because it illustrates a step between the R-S flip-flop and the J-K flip-flop. The inputs R and S produce the same results as those on an unlocked R-S flip-flop, but no change in output will occur unless the toggle input is high. A gated R-S flip-flop is illustrated in Fig. 16 along with a timing diagram to show the effect of the clock input.

#### Master/Slave Flip-Flop

The importance of synchronous flip-flops is illustrated in the construction of the

*master/slave* flip-flop. The master/slave (M/S) flip-flop solves a problem known as *race*. Race occurs when flip-flops are connected in series and triggered by the same clock pulse or when a flip-flop uses its own output as an input. When an input changes just as an output is about to change, an erroneous output may result.

This problem is solved by building a flip-flop that samples and stores its inputs before changing its outputs. Such a flip-flop can be built by placing two gated R-S flip-flops in series. The first, or *master*, flip-flop is active when the clock is positive; it samples and stores the inputs when the clock is 1. The second, or *slave*, flip-flop takes its input from the output of the master, and acts when the clock is negative. Hence, when the clock is 1, the input is sampled, and when the clock is 0, the output is generated. Changes in the output are now isolated from the input, and there is no race condition.

An M/S flip-flop can be made by wiring two R-S flip-flops in series and connecting an inverter between the T inputs. Thus when the T input is 1, the master (first flip-flop) is enabled. When the T input is 0, the slave (second flip-flop) is enabled and the master disabled. An R-S M/S flip-flop is shown in Fig. 17.

#### D Flip-Flop

In a D flip-flop, the *data* input (D) is transferred to the outputs ( $Q$  and  $\bar{Q}$ ) when the flip-flop is enabled by the T input. Fig. 18 shows a typical D flip-flop and its state transition table. The logic level at D

is transferred to Q when the clock is positive. The Q output will retain this logic level, regardless of any changes at D, until the next positive clock pulse.

Toggle Flip-Flop

Fig. 19 shows a *toggle*, or T flip-flop. The timing diagram shows that the flip-flop output changes state with each positive clock pulse. Because of this, the T flip-flop is also called a complementing flip-flop. Examination of the pulses in Fig. 19C shows that the output frequency of the T flip-flop is one half of the input frequency. Thus a T flip-flop is a 2:1 (also called a *modulo-2* or *radix-2*) frequency divider. Two T flip-flops connected in series form a 4:1 divider, and so on.

J-K Flip-Flop

The J-K flip-flop is a common flip-flop. It has no invalid input combinations (a disadvantage of the R-S flip-flop), and it can complement (divide by 2). The J-K flip-flop is illustrated in Fig. 20.

On receipt of a clock pulse, inputs of J = 1, K = 0 sets Q = 1. J = 0, K = 1 resets Q = 0. Simultaneous J = 1, K = 1 causes Q to change state (complement). If J = 0 and K = 0, Q will not change state when the flip-flop is clocked.

Asynchronous Inputs

Most commercially available synchronous flip-flops have some asynchronous inputs. These inputs allow you to change the state of the flip-flop regardless of the state of the clock input. Asynchronous inputs usually found on flip-flops are the *direct reset*, RD, and *direct set*, SD. As their names suggest, these inputs allow the flip-flop to be set or reset asynchronously. Such inputs are used to establish known conditions in a circuit or to interrupt an ongoing process.

COUNTERS

A *counter*, *divider* or *divide-by-n* counter is a circuit that stores pulses and produces an output pulse when a specified number, n, of pulses are stored. In a counter consisting of flip-flops connected in series, a change of state of the first stage affects the second stage and so on.

A *ripple*, *ripple-carry* or *asynchronous* counter passes the count from stage to stage; each stage is clocked by the preceding stage. In a *synchronous* counter, each stage is controlled by a common clock.

*Weighting* is the count value assigned to each counter output. In a four-stage binary ripple counter, the output of the first stage has a weight of 1, the second 2, the third 4 and the fourth 8. Base 10 (decade) counters consist of a divide-by-2 and divide-by-5 counters (encoded in binary-coded decimal or BCD code, as shown in Table 4). A base 12 counter has a divide-by-2 and a divide-by-6 counter.

Most counters have the ability to *clear*

Digital Number Systems

Decimal

The familiar *decimal* or *base-10* system is comprised of 10 symbols (digits or numerals): 0, 1, 2, 3, 4, 5, 6, 7, 8 and 9. The value of each depends on its position in the number. For example: In the decimal number 123, 1 = 100, 2 = 20 and 3 = 3 units.

The first position carries the greatest weight and is known as the *most significant digit (MSD)*, while right-most position is referred to as the *least significant digit (LSD)*. The positional values relative to the decimal point can be expressed in terms of *powers of 10*, also known as scientific notation.

Decimal position values of the number decimal 234.56 in powers of 10 are:

100	10	1	0.1	0.01	Decimal value
10 <sup>2</sup>	10 <sup>1</sup>	10 <sup>0</sup>	10 <sup>-1</sup>	10 <sup>-2</sup>	Power of 10 value
2	3	4	.	5	Decimal number
↑			↑	↑	
MSD			Decimal point	LSD	

Binary

In the *binary* or *base-2* system only two symbols are used: 0 and 1. As in the decimal system, the position of a binary digit determines its weight which is expressed in powers of 2. The left-most position is the *most significant bit (MSB)*, and the right-most position is the *least significant bit (LSB)*.

Position values of the binary number 1101011 are:

64	32	16	8	4	2	1	Decimal value
2 <sup>6</sup>	2 <sup>5</sup>	2 <sup>4</sup>	2 <sup>3</sup>	2 <sup>2</sup>	2 <sup>1</sup>	2 <sup>0</sup>	Power of 2 value
1	1	0	1	0	1	1	Binary number
↑						↑	
MSB						LSB	

Octal

In the *octal* or *base-8* system, 8 symbols are used: 0, 1, 2, 3, 4, 5, 6 and 7. Each positional value can be expressed in powers of 8. Position values for the octal number 7854 are:

512	64	8	1	Decimal value
8 <sup>3</sup>	8 <sup>2</sup>	8 <sup>1</sup>	8 <sup>0</sup>	Power of 8 value
7	6	5	4	Octal number
↑			↑	
MSD			LSD	

Hexadecimal

In the *hexadecimal (hex)* or *base-16* system 16 symbols are used: 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E and F. Each position value can be expressed in powers of 16. Position values for the hexadecimal number FF07 are:

4096	256	16	1	Decimal value
16 <sup>4</sup>	16 <sup>3</sup>	16 <sup>2</sup>	16 <sup>1</sup>	Power of 16 value
F	F	0	7	Hexadecimal number
↑			↑	
MSD			LSD	

Binary-Coded Decimal

In the *binary-coded decimal (BCD)* system the decimal numbers 0 through 9 are represented by 4-bit binary patterns:

BCD	Decimal	BCD	Decimal
0000	0	1000	8
0001	1	1001	9
0010	2	1010	
0011	3	1011	Not Used
0100	4	1100	
0101	5	1101	
0110	6	1110	
0111	7	1111	

The decimal number 789 would be expressed in BCD as:

	7	8	9	Decimal number
	0111	1000	1001	BCD code

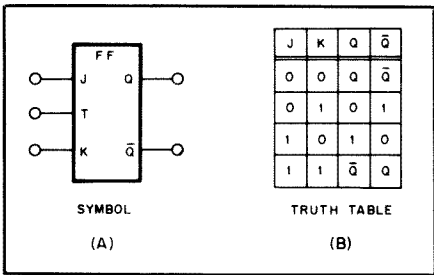

Fig. 20 — A J-K flip-flop. The truth table shows that if J = 0 and K = 0, the output does not change, and if J = 1 and K = 1, the output state is inverted.

Table 4  
Binary-Coded Decimal (BCD) Code

Decimal Number	Binary Weights
	8 4 2 1
0	0 0 0 0
1	0 0 0 1
2	0 0 1 0
3	0 0 1 1
4	0 1 0 0
5	0 1 0 1
6	0 1 1 0
7	0 1 1 1
8	1 0 0 0
9	1 0 0 1

Note: BCD does not use hexadecimal (base 16) numbers A (1010), B (1011), C (1100), D (1101), E (1110) or F (1111).

the count to 0. Some counters can be *preset* to a desired count.

Counters may either count up (increment) or down (decrement). *Up* counters count in increasing weighted values (for example: 0000, 0001, 0010, . . . , 1111). *Down* counters work in the reverse order. There are also *up/down* counters that can be commanded to count either up or down.

REGISTERS

Groups of flip-flops may be used to temporarily store data. Such a data-storage

device is called a *register*. There are two classes of registers: *shift registers* and *word* or *byte registers*. Registers are used in counters, data-storage devices and sequence generators.

Shift Registers

A shift register is a group of flip-flops connected so that when a clock pulse occurs, each flip-flop assumes the state of the preceding flip-flop. The first flip-flop of the group usually receives its input from

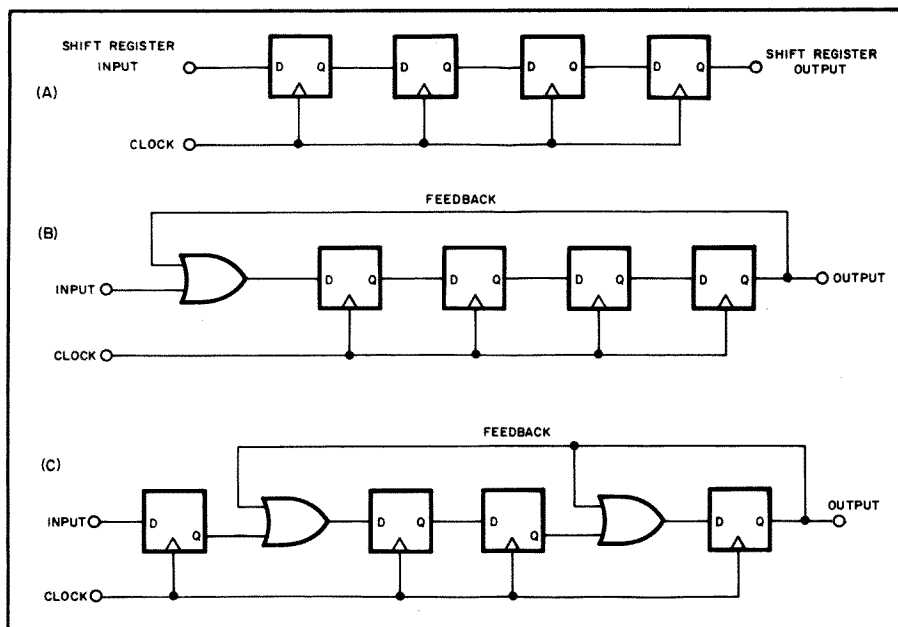

Fig. 21 — Shift registers. Four D flip-flops connected as a simple shift register are shown at A. B shows the same flip-flops used as a ring counter. Notice that the feedback is ored with the input. In C, the feedback is ored with the inputs to the third and fourth flip-flops, creating a pseudorandom number generator.

an external logic signal. Shift registers may provide parallel outputs (an output from each flip-flop), and they may provide a means to directly set the state of each flip-flop (parallel loading) synchronously or asynchronously. Fig. 21A illustrates four D flip-flops connected as a shift register.

Shift registers can be used to delay or synchronize data. In this application, the register is constructed so that a desired bit is at the output of the register during a specified clock pulse. Any output of a shift register can be fed back to its input to produce an almost infinite array of possibilities. The *ring counter* (Fig. 21B) is a shift register with its output fed back to its input. When a clock pulse is applied to

a ring counter, the bit pattern stored in the register is rotated either left or right. Shift registers with several feedback paths can be used as *pseudorandom-number generators* (Fig. 21C). The output of such a generator is a sequence of bits that meets one or more criteria of true randomness. Pseudorandom-number generators have applications in noise generators and spread-spectrum key generators.

#### Byte and Word Registers

A byte register or a word register is simply a group of flip-flops that is thought of as a single register. Such registers are used in computers for temporary data storage. The number of flip-flops in a word

register depends on the word length of the computer. Word length and computer architecture will be more thoroughly discussed in later sections of this chapter.

#### ONE-SHOT MULTIVIBRATOR

A *one-shot* or *monostable* multivibrator is a circuit that has one stable state and an unstable state. When the one-shot is *triggered* by a clock pulse, it assumes its unstable state for a period of time determined by circuit components. Thus, the one-shot multivibrator puts out a pulse of some predetermined duration ( $T$ ). If a one-shot multivibrator is triggered while it is in the unstable state, two things may happen. A *non-retriggerable* multivibrator is not affected by the second trigger pulse. A *retriggerable* multivibrator will start "counting" its pulse duration ( $T$ ) from the most recent trigger pulse. Both types of one-shots are common.

A 555 timer IC connected as a one-shot multivibrator is shown in Fig. 22. The one-shot is activated by negative-going pulse between the trigger input and ground. The trigger pulse causes the output ( $Q$ ) to go positive and capacitor  $C$  to charge through resistor  $R$ . When the voltage across  $C$  reaches two-thirds of  $V_{CC}$ , the capacitor is quickly discharged to ground and the output returns to 0. The output remains at logic 1 for a time determined by

$$T = 1.1 RC \quad (\text{Eq. 1})$$

where

$R$  = resistance in ohms

$C$  = capacitance in farads

#### ASTABLE MULTIVIBRATOR

An *astable* or *free-running* multivibrator is a circuit that alternates between two unstable states. It can be synchronized by an input signal of a frequency that is slightly higher than the astable multivibrator free-running frequency. An astable

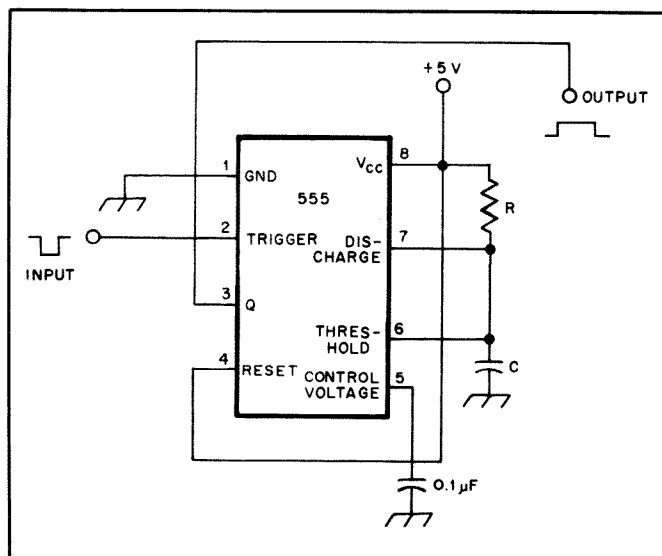

Fig. 22 — A 555 timer connected as a one-shot multivibrator. See text for a formula to calculate values of  $R$  and  $C$ .

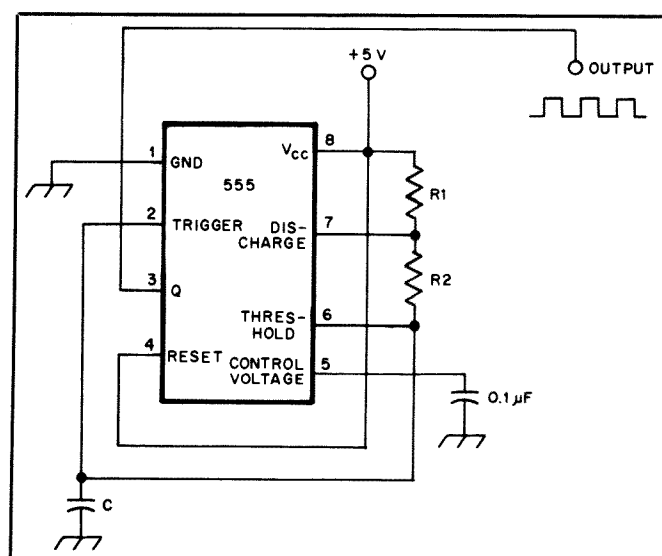

Fig. 23 — A 555 timer connected as an astable multivibrator. See text for formula to calculate values of  $R_1$ ,  $R_2$  and  $C$ .

Fig. 24 — Pulse sequences showing 50% (A), 80% (B) and 20% (C) duty cycles.

multivibrator creates a sequence of pulses at a desired frequency and width.

An astable multivibrator circuit using the 555 timer is shown in Fig. 23. The capacitor  $C$  charges to two-thirds  $V_{cc}$  through  $R_1$  and  $R_2$  and discharges to one-third  $V_{cc}$  through  $R_2$ . The ratio of  $R_1$ : $R_2$  sets the *duty cycle* of the pulses. The duty cycle is the ratio of the time that the output is high to the total period of the output cycle (Fig. 24). The

output frequency is determined by

$$f = \frac{1.46}{(R_1 + 2R_2)C} \quad (\text{Eq. 2})$$

where

$R$  = resistance in ohms

$C$  = capacitance in farads

## SUMMARY

Digital logic is playing an increasingly

important role in Amateur Radio. Most of this logic is binary and can be described and designed using Boolean algebra. Using the NOT, AND and OR gates of combinational logic, designers can build sequential logic circuits that have memory and feedback. The simplest memory circuit is called a flip-flop, or latch, and these latches can be combined to form such useful circuits as counters, shift registers and byte registers.

# Digital Integrated Circuits

*Integrated circuits* are the cornerstone of digital logic devices. An integrated circuit is a miniature electronic module of components and conductors manufactured as a single unit. Today's complex digital equipment would be impossible with vacuum tubes or even discrete transistors as active elements.

As one generation of ICs outshined the previous one, it became necessary to classify them according to the number of gates on a single chip. These classifications are defined below.

**Small-scale integration (SSI)** — 10 or fewer gates on a chip.

**Medium-scale integration (MSI)** — 10-100 gates.

**Large-scale integration (LSI)** — 100-1000 gates.

**Very-large-scale integration (VLSI)** — 1000 or more gates.

## COMPARING LOGIC FAMILIES

When selecting logic devices for a circuit, a designer is faced with the choice between many families and subfamilies of logic ICs. Which subfamily is right for the application at hand is often a function of several parameters. The characteristics that are usually important are logic speed, power consumption and fan-out.

### Impedance

One parameter that is discussed in the following sections is gate impedance. The ideal gate would have low output impedance, enabling it to deliver high current without dropping considerable voltage in its output stages. The ideal gate would have infinite input impedance and would, therefore, draw no current. Unfortunately, such a gate does not exist, and the

designer must compromise on input and output impedances.

### Speed

Logic devices operate at widely-varying clock speeds. Standard TTL devices can only operate up to a few MHz, while some ECL ICs can operate at several GHz. Gate propagation delay determines the maximum clock speed at which an IC can be operated; the clock period must be long enough for all signals within the IC to propagate to their destinations. ICs that use capacitively coupled inputs have minimum, as well as maximum, clock rates. While the designer might want to use the fastest available ICs, higher speed usually results in higher power consumption.

### Power Consumption

In some applications, power consumption by logic gates is a critical design consideration. This power consumption can be divided into two parts: *static power* and *dynamic power*. Gates are either holding a state (high or low), or they are changing states, and each of these conditions has different power requirements. The power that is consumed when a gate changes state is called dynamic power. The power consumed when a gate is holding a state is called static power. Calculating the total power that will be required by an IC with several gates performing diverse functions is a complex task. Nominal power requirements, however, can be used to compare logic subfamilies.

### Fan-out

A gate's output can only supply a limited amount of current. Therefore, a single output can only drive a limited number of in-

Fig. 25 — Gate A (fan-out = 2) is connected to the two buffers (B and C), each with a fan-out of 2, to achieve total fan-out of 4.

puts. The measure of driving ability is called *fan-out*. Fan-out is expressed as the number of inputs (of the same subfamily) that can be driven by a single output. If a logic family that is otherwise desirable does not have sufficient fan-out, consider using noninverting buffers to increase fan-out (Fig. 25).

### Other Considerations

The parameters mentioned above are the basic considerations that influence the selection of a logic subfamily for a specific application. These considerations have complex interactions that come into play in demanding low-current, high-speed or high-complexity circuits. If you are designing a circuit, consult the application notes for the logic devices that you are going to use. Application notes contain speed, power-consumption and fan-out specifications, as well as other useful information.

## DIGITAL-LOGIC IC FAMILIES

A number of families of digital logic ICs fall under the two broad categories of *bipolar* and *metal-oxide semiconductor*

(MOS). Numerous manufacturing techniques have been developed using both bipolar and MOS technologies. Each family has its own inherent advantages and disadvantages, and each of the surviving families has found its special niche in the market.

## BIPOLAR LOGIC FAMILIES

**Bipolar** semiconductor ICs employ NPN and PNP junction transistors. While early bipolar logic was faster and had higher power consumption than MOS logic, these distinctions have been blurred as manufacturing technology has developed. There are several families of bipolar logic devices, and within some of these families there are subfamilies.

**Direct-coupled-transistor logic (DCTL)** was the first commercial IC family. It is now obsolete. It had poor noise immunity and high current consumption.

**Resistor-transistor logic (RTL)** was the earliest popular IC logic family. It suffered from low speed, poor noise immunity and low fan-out. **Diode-transistor logic (DTL)** reduced power requirements but was slower than other bipolar logic families. Both RTL and DTL are no longer used in new designs and are available for replacement purposes only. **High-Threshold Logic (HTL)** is a variation of DTL that uses higher supply voltages (around 15 V) and Zener diodes at gate inputs to achieve greater noise immunity. **Resistor-capacitor-transistor logic (RCTL)** is a variation of RTL. RCTL gates have bypass capacitors across their input resistors to increase speed.

## Transistor-Transistor Logic (TTL)

TTL (also known as T<sup>2</sup>L) has seen widespread acceptance because it is faster and more immune to noise than RTL and DTL. The TTL family is divided into standard TTL and variations. The transistors in standard TTL circuits saturate, thus reducing operating speed. The variations cure this by clamping the transistors with *Schottky* diodes to prevent saturation or by using gold dope to reduce transistor recovery time. Both manufacturing processes are used, but Schottky-clamped TTL is faster.

Most TTL ICs are identified by numbers beginning with 54 or 74. The 54 prefix denotes a military temperature range of -55 to 125°C, while 74 indicates a commercial temperature range of 0 to 70°C. Standard TTL ICs have a 2, 3 or 4-digit device identification number immediately following the prefix (for example, 5400 and 74174). Standard TTL devices are usable up to 35 MHz. One or two letters in the middle of an ID number indicate the special TTL subfamily:

- AS — Advanced Schottky
- ALS — Advanced low-power Schottky
- H — High speed (up to 50 MHz)
- L — Low power (up to 3 MHz)
- LS — Low-power Schottky (up to 45 MHz)

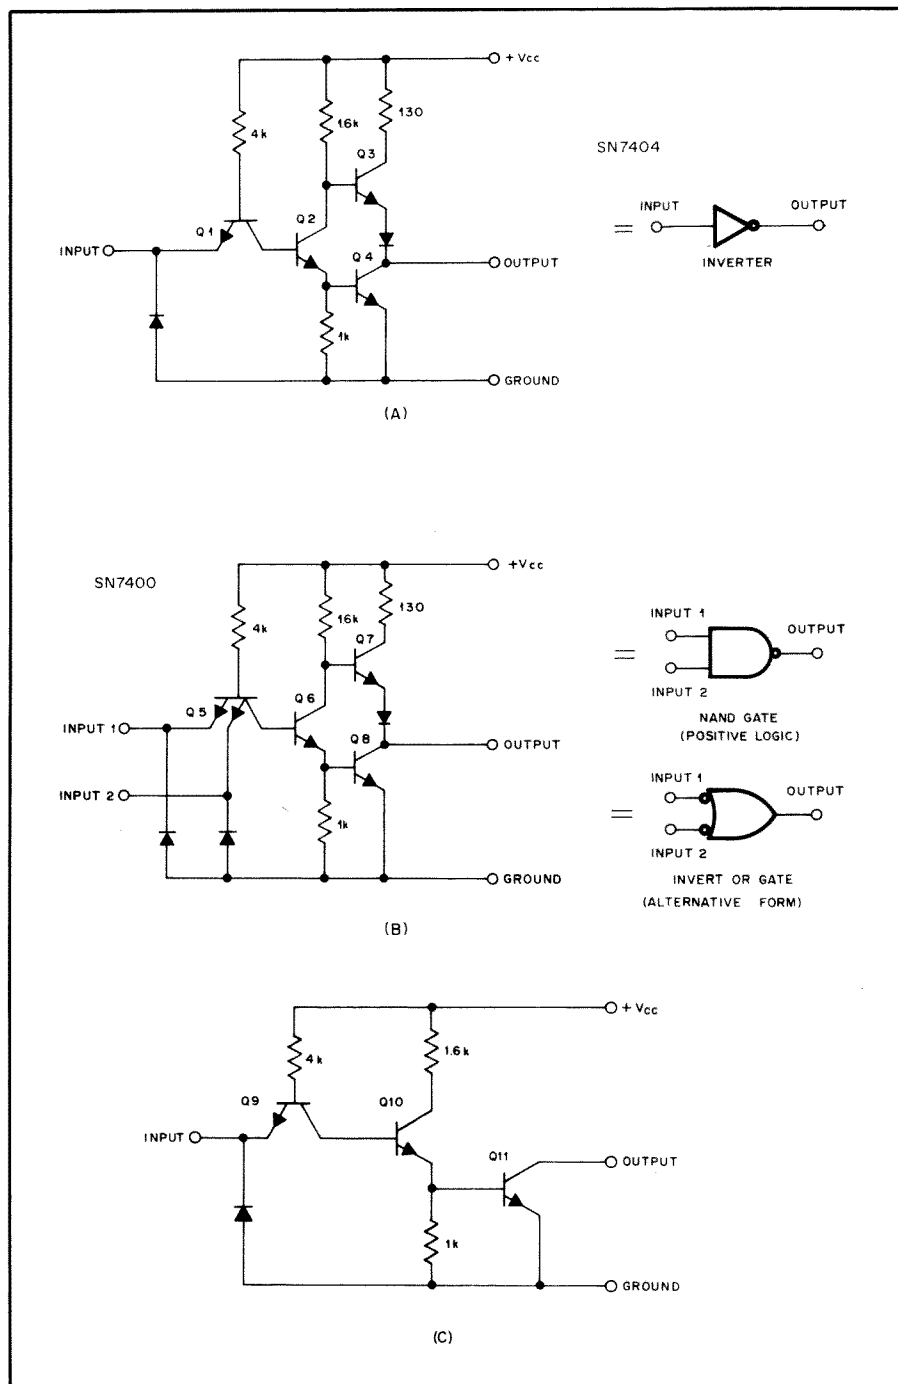

Fig. 26 — TTL circuits and their equivalent logic symbols. The circuits in A and B have totem-pole outputs, while C has an open-collector output. Indicated resistor values are typical. Identification of transistors is for text reference only; these are *not* discrete components.

S — Schottky (some up to 125 MHz)

## TTL Circuits

One section of a 7404 hex inverter is represented schematically in Fig. 26A. A low applied to the input will cause Q1 to conduct. This will cause Q2 to be near cutoff, in turn biasing Q3 into saturation and Q4 near cutoff. As a result, the output will be high, about 1 V below Vcc. If the signal at the input is high, the conduction state of each transistor reverses, and the output drops nearly to ground poten-

tial (low). The input diode protects the circuitry by clamping any negative potential to approximately -0.7 V, limiting the current in Q1 to a safe value. The output diode at the emitter of Q3 is required to ensure that Q3 is cut off when the output is low.

The circuit in Fig. 26B, one section of a 7400 gate, is very similar to that of A. The difference is that Q5 is a multiple-emitter transistor with one input to each emitter. A low at either input will turn on Q5, causing the output to go high. Both inputs must be high to produce a low out-

Fig. 27 — The outputs of two open-collector output AND gates are shorted together (wire ANDed) to produce an output the same as would be obtained from a four-input AND gate.

put. This is a NAND gate.

### TTL Outputs

In the TTL circuit of Fig. 26A, transistors Q3 and Q4 are arranged in a totem-pole configuration. This output circuit has a low source impedance, allowing the gate to supply or sink substantial output current. The 130-ohm resistor between the collector of Q3 and  $+V_{cc}$  limits the current through Q3, protecting Q3 if the gate output is short-circuited.

Some TTL gates employ *open-collector* outputs, as shown in Fig. 26C. Open-collector outputs have an advantage over totem-pole outputs: they can be *wire-ANDed*. In a wire-AND circuit, several open-collector outputs can be connected to a single *pull-up* resistor. When all of the outputs are high, the point where they are connected will be high. If any of the outputs are low, the connection will be low. This circuit implements the logical AND function, as shown in Fig. 27. Open-collector outputs are also useful for interfacing TTL gates to gates from other logic families. TTL outputs have a minimum high level of 2.4 V and a maximum low level of 0.4 V. A pull-up resistor, typically 2.2 k $\Omega$ , can be used to raise the high voltage level to 5 V, which may be needed to drive a non-TTL circuit. Although +5 is the recommended power-supply voltage for TTL, the pull-up resistor on an open collector can be connected to a different voltage, providing a high logic level that is not 5 V.

There is another type of output that is available in TTL and other logic families. This output is called the *three-state output*. Three-state output devices are used to connect two or more outputs to a single input in such a way that *only one* of the outputs affects the input. To accomplish this, each output can take on a third, high-impedance, state (as well as the standard high and low states). When the output is in the third state, it is essentially disconnected from the circuit. Outputs in the high-impedance state do not affect the input to which they are connected; only the output that is in a normal high or low state will affect the input. Care must be taken to ensure that all of the outputs but one are in the high-impedance state. Three-state devices are used in computers to allow several

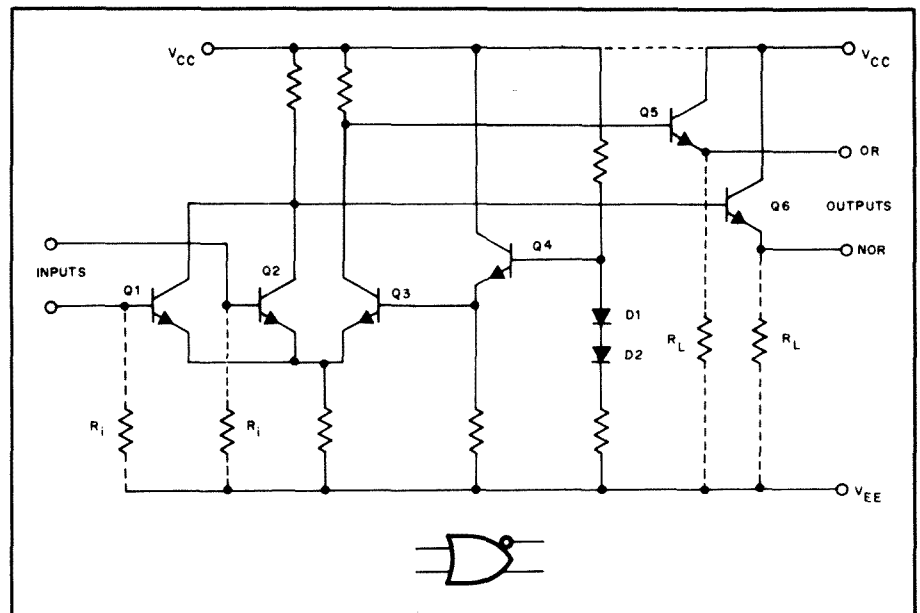

Fig. 28 — Circuit topology of the ECL family. The functions of the various components are explained in the text. The availability of the complimentary output is indicated by the modified logic symbol.

devices to share a common set of wires (called a *bus*).

Typically, TTL devices have a fan-out of 10 within a subfamily. Buffers may be used to increase fan-out.

### TTL Inputs

If TTL inputs are left open, they assume a high logic state. However, greater noise immunity will be realized if pull-up resistors are used. A pull-up resistor is used to connect an input to the supply voltage. When operated with a +5-V supply, any input level between 2.0 and 5.5 V is defined to be high. A level less than 0.8 V is an input low.

### Decoupling

When a TTL gate changes state, the amount of current that it draws changes rapidly. These changes in current, called switching transients, appear on the power supply line and can cause false triggering of other devices. For this reason, the power bus should be adequately decoupled. For proper decoupling, use 0.1  $\mu\text{F}$  from  $V_{+}$  to ground at each standard TTL IC and 0.01  $\mu\text{F}$  at each L, LS or S device.

### Emitter-Coupled Logic (ECL)

ECL, also called current-mode logic (CML), has exceptionally high speed, high input impedance and low output impedance. Some ECL devices can operate at frequencies higher than 1.2 GHz. This family is different from the other bipolar logic families; the transistors operate in a nonsaturated mode that is analogous to that of some linear devices. ECL devices are used in UHF frequency counters, UHF synthesizers and high-speed computers.

A significant feature of ECL gates is that complementary output functions are

available from each circuit. For example, the circuit of Fig. 28 provides both an OR output and a NOR output. Q1 or Q2, together with Q3 forms a differential amplifier. When the Q2 collector goes high, the Q3 collector goes low. These levels then appear at the emitters of the output buffers, Q5 and Q6. Q4, D1 and D2 and associated circuitry form a bias generator. The reference voltage established at the base of Q3 determines the input switching threshold.

The typical logic swing for ECL devices is only 800 mV. ECL devices are characterized for use with a -5.2-V power supply, but operation from other supplies is possible. If the  $V_{cc}$  terminal is connected to +2.0 V and the  $V_{ee}$  terminal connected to -3.2 V, the device can drive a 50-ohm load. The power output obtained this way is about 1 mW. Heat sinking is sometimes necessary because ECL ICs dissipate a great deal of power.

Several ECL subfamilies are now being produced. High speed and low power dissipation are largely conflicting goals, so different subfamilies are offered to allow the designer to choose the trade-offs. ECL subfamilies are compatible, but only over a limited temperature range. The differences between subfamilies are mostly in resistance values and the presence or absence of input and output pull-down resistors.

### Other Bipolar Logic Families

There are several bipolar logic families that are used *within* ICs to increase functional density and to give some analog function to bipolar ICs. These logic families are generally *not* present at the inputs and outputs of ICs, and are not encountered by the user.

*Integrated Injection Logic (I<sup>2</sup>L)* has increased density and decreased power consumption at speeds near those of TTL. It can handle both digital and analog operations on a single chip. Current-Hogging Logic (CHL) is a saturated-logic variation of I<sup>2</sup>L and has higher noise immunity.

*Complementary-Constant-Current Logic (C<sup>3</sup>L)* operates at faster than I<sup>2</sup>L speeds without sacrificing high chip density.

*Triple-Diffused Emitter-Follower Logic (3D-EFL)* is an unsaturated bipolar logic family that takes its name from the triple-diffusion fabrication process used to simplify production.

## METAL-OXIDE SEMICONDUCTOR (MOS) LOGIC FAMILIES

While bipolar devices use PNP and NPN junction transistors, MOS devices are composed of N-channel or P-channel field-effect transistors (FETs). MOS is characterized by simple device structure, small size (high density) and ease of LSI fabrication. MOS families are used extensively in microprocessors, digital watches and calculators.

### P-Channel MOS (PMOS)

PMOS, in which P-type dopant is used for the source and drain, is the oldest and simplest MOS process. Electrical current in a PMOS device is conducted by the flow of positive charges (holes). PMOS power consumption is lower than that of bipolar logic, but its operating speed is slower. The only extensive use of PMOS is in calculators and watches, where low speed is acceptable and low power consumption and cost are desirable.

### N-Channel MOS (NMOS)

In NMOS, N-type material is used for FET sources and drains, and electrons carry current. Since electrons flow faster than holes, NMOS has at least twice the speed of PMOS. NMOS also has greater gain than PMOS and supports greater packaging density through the use of smaller transistors.

### Complementary MOS (CMOS)

CMOS uses both P-channel and N-channel devices on the same substrate to achieve high noise immunity and low power consumption (less than 1 mW per gate and negligible power during standby). This accounts for the widespread use of CMOS in battery-operated equipment.

A notable feature of CMOS devices is that the logic levels swing to within a few millivolts of the supply voltages. The input switching threshold is approximately one half the supply voltage ( $V_{dd} - V_{ss}$ ). This characteristic contributes to high immunity to noise on the input signal or power supply lines. CMOS input-current drive requirements are miniscule, so their fan-out is great, at least in low-speed systems. (For high-speed systems, the input capacitance increases the dynamic

Fig. 29 — Internal structure of a CMOS gate.

Fig. 30 — Comparison of speed and power capabilities of various logic families.

power dissipation and limits the fan-out.) There are now a number of CMOS logic IC subfamilies in production.

The 4000A series is the original commercial line. This series operates with supplies of 3 to 12 V.

A subfamily having some improved characteristics is the 4000B (for buffered) series. The B series can be powered from supplies of up to 18 V. This feature makes the devices especially attractive for automotive applications. The output impedance of buffered ICs is independent of the input state. An unbuffered series, designated the 4000UB, meets all the B-series specifications except that the logic outputs are not buffered. Also, input logic levels must be within 20 percent of the supply voltages. Several trade-offs must be considered when choosing between buffered and unbuffered ICs. Buffered devices have greater noise immunity and drive capability but lower speed than unbuffered

types. Some special-purpose 4000-series ICs have three-state output circuits. The third state is neither high or low, but is a high-impedance condition, which allows several outputs to be paralleled for wire ORing or multiplexing. (See preceding discussion of TTL outputs.)

The 54C/74C series is designed to be a CMOS plug-in replacement for low-power TTL devices in some applications. The 54HC/74HC is a subfamily of high-speed CMOS devices using a silicon-gate CMOS process to attain speeds similar to Schottky TTL. 54HC/74HC devices were designed specifically to replace 54LS/74LS devices. These have input, output and supply parameters tailored to the 54LS/74LS series, resulting in the relatively high speed of bipolar logic and low power consumption and high noise immunity of CMOS.

### Special Considerations

A simplified diagram for a CMOS logic

inverter is given in Fig. 29. Some of the diodes in the input- and output-protection circuits are an inherent part of the manufacturing process. Even with the protection circuits, CMOS ICs are susceptible to damage from static charges. To protect against damage from static, the pins should not be inserted in Styrofoam™ as is commonly done with TTL ICs. Instead a spongy conductive material is available for this purpose. Before removing a CMOS IC from its protective material, make certain that your body is grounded. A conductive bracelet connected to the ground terminal of a 3-wire ac outlet through a 10-megohm resistor is adequate for this purpose.

All CMOS inputs should be tied to an input signal, + supply voltage or ground.

Unterminated CMOS inputs, even on unused gates, may cause gate outputs to oscillate. Oscillating gates draw high current and overheat.

The low power consumption of CMOS ICs made them attractive for satellite applications, but standard CMOS devices have proven to be sensitive to low levels of radiation — cosmic rays, gamma rays and X rays. Now, radiation-hardened CMOS ICs are able to tolerate  $10^6$  rads, making them suitable for space applications.

#### Silicon-on-Sapphire (SOS)

SOS is a fabrication technique that takes its name from depositing a thin silicon film on an insulating sapphire substrate. This minimizes the parasitic capacitance normally found between the source, drain and a

silicon substrate. SOS technology has been used to produce CMOS ICs with greatly reduced gate propagation times.

#### SUMMARY

There are many types of logic ICs, each with its own advantages and disadvantages. If you want low power consumption, you should probably use CMOS. If you want ultra-high-speed logic, you will have to use ECL. The graphs in Fig. 30 should give you some idea of what logic family and sub-families are acceptable in your circuit. Whatever the application, consult up-to-date literature when designing logic circuits. IC data books and applications notes are usually available from IC manufacturers and distributors.

## Digital Interfacing

The term *interface* is used to describe a boundary between, or a physical or logical interconnection of, two devices, circuits or systems. *Physical interfaces* may be electrical and/or mechanical. Electrical interfaces must match such parameters as signal level and circuit impedance. *Mechanical interfaces* involve the mating of connectors and specific pin assignments within those connectors. *Logical interfaces* provide communication between different modules in software.

Different interfacing tasks call for different levels of formality and standardization. Designers are free to define their own interfaces between logic families on a circuit board or circuit boards within a piece of equipment. When interfacing between two computers or between a terminal and a modem, however, existing interface standards should be followed.

#### INTERFACING LOGIC FAMILIES

Each semiconductor logic family has its own advantages in particular applications. For example, the highest frequency stages in a UHF counter or a frequency synthesizer would use ECL. After the frequency has been divided down to less than 25 MHz, the speed of ECL is unnecessary, and its expense and power dissipation are unjustified. TTL or CMOS are better choices at lower frequencies.

Each logic family has its own input voltage and current requirements, so they can't be mixed with satisfactory results. The term *interface* is used to describe the point at which one logic family ends and another begins.

There are a number of ICs intended especially for mating different logic families. The CD4049UB and CD4050B

hex buffers are designed to drive TTL gates from CMOS input signals. TTL-to-ECL and ECL-to-TTL conversion can be implemented with the N1017 and N1068 ICs manufactured by Signetics and others. Unfortunately, these components aren't always conveniently available to the small-quantity purchaser, so logic interface sometimes must be accomplished by other circuitry.

A knowledge of the internal circuits of integrated circuits and their input/output (I/O) characteristics will allow the designer to devise reliable digital interfaces. Typical internal structures have been illustrated for each common logic family. The I/O characteristics of the common logic families are listed in Table 6. This information was compiled from various industrial publications and is intended only as a guide. Certain ICs may have characteristics that vary from the values given.

The following section discusses some specific logic conversions. Often more than one conversion scheme is possible, depending on whether the designer wishes to optimize power consumption or speed. Usually one must be traded off for the other. Where an electrical connection between two logic systems isn't possible, an optical isolator can sometimes be used.

#### TTL Driving CMOS

A CMOS gate is easily driven by a TTL device when both are powered by a +5-V source. However, the totem-pole output structure of most TTL ICs prevents a high output level of sufficient potential to properly activate a CMOS input. A pull-up resistor connected from the interface point to the power bus will remedy this problem. The maximum usable value for

this resistor is 15 k $\Omega$ , but the circuit capacitance, coupled with this large resistance, will reduce the maximum possible speed of the CMOS gate. Lower resistance values will generate a more favorable RC product at the expense of increased power dissipation. A standard TTL gate can drive a pull-up resistor of 330  $\Omega$ , but a low-power version is limited to a 1.2 k $\Omega$  minimum. The resistor pull-up technique is illustrated in Fig. 31A.

When the CMOS device is operating on a power supply other than +5 V, the TTL interface is more complex. One fairly simple technique uses a TTL open-collector output connected to the CMOS input and a pull-up resistor, the other end of which is connected to the CMOS supply. Although this method works in many applications, the common-base level shifter of Fig. 31B will translate a TTL output signal to a +15-V CMOS signal while preserving the full-voltage immunity of both gates. An operational amplifier configured as a comparator, as in Fig. 31C, makes an excellent converter from TTL to CMOS using dual power supplies. An FET op amp is shown because its output voltage can usually swing closer to the rails (+ and - supply voltages) than a bipolar unit. Where the pulse rate is below 10 kHz or so, a 741 op amp may be used.

#### CMOS Driving TTL

The 4049UB and 4050B devices already mentioned can drive two standard TTL loads when a common +5-V supply is used. Most A-series CMOS ICs can't sink enough current to drive TTL gates to a reliable low input state. Gates from the B series can drive one low-power TTL load directly. The 74C00 family is capable of

Table 6

Electrical Characteristics of Common Logic Families

	Standard TTL (active pull-up) $V_{CC} = +5.0\text{ V}$	Schottky TTL (74S) $V_{CC} = +5.0\text{ V}$	High-speed TTL (74H) $V_{CC} = +5.0\text{ V}$	Low-power TTL (74L) $V_{CC} = +5.0\text{ V}$	Schottky low-power TTL (74LS) $V_{CC} = +5.0\text{ V}$	ECL III (1600 series) $V_{CC} = 0\text{ V}$ , $V_{EE} = -5.2\text{ V}$	ECL 10 k

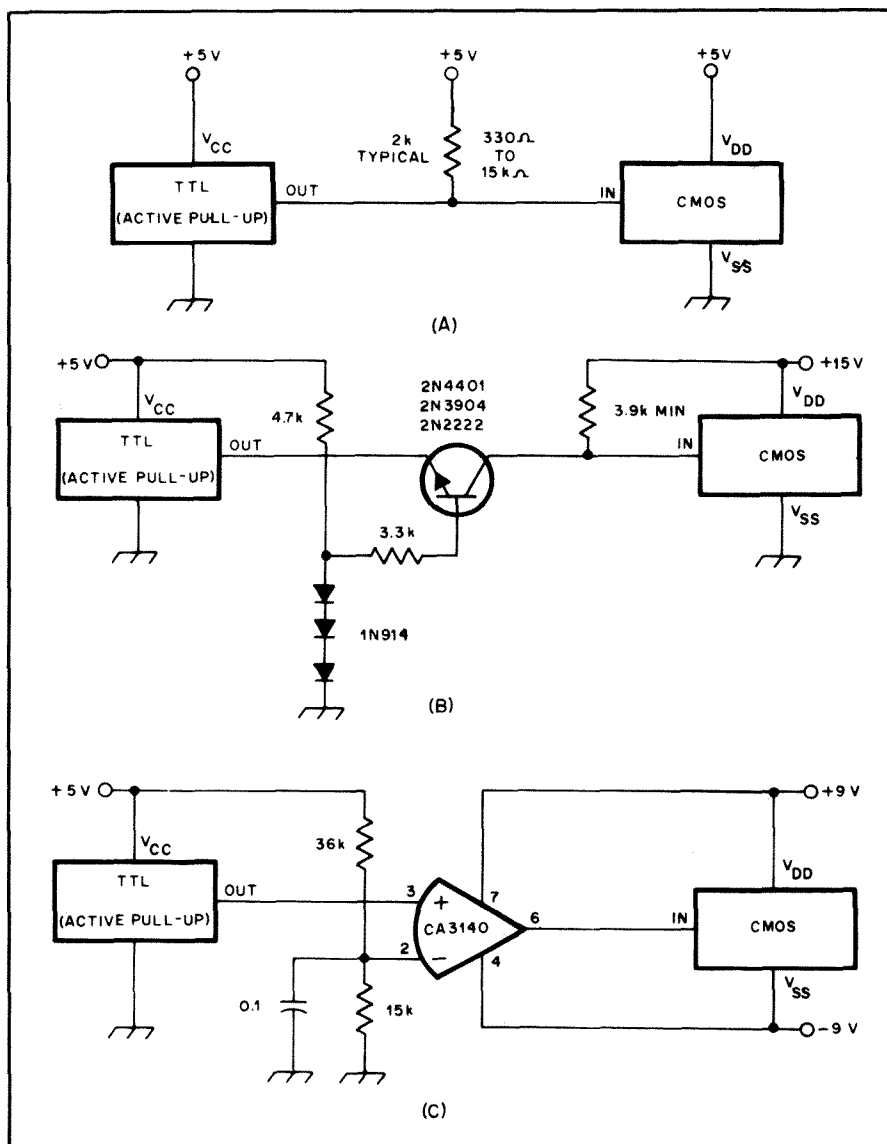

Fig. 31 — Methods for driving CMOS loads from TTL sources. The circuit complexity depends on the power supply voltages. The operation of these circuits is discussed in the text.

direct connection to low-power TTL with a fan-out of two. The drive capability of CMOS gates can be increased by connecting identical gates in parallel, but this practice is not recommended unless all the gates are contained in a single IC package.

Fig. 32A shows a simple method for driving a TTL load from a CMOS source operating with a higher-voltage power supply. The diode blocks the high voltage from the CMOS gate when it is in the high output state. A germanium diode is used because its lower forward-voltage drop provides higher noise immunity for the TTL device in the low state. The 68-kΩ resistor pulls the input high when the diode is back biased.

Standard TTL inputs draw 1.6 mA in the low state. A pull-down resistor for this purpose can be no larger than 220 Ω. To pull a 220-Ω resistor up to an acceptable high level requires 10 mA, which is beyond the capabilities of most CMOS devices. When a pull-down resistor is used, a dual-gate MOSFET having high transconductance makes a good buffer between CMOS and TTL circuits. This scheme is diagrammed in Fig. 32B. The CMOS power supply voltage isn't critical when this system is used, because the output impedance of the CMOS device is high compared to the pull-down resistance, and the protective diodes in the FET can sink more current than the CMOS IC can source. In fact, this circuit can also be used with split supplies, provided that the positive CMOS output excursion is at least 5 V.

#### TTL Driving ECL

When a common power supply is used, the resistor network of Fig. 33A will allow a standard TTL gate to drive an ECL input at the maximum TTL speed. Although shown with V<sub>CC</sub> connected to +5 V and V<sub>EE</sub> grounded, the same circuit will work

CMOS (4000A)			CMOS (4000B)			CMOS (74C00)

with  $V_{cc}$  connected to ground and  $V_{ee}$  (and the "ground" terminal of the TTL device) connected to  $-5$  V. This arrangement provides full noise immunity for the ECL circuit. Where speed is not a consideration, a TTL output can be connected to an ECL input with a pull-up resistor.

Independent TTL and ECL circuits can be coupled by the interfaces in Fig. 33B and C. In B, the TTL gate is divorced from the voltage-divider network when the output is high. In this state the junction of the 1.2-k $\Omega$  and 12-k $\Omega$  resistors assumes a potential of nearly  $+5$  V. When the TTL output goes low, the anode end of the diode string is pulled down to about  $+2.5$  V. This 2.5-V logic swing is attenuated and shifted to the proper nonsaturating ECL levels by the resistor network.

An emitter-follower stage is used in Fig. 33C. The  $-1.8$ -V potential at the ECL input established by the resistor network prevents the transistor from turning on when the TTL output is low. A germanium diode provides a stiff voltage reference in the low state and prevents excessive conduction in the upper transistor of the IC output structure. The voltage translation process is similar to that in Fig. 33B. Returning the collector to  $+5$  V rather than ground keeps the transistor well out of saturation.

### ECL Driving TTL

The complementary output of ECL gates can be used to advantage in converting to TTL levels. Modern ECL ICs have emitter-follower outputs that are ideal for switching the base-emitter junctions of bipolar transistors. For coupling logic circuits having a common 5- or 5.2-V power supply, the PNP-transistor and pull-down-resistor combination of Fig. 34A may be used. A positive supply is shown, but the circuit will also work with negative supplies. The circuit in Fig. 34B will condition  $-5.2$ -V ECL

signals to drive  $+5$ -V TTL gates. Transposing the OUT and  $\overline{\text{OUT}}$  connections of the ECL device will effect a logic inversion with the translation. This technique can also be applied to flip-flops, which have Q and  $\overline{Q}$  outputs.

### CMOS Driving ECL

Speed is rarely a consideration when mating a relatively slow logic family to one that is very fast — the system cannot be

faster than the slowest logic element used. The speed of ECL ICs comes from keeping the transistors out of saturation, and it is for this reason that the defined input-logic swing is only about 400 mV. However, the input levels can be anywhere within the range of the power supply without damaging the device. Negligible input current is required for either logic state, so when a common 5- or 5.2-V power supply is used, CMOS can drive ECL directly. A variety of circuits can be used between CMOS and ECL systems having different power supplies. The scheme illustrated in Fig. 35A is useful when a split power supply is used for the CMOS logic. The advantage of using a MOSFET converter is that the fan-out (to other CMOS devices) is not compromised. Fig. 35B shows a  $+15$ -V CMOS system driving a  $-5.2$ -V ECL gate through a PNP transistor. Altering some of the resistance values will make this circuit work with split-supply CMOS as well. This conversion method results in a logic inversion, but that problem usually can be remedied at the ECL output.

### ECL Driving CMOS

Some voltage amplification is required if an ECL gate is to drive CMOS. When the ECL supply is negative and the CMOS supply is positive, the circuit of Fig. 34B illustrated for ECL-to-TTL conversion may be used. All of the resistors can be made much larger with CMOS for reduced power consumption.

The differential comparator arrangement

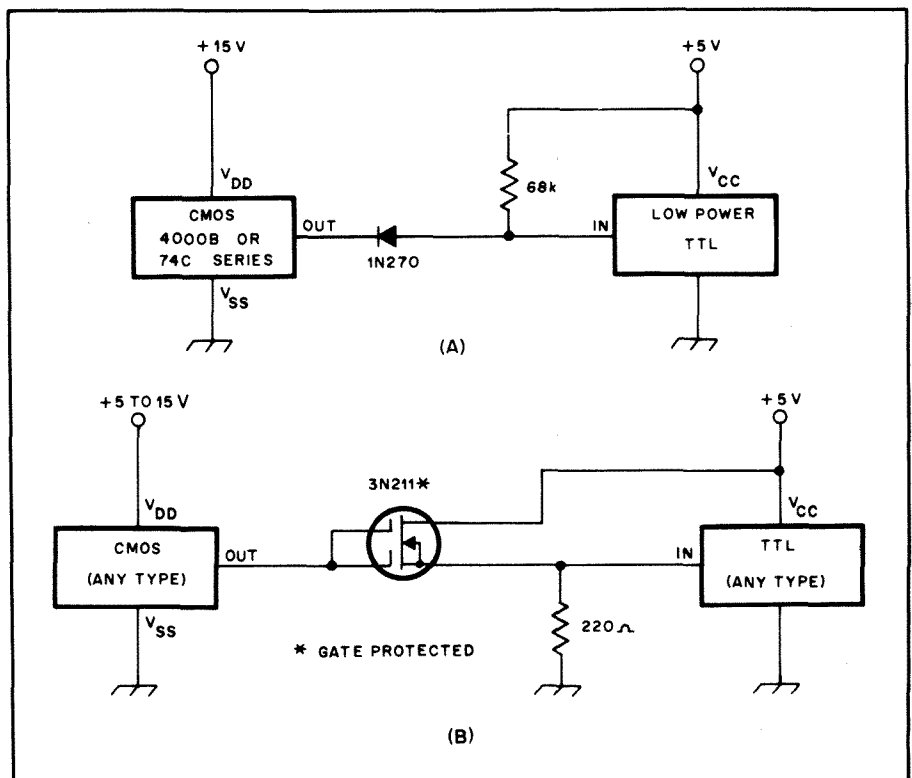

Fig. 32 — CMOS-to-TTL interface circuits. When both devices operate from a  $+5$ -volt supply, the diode in A can be eliminated. The circuit in B will work with a wide range of supply voltages and logic subfamilies.

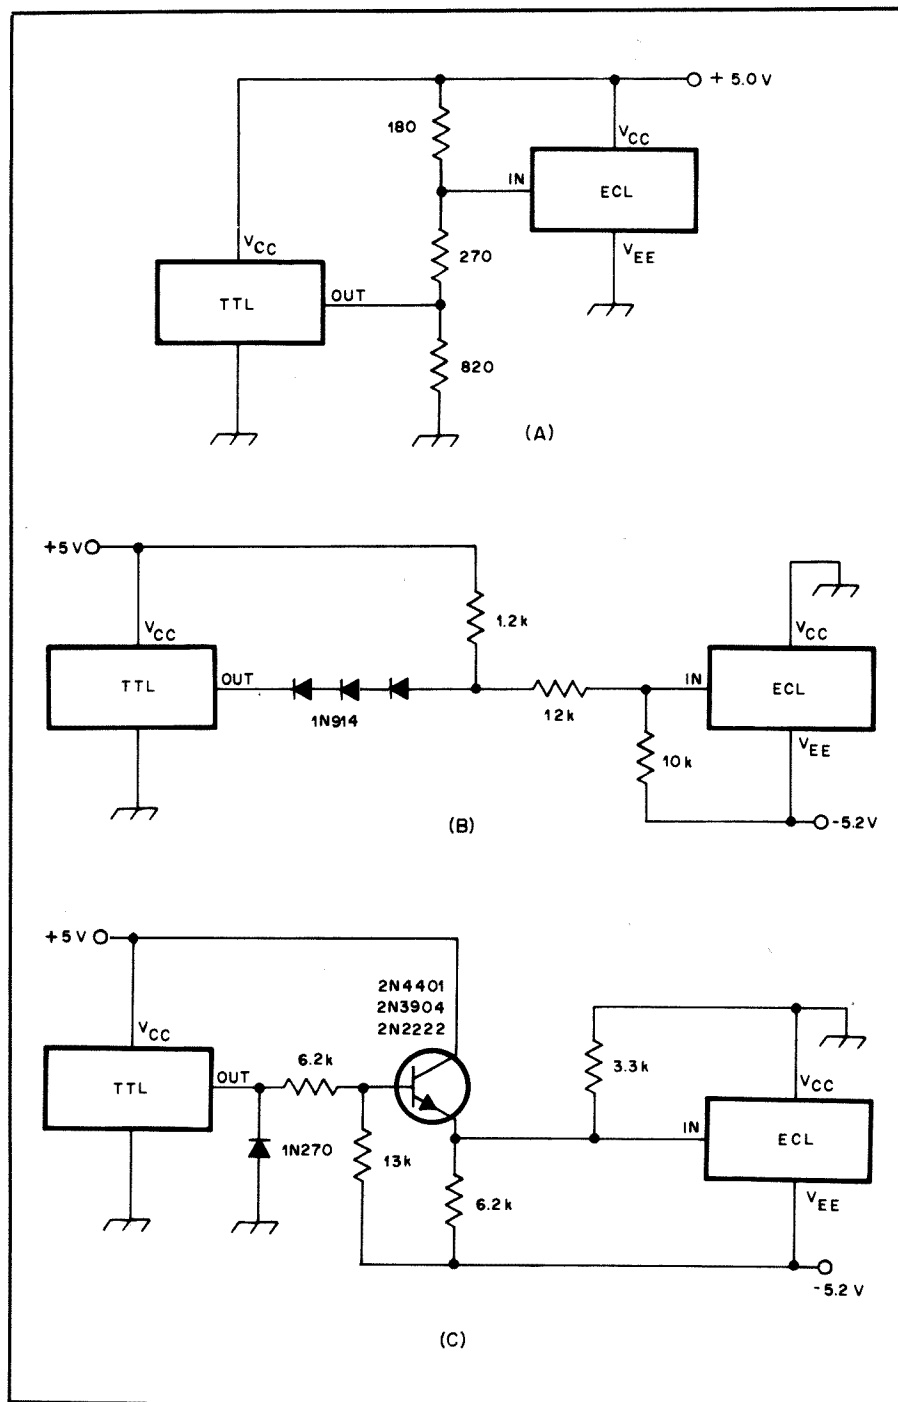

Fig. 33 — These circuits allow TTL gates to drive ECL systems using various power supply arrangements. Each is discussed in the text.

in Fig. 36A is another good translation method. If the CMOS circuit has split power supplies, the  $-V$  terminal of the op amp should be returned to  $V_{ss}$ . With split CMOS supplies the op amp can be connected directly to the CMOS input; the resistor and diode are unnecessary. If complementary ECL outputs aren't available, one of the comparator inputs should be biased to some potential between the two ECL logic levels.

Fig. 36B shows a way to obtain the required CMOS logic swing when both families are powered from the same sup-

ply. This NPN-PNP saturated amplifier will also work when a common negative supply is used.

#### Summary

Most logic families and subfamilies can be interconnected. As the schematics in the preceding sections show, interface circuits are not complex. As in the initial logic family selection, high speed and low power consumption must be juggled when designing interface circuits. You will construct successful interfaces if you remember to stay within the current and voltage limits

for gate inputs and do not draw excessive current from gate outputs.

#### OPTOCOUPLEDERS

An *optocoupler*, or *optoisolator*, is an LED and a phototransistor in a single IC package. Because they use light instead of an electrical connection, optoisolators provide a clean interface between circuits using widely differing voltages. Most LEDs in optocouplers are infrared emitters, although some operate in the visible light spectrum.

Fig. 37A shows the schematic diagram of a typical optocoupler. In this case, the base of the phototransistor is brought outside the package. Access to the base lead is useful for controlling the transistor when the LED is not energized.

The figure of merit for an optocoupler is the current transfer ratio (CTR), the ratio of  $I_E$  to  $I_F$ , where  $I_E$  is the phototransistor emitter current and  $I_F$  is the forward current through the LED. A Darlington phototransistor is used in some devices to establish a more favorable transfer characteristic. The schematic of an optocoupler with a Darlington phototransistor is shown in Fig. 37B.

In optocouplers with an internal light path, the light is transmitted from the LED to the phototransistor detector by means of a plastic light pipe or air gap. There are other configurations such as ones with an external reflective light path and others with an external light gap. An *optical shaft-encoder* is an array of open optocouplers chopped by a rotating wheel.

It is possible to make an optocoupler from a separate emitter and photodetector for applications such as a punched-tape or punched-card reader. Also, separate emitters and photodetectors are used for transmission of digital pulses over considerable distances. Amateur Radio applications of this type include use of light pipes to connect different pieces of equipment in the presence of high RF fields. Amateurs should consider optical coupling to minimize radio-frequency interference between digital and analog equipment such as computers and radios.

An optoisolator packaged with a triac forms a *solid-state relay* that can replace electromechanical units in many applications. The advantages of this scheme include freedom from contact bounce, arcing, mechanical wear and noise. Some solid-state relays are capable of switching 10 A at 117 V from CMOS signals.

Optical isolators can solve problems that might otherwise require complex circuits. Using optical isolators, low-voltage logic circuits can control high-voltage "real-world" devices, such as radio transceivers. Thus, optical isolators are critical to many digital control circuits. When designing circuits with optical isolators, check the current transfer ratio, isolation voltage and

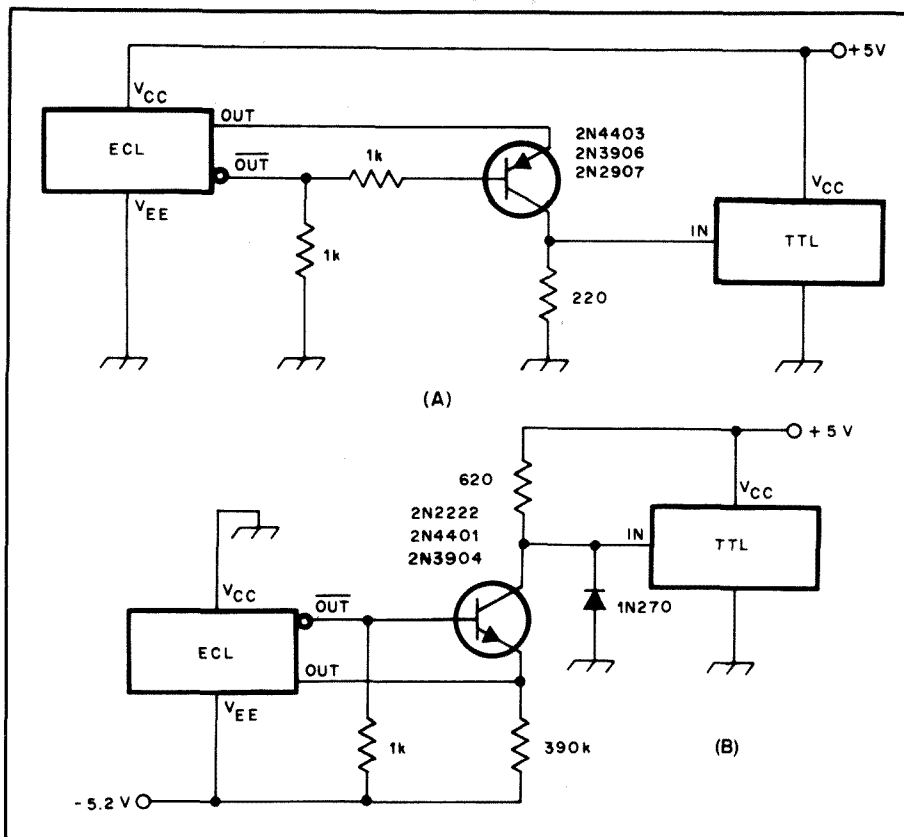

Fig. 34 — Bipolar transistors are used in these ECL-to-TTL converters.

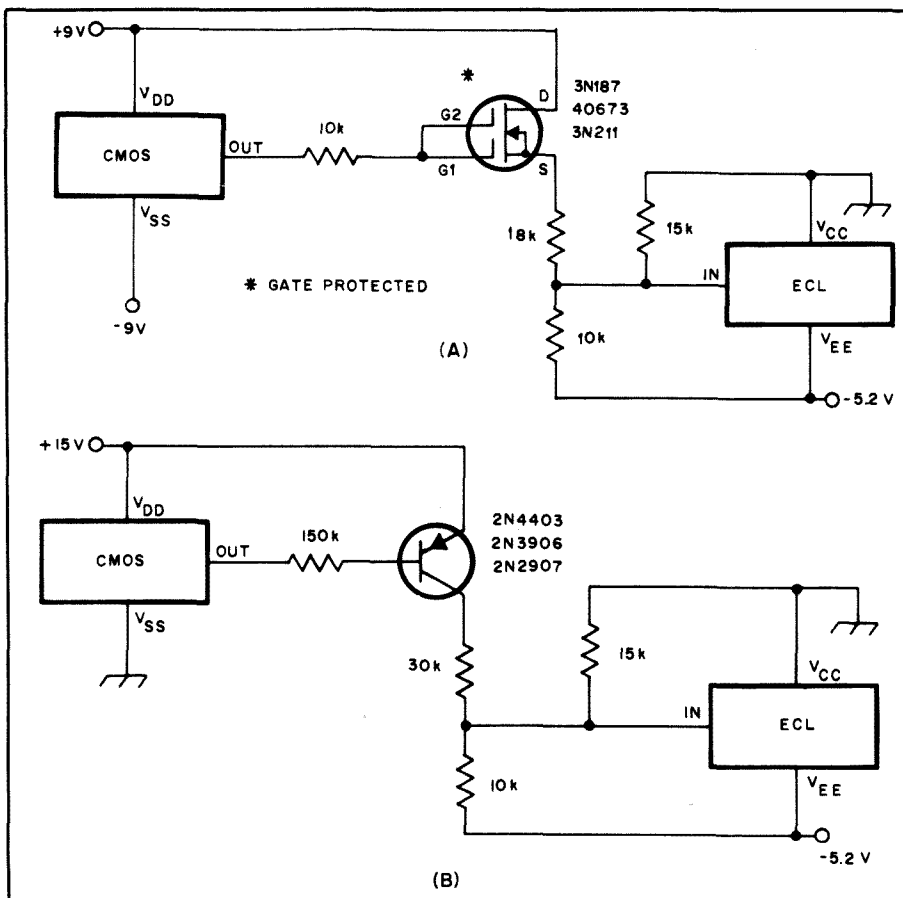

Fig. 35 — Split-supply CMOS logic can drive ECL through a MOSFET, as in A. When the CMOS system is powered from a single high-voltage supply, the bipolar transistor circuit of B can be used. Note that this results in a logic inversion.

switching speed specifications.

## INTERFACING EXTERNAL DEVICES

There are numerous considerations in design of an interface for connection with an external device. If the external device already exists and cannot be changed, the interface design task is largely a matter of meeting the established requirements of the external device. Key questions are: What type of connector is used, and what are the pin assignments? What voltage or current levels are required? What is the data rate? What is the signaling format?

If the external device can be modified or has yet to be designed, it is prudent to investigate existing standards and conventions for interfacing such devices. To do otherwise would be not only "reinventing the wheel" but limiting the possibilities of interfacing with other similar devices. An interface standard encountered often in Amateur Radio is the Electronic Industries Association (EIA) RS-232-C and its International Telegraph and Telephone Consultative Committee (CCITT) counterparts V.24 and V.28. Details of these and other established standards are presented in Chapter 19. To understand these standards, it is necessary to know something about how data is communicated among devices.

## Parallel and Serial Signaling

Within a piece of digital equipment, it is normal to handle a number of associated bits in *parallel* — all the bits in a group (byte or word) are handled at the same time. Typically, but not always, there are 8 associated bits, and 8 conductors to move the information from one circuit to another. The requirement for 8 separate conductors is not a problem within a piece of equipment. When transmitting digital information over long distances, however, providing 8 wires or 8 simultaneous communications channels may be too expensive for the application.

The solution to this problem is *serial* signaling, in which each of the bits is sent in turn, in agreed sequence, over a single channel or wire. Continuing with 8 bits as an example, it is convenient to name the bits  $b_0$ ,  $b_1$ ,  $b_2$ ,  $b_3$ ,  $b_4$ ,  $b_5$ ,  $b_6$  and  $b_7$ . (The subscripted figures represent each bit's binary weight.) One of the things that must be specified for serial communications is whether  $b_0$  (the least-significant bit or LSB) or  $b_7$  (the most-significant bit or MSB) is sent first. Serial signaling makes it possible to send multi-bit binary-coded data over a single digital channel.

A graphic illustration of parallel and serial signaling is given in Fig. 38. In most amateur digital communications (either via radio or telephone lines), serial transmission is used to minimize cost and complexity.

## Operational Mode

The number of channels needed for either serial or parallel signaling depends

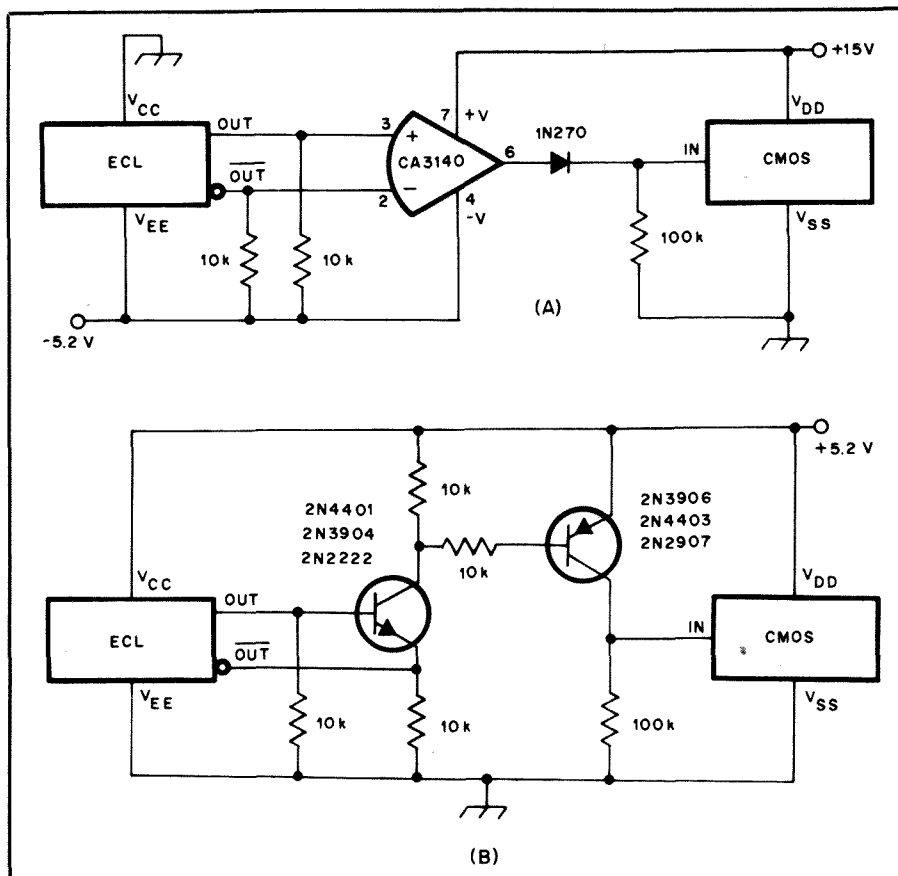

Fig. 36 — ECL-to-CMOS interface circuits. A method useful when different power supplies are used is illustrated in A. The diode prevents the  $-5.2$ -volt LOW level from damaging the CMOS device. When a common supply is available, the two-transistor amplifier/translator shown at B may be used.

Fig. 37 — Optocouplers consisting of an LED and phototransistor detector. The device shown at A uses a typical single-transistor detector, while B has a Darlington phototransistor for improved transfer ratio.

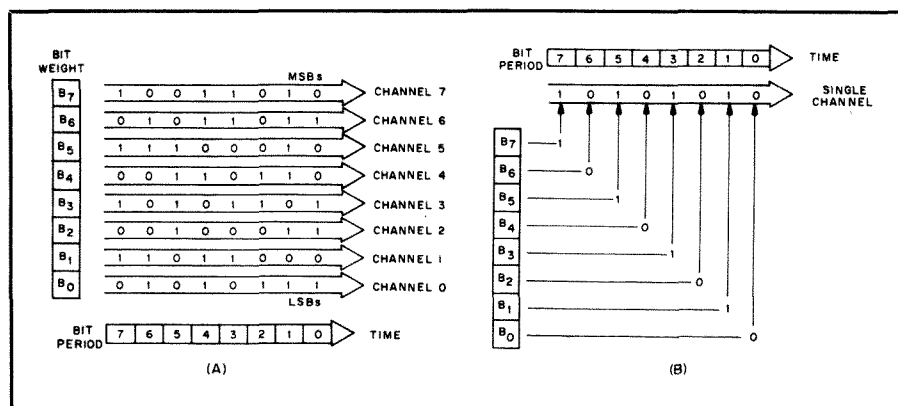

Fig. 38 — Parallel (A) and serial (B) signaling. Parallel signaling in this example uses 8 channels and is capable of transferring 8 bits per bit period. Serial transfer uses only one channel and can send only one bit per bit period.

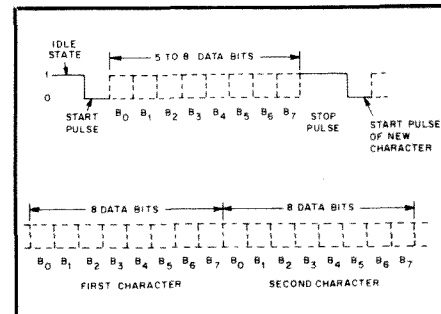

Fig. 39 — Serial data transmission format. In asynchronous signaling at A, a start pulse of one bit period is followed by the data bits and a stop pulse of at least one bit period. In synchronous signaling at B, the data bits are sent continuously without start or stop pulses.

on the operational mode.

**Simplex** operation involves only one-way transmission. So only those channels needed to get the information from the sender to the receiver are necessary.

**Half-duplex** operation is similar to simplex except that the direction of transmission can be reversed. This permits two-way communication without the need for a separate channel each way. The penalty is that the channel must be shared and cannot provide full-time communications in both directions.

**Full-duplex** operation is simultaneous two-way signaling. For parallel transfer of 8 bits in both directions, 16 channels are required. Full-duplex serial communication requires two channels. Full-duplex operation has the advantage of being able to provide communications in both directions at once.

## Synchronization

In order to correctly receive data, the receiving interface must know when data bits will occur — it must be *synchronized* with the sender. There are two types of synchronization. In *asynchronous* communication, the receiver synchronizes on each incoming character. In *synchronous* communication, data is sent in long blocks, without start and stop bits or gaps between characters. Each of these schemes has its advantages and disadvantages.

## Asynchronous Communications

In asynchronous communications, each character transmitted begins with a *start bit* and ends with a *stop bit* (Fig. 39). The start bit (usually a zero) tells the receiver to begin receiving a character. The stop bit (usually a one) signals the end of a character. Between characters, the transmitting circuit sends the stop-bit state (steady one or zero). Because the receiver is always told when a character begins and ends, characters need not be sent at regular intervals. This is especially useful when there is a person typing the input characters; the typist is usually slower than the data communications equipment and may not type at an

even pace. One disadvantage of asynchronous communications is the inclusion of the start and stop bits, which are not "useful" data; if you are transmitting 8 data bits, a start bit and a stop bit, 2 of the 10 bits transmitted, or 20% of the bits, are *overhead*, used only for synchronization. On the other hand, asynchronous communications are rather simple. Because the receiver is newly synchronized at the beginning of each character, it does not need complex circuits to keep it synchronized. Because the characters need not be sent in a steady stream, no stringent demands are made on the person or process generating the characters. Amateur RTTY is usually asynchronous.

### Synchronous Communications

In synchronous communications, data is sent in *blocks*, usually longer than a single character (Fig. 39). At the beginning of each block, the sender transmits a special sequence of bits that the receiver uses for initial synchronization. After becoming synchronized at the beginning of a block, the receiver must stay synchronized until the end of the block. Because the sender and receiver may be using slightly different clock frequencies, it is usually not adequate for the receiver to merely get synchronized initially and then depend on its internal clock. There are several ways for the receiver to stay synchronized. The transmitter may send the clock signal on a separate channel, but this is wasteful. The modulation technique used on the communications channel may convey clock information (Fig. 40C), or the clock might be implicit in the transmitted data (Fig. 40D).

One disadvantage of synchronous transmission is that the data must be sent as a continuous stream; characters must be placed in a buffer until there are enough to make a block. Also, while errors in asynchronous signaling usually only affect one character (the receiver can get re-synchronized at the beginning of the next character), error recovery on synchronous channels may be a longer process involving several lost characters or an entire lost block. The major advantage of synchronous signaling is that it does not impose 20% overhead (the start and stop bits) on each character. This is an important consideration during large data transfers. As AMTOR and packet radio become popular, synchronous communication will play a major role in Amateur Radio.

### Data Rate

There are limitations on how fast data can be transferred. First, the sending equipment has an upper speed at which it can produce the data in a continuous stream. Second, the receiving equipment has an upper limit on how fast it can accept and process data. Third, the signaling channel itself has a speed limit, often based on how fast data can be sent without errors. Final-

Fig. 40 — Recovering the clock (A) when the data (B) is transmitted allows a receiver to maintain synchronization during synchronous communication. The modulation method shown at C results in a transition of the received carrier at the beginning and end of each clock period. The encoding method shown at D results in a data transition in the middle of each clock period. Either of these methods provides enough information for clock recovery.

ly, standards and the need for compatibility with other equipment may have a strong influence on the data rate used.

Data rate can be expressed in a number of ways, but the basic method is to refer to the number of events or symbols per second. The usual symbol is the bit, and data rate is often given in bits per second (abbreviated bit/s). The *baud* (abbreviated Bd) is a unit of symbols per second; in simple signaling systems, bauds equal bits per second.

Within a given piece of equipment, it is desirable to use the highest possible data rate. When external devices are interfaced, it is normal practice to select the highest standard signaling rate at which both the sending and receiving equipment can operate. Standard speeds used in 8-bit serial data transmission include 110, 150, 300, 600, 1200, 2400, 4800 and 9600 bits per second.

### Error Detection in Data Transfers

Whenever data transfers are subject to errors, it is important to include some method of detecting and correcting errors. In data communications, there are numerous techniques for error detection and correction. The technique employed in any specific circumstance depends on the types of errors likely to be encountered in the communications media. Some of these techniques are discussed in Chapter 19.

#### Parity Check

For some data transfers, *parity check* provides adequate error detection. To use the parity check, a *parity bit* is transmitted along with the data bits. In systems

using *odd parity*, the parity bit is selected such that the transmitted character (data bits and parity bit) has an odd number of ones. In *even parity* systems, the parity bit is chosen to give the character an even number of ones. For example, if the data 1101001 (which has an even number of ones already) is to be transmitted in an even parity system, the parity bit should be a 0 (maintaining even parity). If the same data is to be transmitted in an odd parity system, the parity bit should be a 1, resulting in a total of 5 ones. When a character is received, the receiver checks parity by counting the ones in the character. If the parity is correct (odd in an odd system, even in an even system), the data is assumed to be correct. If the parity is wrong, an error has been detected.

Parity checking only detects a small fraction of possible errors. This can be intuitively understood by noting that a randomly chosen word has a 50% chance of having even parity and a 50% chance of having odd parity. Fortunately, on relatively error-free channels, single-bit errors are the most common, and parity checking will always detect a single bit in error. Parity checking is a simple error-detection strategy, and because it is easily implemented, it is frequently used.

### Parallel Input/Output Interfacing

There are a number of parallel input/output (PIO) ICs available. Typically they have eight data lines and one or more *handshaking* lines. Fig. 41 shows a simplified diagram of a PIO chip and its lines to an external device. The term

Fig. 41 — Parallel interface with READY and STROBE handshaking lines.

“handshaking” includes a number of functions needed to coordinate the data transfer. One of these is the READY line, which, when it makes the transition from 0 to 1, indicates that data is now available on all 8 data lines. If only the ready line is used, the receiver may not be able to keep up with the data. In that case, a STROBE line is added to enable the receiver to tell the transmitter that it is ready to receive the next character. There are many other handshaking strategies that may be used during parallel signaling. The Centronics standard (Table 7) is commonly used for sending parallel data to printers.

### Serial Input/Output Interfacing

Serial I/O (SIO) interfacing is more complex than parallel I/O. Fortunately there are a number of ICs available to handle the job. The advantages of serial data transfers and the general formats for asynchronous and synchronous serial transmission have been discussed earlier in this chapter. What is left to understand SIO is a discussion of the conversion process.

Within computers and other digital circuits, data is usually operated on, stored and transmitted in parallel. So, at the terminals of a serial interface, data must be converted from parallel to serial and back again. Serial-to-parallel and parallel-to-serial conversion is normally done with a shift register. The *universal asynchronous receiver/transmitter* (UART) is a shift-register device designed to handle these data conversions. The UART is capable of operating in the full-duplex communications mode. Furthermore, it can simultaneously send and receive data. UARTs can be programmed to select the number of data bits and whether the parity is odd, even, or not used. The UART transmitter accepts data in parallel form and shifts it out in asynchronous serial format. The transmitted serial format includes a start pulse, data pulses and stop pulses of various lengths. The receiver operates by shifting the serial pulses into a register. Then, when the specified number of bits have been stored in the shift register and a stop bit is detected, the data is made available in parallel form.

The *universal synchronous receiver/transmitter* (USRT) is similar to the UART but is for synchronous operation. A more popular device is the *universal synchronous/asynchronous receiver/transmitter* (USART), which combines

Table 7

### Centronics Parallel-Printer Interface

Pin	Name	Source	Meaning
1	STROBE	Computer	Data lines are valid
2-9	D <sub>0</sub> -D <sub>7</sub>	Computer	Data to be printed
10	ACKNOWLEDGE	Printer	Data has been accepted
11	BUSY	Printer	Printer can't receive data
12	PAPER OUT	Printer	No paper in printer

32	ERROR	Printer	Printer error
20-27	RETURNS	—	Grounds for D <sub>0</sub> -D <sub>7</sub>

Fig. 42 — RS-232-C transmission-line drivers and receivers. A is a 1488 quad line driver. B is a 1489 quad line receiver. Note that pins 2, 5, 9 and 12 of the 1489 are response-control lines that are typically connected via 330-pF capacitors to ground.

both a UART and a USRT on one chip.

### Signaling on Line

Inside equipment and for short runs of wire between equipment, the normal practice is to use neutral keying; that is, simply to key a voltage such as +5 V on and off. In neutral keying, the off condition is considered to be 0 V. Over longer runs of wire, the capacitance between conductors and the inductance of the conductors becomes of concern. As the capacitance increases, more time is needed to make the transition from 0 to 1 or vice versa. This decreases the maximum speed at which data can be transferred on the wire, and may also cause the 1s and 0s to be different lengths. This is known as *bias distortion*. Also, on longer lines, there is a possibility of picking up noise, which can make it difficult for the receiver to decide exactly when the transition takes place.

Because of these problems, *polar* or *bipolar* keying is used on longer lines. Polar keying uses one polarity (for example +) for a logical 1 and the other (— in this example) for a 0. This means that the decision threshold at the receiver is 0 V for polar keying. Thus, any positive voltage can be taken as a 1, and any negative voltage becomes a 0.

Since neutral keying is usually used inside equipment, and polar keying is desirable for lines leaving the equipment, signals must be converted between polar and bipolar. The old way of doing this was to use an electromechanical polar relay.

Today, op-amp circuits handle this conversion. Even more convenient than the op amp, however, are ICs called *line drivers* and *line receivers*. There are a number of different types available, but the most popular ones are the 1488 quad line driver and the 1489 quad line receiver. “Quad” signifies that there are four drivers or receivers in the same IC package. Diagrams of the 1488 and 1489 with their pin assignments are shown in Fig. 42. The 1488 is capable of converting four data streams at standard TTL logic levels to output levels that meet EIA RS-232-C or CCITT V.24 standards. The 1488 can also be used to interface DTL/TTL to MOS, DTL/TTL to HTL, and DTL/TTL to RTL. The 1489 has four receivers that can convert RS-232-C or V.24 levels to TTL/DTL levels.

### Summary

There are many types of digital interface, but a given interface can be categorized by answering several questions: Is it a parallel or a serial interface? Is it internal to a device, or is it between two devices? Does the interface signal asynchronously or synchronously? What recognized standards might apply to the interface? Once these broad questions have been answered, you can begin to study the interface in detail.

### DIGITAL AND ANALOG INTERFACING

Until now, we have confined our discussion to digital electronics — the generation

## A/D and D/A Experimentation in Amateur Radio

Analog-to-digital and digital-to-analog conversion have found important applications in the commercial and consumer worlds. These widespread applications have made A/D and D/A technology available to amateur experimenters. Two examples of this consumer-oriented digital signal processing are digital voice transmission and digital high-fidelity audio.

The telephone companies pioneered the digital transmission of voice on a large scale in the early 1960s. Most digital voice transmissions in North America use the AT&T "mu-law" standard — an 8-kHz sampling rate and 8 bits per sample. The resulting signal has an audio bandwidth of 4 kHz and requires a transmission speed of 64,000 bits per second. Mu-law encoding differs from standard A/D conversion in that the steps defined by the 256 quantizing levels are not evenly spaced. This technique causes the quantizing noise to vary with signal level, giving a nearly constant signal-to-noise ratio over a wide range of speech amplitudes. Because of the widespread use of digital speech transmission within the telephone network, mu-law coder-decoder (CODEC) ICs containing A/D and D/A converters and filters have become available at reasonable prices from several manufacturers. These ICs make excellent building blocks for experiments in digital voice communication.

Another consumer product that employs digital signal processing is the high-fidelity Compact Disk Digital Audio System, commonly referred to as the CD. A CD player uses a laser to scan a 12-cm disk that holds up to 74 minutes of very high fidelity digitized audio. The two audio channels are each sampled at a rate of 44.1 kHz, 16 bits per sample. Based on the rule of thumb 6 dB/bit, the quantizing signal-to-noise ratio is approximately 96 dB! As CD technology becomes more popular and more manufacturers produce inexpensive ICs that perform the necessary functions, experimenters will be able to adapt some of these parts to amateur applications. In particular, the CD system uses a sophisticated form of forward error correction (FEC), and ICs developed for this purpose may be very useful in improving the error performance of high speed amateur digital transmissions.

As amateurs gain experience with digital audio, the prospect of integrating this technology with packet radio will become attractive. Voice packet switching represents a way in which amateurs with diverse interests might join forces to build an "integrated voice/data network" capable of satisfying a wide range of communication needs. The basic technology needed is here today; all we need are enough creative and motivated amateurs to make this a reality.

— Phil Karn, KA9Q

Fig. 43 — Analog-to-digital conversion of a complex wave. In this illustration, the voltage of the analog waveform is converted to the closest digital voltage level at the sample times. At each sample time, the digital code corresponding to the digital voltage level appears on output on the parallel outputs of the converter.

and manipulation of bits. It will come as no surprise, however, that it is an analog world. Virtually all measurable values in the physical universe are continuously variable and are thus analog. How can the many advantages of digital processing be applied to the analog world? We must employ *analog-to-digital conversion* (ADC) and *digital-to-analog conversion* (DAC).

### Why Convert?

There are many reasons for using digital techniques on analog signals. Analog signals have the undesirable characteristic that they often pick up noise, and it is difficult or impossible to remove the noise from the signal. Digital signals, on the other hand, are not likely to pick up noise (errors), and once noise has been introduced, it can often be detected and cor-

rected. When an analog signal has been *digitized*, it is subject to the whole spectrum of logical and computerized manipulation. It can be sent from place to place in digital form. It can be stored without corruption. It can be digitally filtered. In short, anything that can be done to or with a collection of bits can now be done to or with the original analog information. Digital signal processing is becoming common as more and more digital computers are connected to the analog "real world."

### Analog to Digital Conversion

The object of analog to digital conversion is to change an analog signal into a collection of bits that accurately represents that signal. This is done by measuring the amplitude of the analog signal and then expressing that amplitude as a binary number (Fig. 43). As we have seen previously, binary numbers can be easily expressed and manipulated by electronic digital circuits. The process of measuring an analog signal and converting it to a binary number is called *sampling*. Correct sampling involves

two things: *sampling rate* and *sampling resolution*.

### Sampling Rate

Each digital sample represents the amplitude of the analog signal at a specific time. As the amplitude of the signal changes, the binary number representing the amplitude must change. The rate at which the binary number is updated is called the *sampling rate*. Fig. 44 shows that if the sampling rate is too low, the digital amplitude values will represent a low-frequency *alias*, as well as the original analog signal. This condition is called *under sampling*. In order for the digital samples to correctly represent the analog signal, the sampling frequency must be at least two times the highest frequency component of the analog signal. This rule and its mathematical proof are the *Nyquist Sampling Theorem*, and the minimum sampling rate is called the *Nyquist rate*.

To apply the Nyquist Theorem, you must know the highest frequency component in the signal that you want to sample. For example, if you want to sample a signal that has components as high as 3 kHz, the theorem specifies a minimum sampling rate of 6 kHz. In practice, it is desirable to sample above the Nyquist rate. This is because the output of an A/D converter contains not only the original signal, but "double sideband" images of the original signal, centered at multiples of the sampling frequency.

Fig. 45 shows the spectrum of an analog signal and the spectrum at the output of an A/D converter. For clarity, only the first image spectrum (centered at the sampling frequency) is shown. The image must be eliminated if the digital sample is to correctly represent the analog signal. If the sampling frequency is below the Nyquist rate, the image overlaps the desired signal (Fig. 45A). Because of the overlap, the image cannot be eliminated without eliminating some of the desired signal. This is called *aliasing*, and is the result of under sampling. When the sampling rate is equal to the Nyquist rate, the image is just adjacent to the desired signal (Fig. 45B). In this case, an ideal filter (with vertical skirts) could eliminate the image.

Only when the sampling rate is above the Nyquist rate is there some separation be-

Fig. 44 — A sine wave sampled below the Nyquist rate. Notice that the samples specify an alias signal as well as the original sine wave.

Fig. 45 — The unfiltered spectral output of an A/D converter. The unshaded spectrum is that of the analog signal being sampled.  $F_A$  is the highest frequency in the analog signal. The shaded spectrum is the first set of sampling products, centered at the sampling frequency ( $F_S$ ). A shows undersampling, B shows sampling at the Nyquist rate, and C shows reasonable oversampling. The dotted lines in B and C represent the filter passbands that would separate the desired signal from the sampling products.

Table 8

#### Signal-to-Noise Ratios for Ideal Analog-to-Digital Conversion

Number of Bits	Amplitude Levels	Signal-to-Noise Ratio (dB)
3	8	18
4	16	24
5	32	30
6	64	36
7	128	42
8	256	48
9	512	54
10	1024	60
11	2048	66
12	4096	72
13	8192	79
14	16384	84
15	32768	90
16	65536	96

tween the desired signal and the image spectrum (Fig. 45C). With this gap between the two spectra, real filters can filter out the image and leave the desired signal unattenuated. The higher the sampling rate with respect to the highest frequency in the analog signal, the farther the undesired image is from the desired signal.

#### Sampling Resolution

Analog signals are infinitely variable; they can take on an infinite number of amplitudes. An A/D converter with  $n$  out-

put bits can only represent  $2^n$  amplitudes (Table 8). Thus, the A/D converter cannot perfectly represent the amplitude of an analog signal. The number of bits in an A/D converter is the *resolution* of the converter. When an analog signal looks like a straight line, the output of an A/D converter has a "stair step" characteristic — it is *quantized* (Fig. 46). Fig. 46 shows the difference between an analog signal and a three-bit digital representation of that signal. At each sampling instant, there is a difference between the analog signal and the closest available digital value. This difference is called *quantization error*. Quantization error introduces noise, called *quantization noise*, to the sampled signal. The higher the resolution of the A/D converter, the lower the quantization error and the smaller the quantization noise. The relationship between resolution (in bits) and quantization noise (for an ideal A/D converter) can be expressed as

$$S/N = -20 \log \left( \frac{1}{2^n} \right) \quad (\text{Eq. 3})$$

where

$n$  = the resolution of the A/D converter in bits

$S/N$  = the signal-to-noise ratio in dB

This relationship can also be approximated as:

$$S/N = 6 \times n.$$

#### Practical Considerations

From the preceding discussions of sampling rate and resolution, we see that large, frequent samples are ideal for A/D conversion. In practical circuits, however, these characteristics conflict with each other and with external constraints. Large samples require longer sampling times, imposing a maximum sampling rate. Samples must be transmitted to the device that is to process them, and communications channels can only handle a limited number of bits per second. Finally, the device that is processing the samples has a maximum processing speed. With all of these varying constraints and the fixed constraints of the Nyquist Theorem and  $S/N$  equations, what is an acceptable A/D sample? Two industry standards are worth mentioning: the standard for digital telephony is 8-bit samples and a 8-kHz sampling frequency; the Compact Disk Digital Audio System takes 16-bit samples at 44.1 kHz. These systems, and their impact on amateur experimenters, are explored in the sidebar.

#### Digital to Analog Conversion

Once an analog signal has been turned into a digital bit-stream and manipulated, stored or communicated, it is sometimes converted back into an analog signal. Frequency and voice synthesizers must also convert digital information into analog signals. This process is called digital-to-

Fig. 46 — Comparison of a linear, analog transfer function with a quantized, digital transfer function. The difference between the two transfer functions results in quantization error, as shown at the bottom of the figure.

analog (D/A) conversion. In D/A conversion, each bit in a digital sample is converted to a voltage or current that is weighted to correspond to the bit's binary value. The resulting analog signals are summed to obtain an analog representation of the binary number. Fig. 47 shows a D/A converter using switched current sources. The output of a D/A converter is called a *digitally synthesized waveform*. Digitally synthesized waveforms are quantized, and the abrupt changes that characterize quantized signals appear on D/A converter outputs. These abrupt changes manifest themselves as unwanted high-frequency components in the output of the D/A converter. They must be removed by filtering. The correct filter for this application is a low-pass filter with cutoff frequency at or below one-half the sampling frequency.

#### Summary

D/A and A/D conversion allow digital circuits to act upon and generate analog signals. Correct A/D conversion requires sampling at or above the Nyquist rate and enough bits per sample to yield a good signal-to-noise ratio. D/A conversion produces an analog signal from a sequence of digitally encoded amplitudes.

#### HYBRID ANALOG AND DIGITAL ICs

There is a growing number of integrated circuits that have both analog and digital inputs and outputs. Some of these chips switch analog signals by means of digital control signals. Others are signal processors.

#### Analog Switches and Multiplexers

*Bilateral switches* are CMOS devices that act as digitally-controlled, SPST, solid-state switches. The signals on the input/output ports of these switches may be either analog or digital. The switches are controlled by digital signals. The block diagram of a quad bilateral switch is shown in Fig. 48.

Analog multiplexers are devices that use

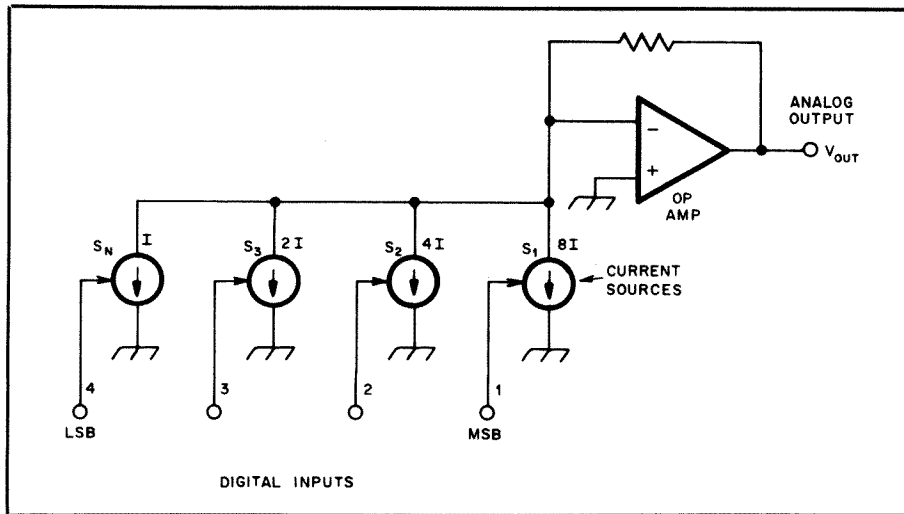

Fig. 47 — A D/A converter using four appropriately weighted current sources and a summing current-to-voltage converter. Notice that the MSB, representing  $2^3 = 8$ , generates 8 times the current generated by the LSB, which represents  $2^0 = 1$ .

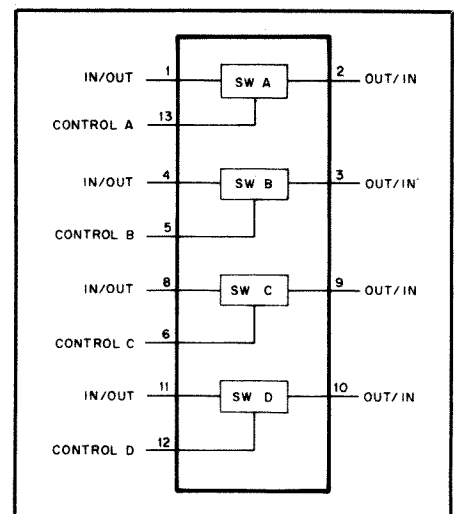

Fig. 48 — Block diagram of a CMOS 4066 quad bilateral switch. Each switch has its own control input.

bilateral switches to implement single-pole multiple-throw switches. Analog multiplexers are bilateral; pins are not strictly inputs or outputs, but can be either inputs or outputs. Unlike bilateral switches, analog multiplexers do not use a single binary control for each switch. Instead, analog multiplexers use binary-coded control inputs. For example, the analog multiplexer represented in Fig. 49 selects one of 8 IN/OUT lines using three digital-control inputs.

Analog bilateral switches and multiplexers can be used to switch signals, control the gain of an amplifier, select among resistive and reactive components, and perform numerous other tasks. Typically, these devices can handle signals up to 15 V peak-to-peak, provided that the power supply can handle the signal excursions. Complex analog multiplexing schemes can be realized by using digital logic to control analog switches.

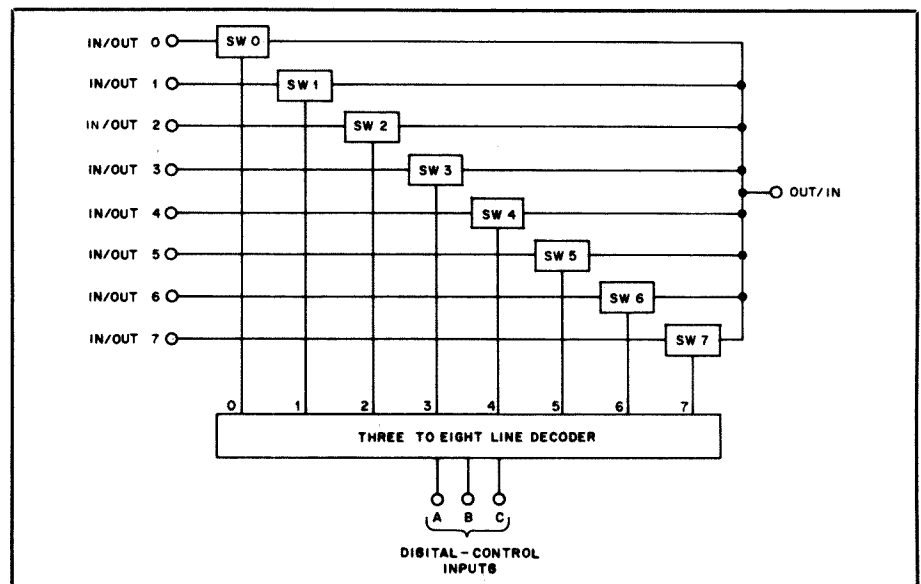

Fig. 49 — Block diagram of an 8-channel analog multiplexer/demultiplexer.

### Sample-and-Hold Amplifiers

A sample-and-hold (S/H) amplifier uses a capacitor to store a sample of input voltage. The charge on this capacitor tracks or samples the input voltage until the amplifier is put into the HOLD mode. At this time, the capacitor stops tracking and holds the input voltage (Fig. 50). S/H amplifiers have numerous applications in A/D and D/A converters. They are also used in data-acquisition and synchronous-demodulation applications.

### Switched-Capacitor Filters

The switched-capacitor filter (SCF) is an IC that can be used as a low-pass, high-pass, band-pass or notch filter with as many as five poles on a single chip. SCFs are easy to use: filter type, Q and bandwidth are determined by external resistors, and the center frequency of the filter is determined by an external clock signal. Furthermore, frequency and bandwidth

can be digitally controlled. Currently-available SCFs have dynamic ranges of around 80 dB and Qs up to 50, and they are usable at frequencies up to 250 kHz. Radio amateurs are using SCFs as CW and RTTY audio-bandpass filters and in DTMF and modem waveform generators.

### SUMMARY

Interfaces take many forms. There are interfaces between IC families, interfaces between circuit boards, interfaces between digital devices and interfaces between digital and analog domains. Each type of interface places different demands on circuit designers. It is important to know what kind of interface you are designing, what its power requirements and restrictions are, what speed it will operate at, how noise is likely to be introduced into it and what standards might apply to the inter-

face. Only when you understand these characteristics can you design and build a successful interface.

Fig. 50 — Simplified diagram of a sample-and-hold (S/H) amplifier. When the switch is in the SAMPLE position, the voltage across the capacitor is equal to the input voltage. When the switch is in the HOLD position, the capacitor retains its charge, presenting a sample of the input voltage to the S/H output.

# Memory Devices

Computers and other digital circuits usually rely on stored information. This stored information may be data to be acted upon or instructions to direct circuit actions. Digital information is stored in *memory devices*.

A memory device consists of a large number of *memory locations* or *words*. Each word, in turn, is composed of some number of *memory cells*, each capable of remembering one bit of binary information. The number of bits in each word, equal to the number of memory cells per memory location, is variable. Eight-, 16- and 32-bit words are common.

In order to store data in, or retrieve data from, a memory device, it is necessary to gain access to specific memory cells. The words *write* and *read* are used to signify storage and retrieval, respectively.

Memories can be divided into broad categories based on what memory cells can be accessed at a given instant. *Sequential-access memories* (SAMs) must be accessed by stepping past each memory location until the desired location is reached. Magnetic tapes implement SAM; to reach information in the middle of the tape, the tape head must pass over all of the information on the beginning of the tape. Two special types of SAM are the *queue* and the *push-down stack*. In a queue, also called a *first-in, first-out* (FIFO) memory, locations must be read in the order that they were written. The queue is a "first-come, first-served" device, like a line at a ticket window. The push-down stack is also called *last-in, first-out* (LIFO) memory. In LIFO memory, the location written most recently is the next location read. LIFO can be visualized as a stack; items are added to and removed from the "top" of a push-down stack.

The second category of memory is *random-access memory* (RAM). Random-access memory allows any memory cell to be accessed at any instant, with no time wasted stepping past "preceding" locations. Random-access memory is like a bookcase; any book can be pulled out at any time.

It is usually faster to access a desired word in random-access memory than it is to access a word in SAM. Also, all words in random-access memory have the same access time, while each word in a SAM has a different access time. Generally, the semiconductor memory devices internal to computers are random-access memories. Magnetic devices, such as tapes and disks, have at least some sequential access characteristics. We will leave tapes and disks for a later section and concentrate here on random-access, solid-state memories.

## Addressing

An *address* is the identifier, or name, given to a particular location in memory. Within a memory IC, each word is given

a unique address. The first word in the memory is given the address 0. To access a given word, the binary address of that word is placed on the chip's *address lines*. For example, to access the 11th word in a memory with eight address lines, the address lines would be set to 00001010. For ease of notation, programmers and circuit designers do not write addresses in binary form, but use octal (base-8) or hexadecimal (base-16) notation. In *hex*, 00001010 is written "0A."

## Memory Chip Size

Because, internally, memories are addressed using binary arithmetic, the number of words in an IC and the number of bits in a word are usually powers of 2. An IC with 8 address lines has  $2^8$  or 256 uniquely addressable words. The size of a memory IC is usually expressed as " $M \times N$ ," where  $M$  is the number of words in the IC, and  $N$  is the number of bits in each word. Memory chips as small as  $16 \times 4$  and as large as  $256,000 \times 1$  are common. To understand how memory ICs are organized into large computer memory systems, one must first understand how small memory chips work. We will use a  $256 \times 1$  IC as an example.

## Memory Architecture

Memory chips, no matter how large or small, have several things in common. Each chip must have *address lines*, *data lines* and *control lines* (Fig. 51). A memory IC must have enough address lines to uniquely address each of its words. A  $256 \times 1$  memory must, therefore, have 8 address lines. There must be as many data lines on a chip as there are bits per word in the chip, so the  $256 \times 1$  memory has 1 data line. Data lines are both inputs to the chip (when writing) and outputs from the chip (when reading). Therefore, there must be a control line that distinguishes read operations from write operations. This line is labeled *R/W* in Fig. 51. When *R/W* is 1, the chip is in the write mode.

The final control line on this simple memory is the chip select (*CS*). When *CS* is 1, the chip is selected, and it acts on the *R/W*, address and data information presented to it. When *CS* is low, the data line enters a high-impedance state, so that the deselected chip does not effect operation of devices or circuits attached to it. On actual ICs, *CS* and *R/W* may be inverted or edge-triggered inputs, and there may be other lines on a memory chip. The chip in Fig. 51 does, however, provide a realistic basis for understanding memory chips.

## Writing to Memory

If we want to write a 1 to the 11th word of the  $256 \times 1$  memory in Fig. 51, we must execute the following steps:

- 1) Place the correct address (in this case

Table 9

Comparison of Memory Chips

Type of Memory	Volatile	Frequent Writes	Erasable	Erasable in System
RAM	yes	yes	yes	yes
NVRAM	no	yes	yes	yes
ROM	no	no	no	no
PROM	no	no	no	no
EPROM	no	no	yes	no
EEPROM	no	no	yes	yes
Bubble	no	yes	yes	yes

0A hex or 00001010 binary) on the address lines.

- 2) Place a 1 on the data line.
- 3) Set the *R/W* control line to 1 (write).
- 4) Set *CS* to 1.

This will result in the data on the data line (1) being written to the address on the address lines (00001010).

## Reading from Memory

To read the contents of the 11th word:

- 1) Place the address 00001010 on the address lines.
- 2) Set the *R/W* control line to read (0).
- 3) Set *CS* to 1.

When all of this has been done, the data from address 0A (hex) will be placed on the data line.

## Timing

The above discussion ignores subtle timing requirements. These requirements are strict, and usually insist that data being written to the memory be present for a minimum *setup time* before and *hold time* after the *CS* and *R/W* signals. Timing specifications also specify how long address lines must be stable and when data being read from the memory is valid. Consult manufacturers' data sheets and applications notes for timing information.

## Larger Words

We have shown how a one-bit-wide

memory works. Usually, though, we want a wider memory. Low-cost home computers use 8-bit words, and 16- and 32-bit computers are becoming popular. One way to get wider memory is to use several 1-bit-wide memory chips, as shown in Fig. 52. The address and control lines go to each chip, and each chip's data is used as a single bit in the large word. It is easy to see that when reading from address 0A (hex), the data lines  $D_0$  through  $D_3$  contain the data from address 0A of chips 0 through 3. The same is true when writing to an address. An address placed on the shared address lines (called an *address bus*) now specifies an entire word of data. If all three memory chips were put in a single package, they would make a  $256 \times 4$  IC. This IC would look like the IC in Fig. 51, except that it would have 4 data lines. It would perform like the circuit in Fig. 52. In fact, ICs with 4- and 8-bit words are quite common, and even larger words are available.

### More Address Space

Most tasks require more than 256 words of memory. It is not uncommon for a personal computer to address 256,000 8-bit words. To understand how such large memories are built and addressed, we will look at a  $1024 \times 8$  (1-kbyte) memory built from four  $256 \times 8$  memory chips (Fig. 53).

Ten address lines are needed to address 1024 locations ( $2^{10} = 1024$ ). Eight of the 10 address lines ( $A_0 - A_7$ ) are used as a normal address bus for chips 0 through 3. The remaining 2 address lines ( $A_8$  and  $A_9$ ) are used to choose among the 4 memory chips.  $A_8$  and  $A_9$  are run through a 2-to-4-line decoder. For each of the four combinations of  $A_8$  and  $A_9$ , the decoder places a 1 on a different one of its outputs. When employed in this manner, the 2-to-4-line decoder is called an *address decoder*. To assert the CS input for one of the memory chips, ME must be 1 and the correct output of the 2-to-4-line decoder must also be 1. When an address is placed on  $A_0$  through  $A_9$ , a single memory chip is selected by ME,  $A_8$  and  $A_9$ , and the other 8 address lines address a single word from that chip. The three chips that are not selected enter a high-impedance state and do not affect the data lines. This example shows how large memories are built from small memory ICs.

### Summary

All memories built with more than one memory IC employ the techniques described above. Using the proper memory ICs and address decoding, any size memory with any word length can be built.

### MEMORY TYPES

The concepts described above are applied to several types of random-access, semiconductor memory. Semiconductor memories are categorized by the ease and speed with which they can be written and their ability to "remember" when power is removed

Fig. 52 — A  $256 \times 4$  memory built with four of the ICs in Fig. 51. Address and control signals are decoded by the four ICs, resulting in four bits of data (one bit from each IC) being read or written by the circuit.

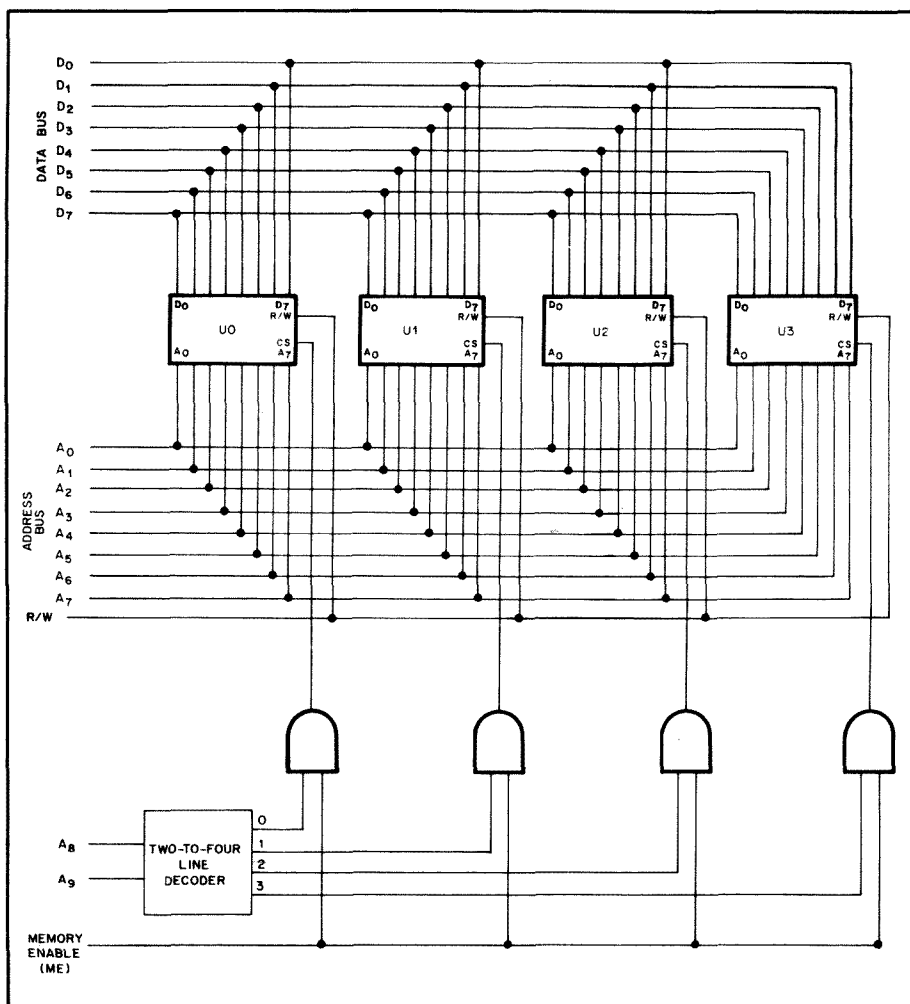

Fig. 53 — A  $1024 \times 8$  memory using four  $256 \times 8$  memory ICs. The high address bits,  $A_8$  and  $A_9$ , select one of the memory ICs. The remaining seven address bits address a byte from the selected IC. Address and data lines shared in parallel by several chips are called a *bus*.

from the circuit.

### RAM

The term "RAM", standing for

"random-access memory," is usually used for semiconductor memories that can be written to or read from with equal ease and speed. It is usually safe to assume that

RAMs are *volatile*, meaning that information stored in RAM will be lost if power is removed.

Two types of RAM are common: *static RAM* and *dynamic RAM*. Dynamic RAMs (DRAMs) store a bit as the presence or absence of charge on MOSFET gate-substrate capacitance. Because the capacitance is not perfect, the charge leaks or degrades slowly and must be refreshed periodically (typically every few milliseconds). This memory refresh is usually performed by a *dynamic RAM controller* IC. A static RAM (SRAM) is an array of flip-flops. When a bit is stored in a flip-flop, the bit will remain until power is removed or another bit replaces it. SRAMs do not need to be refreshed. While SRAMs may seem more desirable, they are neither as simple to manufacture nor as dense as DRAMs. DRAMs are often 1.5 to 4 times more dense than SRAMs. Increased density and ease of manufacture make DRAMs significantly cheaper than SRAMs.

Both bipolar and MOS semiconductors are used to make RAMs. While all bipolar RAMs are SRAMs, MOS techniques can produce both static and dynamic RAMs. Cost, power consumption and access speed are the factors that help designers select static or dynamic, MOS or bipolar RAMs. Generally, MOS RAMs have lower power consumption than bipolar RAMs. Access speed varies widely within and between RAM categories. To select the best RAM for a given application, consult manufacturers' data sheets.

#### Read-Only Memory

Read-only memory (ROM) is non-volatile; its contents are not lost when

power is removed from the memory. Although the name "read-only memory" implies that ROMs can never be written, all ROMs can be written or *programmed* at least once. *Mask ROMs* are programmed by having ones and zeros etched into their semiconductors at manufacturing time.

There are other types of ROMs, called *programmable ROMs* (PROMs), that can be written to after manufacture. *Fusible-link PROMs* are written by burning away specific diodes or transistors in a semiconductor memory array. This type of PROM can be written only once. Two types of PROMs can be erased and reprogrammed. Erasing is done by ultraviolet light for UV PROMs (EPROMs), and electronically for electronically erasable PROMs (EEPROMs). The erasure cycle for EEPROMs is long, and UV PROMs must be removed from operation for reprogramming. These requirements mean that data cannot be written as quickly and easily to ROMs as it can to RAMs.

What (besides their being nonvolatile) distinguishes PROMs from RAMs? Read and write times for RAMs are nearly equal, but PROMs have slow write times (in the millisecond range), and RAM-like read times (measured in nanoseconds). Two other factors make it hard to write to PROMs. First, PROMs must be erased before they can be reprogrammed. Second, PROMs often require a programming voltage higher than their operating voltage. ROMs are practical only for storing data or programs that do not change frequently and must survive when power is removed from the memory. The programs that start up a computer when it is first turned on or the call sign in a repeater IDer are prime candidates for ROM.

#### Nonvolatile RAM

For some tasks, the ideal memory would be as nonvolatile as ROM but as easy to write to as RAM. Low-power RAMs can be used in such applications if they are supplied with NiCd or lithium cells for backup power. A more elegant and durable solution to this memory problem is called a *nonvolatile RAM* (NVRAM, or Xicor NOVRAM™). An NVRAM chip includes both RAM and PROM. When power is first applied or the chip is reset, the contents of the ROM are copied into the RAM. The system using the NVRAM reads and writes to the RAM as though the ROM did not exist. When requested, perhaps before power is turned off, logic in the NVRAM copies the entire contents of the RAM into the ROM for nonvolatile storage. The RAM in a NVRAM is called *shadow RAM*, and it is standard volatile RAM. The backup ROM in NVRAM is EEPROM, and each bit in the ROM can be reversed several thousand times. Since the RAM is only copied into the ROM on command, NVRAM lasts long enough for many applications. NVRAM fills the gap between easily written memory and nonvolatile memory.

#### SUMMARY

With RAM, ROM and NVRAM available in many sizes and packages, you should be able to find a memory IC that meets your design requirements. By using correct address decoding, relatively small memory ICs can be used to build large memory systems. Like most IC technology, memories are changing quickly — getting cheaper, faster, more efficient and smaller. When you are designing memory systems, be sure to consult the *latest* literature.

## Digital Computers

Until the 1970s, digital computers were strictly the tools of industry and education; there were no home computers or hand-held calculators as we know them today. Today, only 10 years later, everything from watches to automobiles is computerized. This revolutionary increase in the availability of computers was made possible by several simultaneous changes in technology that decreased the size, increased the complexity and decreased the price of semiconductors. These advances made possible the construction of the *microprocessor* ( $\mu$ P) IC. This single chip performs all of the control, logical and mathematical functions necessary for computation. A microprocessor, memory and I/O circuits are all that is needed to make a *microcomputer* ( $\mu$ C).

Modern Amateur Radio transceivers,

scanners, digital-code converters, packet-radio controllers and television systems contain *special purpose computers*. These are dedicated microcomputers that perform specialized control tasks and are not available for other uses. Many amateurs also have *general-purpose computers* that they use for Amateur Radio applications. The obvious result of the increase in use of microcomputers by amateurs has been a substantial increase in computerized RTTY. There are many other applications of computers in Amateur Radio; CW sending and receiving, contest duping and logging, computer-aided design (CAD), computer-aided instruction (CAI), satellite tracking, propagation prediction and record keeping are just a few. Amateurs have found numerous opportunities to use

microcomputers, and as pocket computers and single-chip microcomputers become less expensive, they will be found in most amateur stations.

#### COMPUTER ORGANIZATION

A computer consists of a number of interconnected subsystems, each of which performs some specific task. These subsystems may be spread among many chips, or they may be concentrated in a single-chip microcomputer. Fig. 54 illustrates the organization of a typical computer.

#### Input Device

Input devices are used to feed the computer both *data* to work on and *programs* to tell it what to do. Some digital input devices are: switches, keyboards, magnetic disks and tapes, paper cards and tapes,

demodulators and analog-to-digital converters.

### Output Device

Output devices are used to present the results of computer operations to the user or to some other system. Output devices also allow the computer to control external devices. Printers, video displays, LEDs, LCDs, modems, speech synthesizers, plotters, relays, and magnetic disks and tapes are common output devices.

### Memory

The memory subsystem usually has several thousand words of storage, both temporary (RAM) and nonvolatile (ROM). It holds computer programs as well as input, intermediate and output data.

### Arithmetic Logic Unit

The arithmetic logic unit (ALU) performs logical operations (AND, OR, etc.) and arithmetic operations (addition, subtraction, multiplication and division). The ALU may depend on the control unit to supply its data and send its results to memory, or it may be able to access memory itself.

### Control Unit

The control unit directs the operation of the computer. It takes instructions from memory and executes them. In the course of executing an instruction, the control unit may call on the ALU, perform I/O and access memory to read or write data. The control unit maintains the *program counter*, which contains the address of the next instruction that the control unit will fetch for execution. The program counter usually moves from lower addresses to higher addresses, but some instructions cause the control unit to change the contents of the program counter. This is called looping or branching. The control unit and the ALU are usually both in the microprocessor IC.

### Registers

Microprocessor chips have some internal memory locations that are used by the control unit and the ALU. Because they are inside the microprocessor IC, these *registers* can be accessed much more quickly than other memory locations. Some registers are purely internal and cannot be accessed directly by programs. Others can be accessed directly. The registers that can be programmed are divided into *general purpose* and *special purpose* registers. General purpose registers can be used as though they were RAM locations, although they are referred to by name rather than by address. The special purpose registers usually include the program counter, the *accumulator*, the *stack pointer* and a *flag register*. The program counter, as discussed before, contains the address of the next instruction that the computer will execute. The accumulator contains the result of the

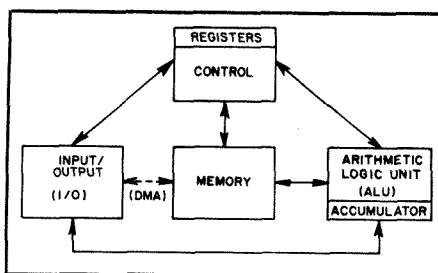

Fig. 54 — Major subsystems in a microcomputer. Not all of the communications paths shown on this diagram are present in every computer. DMA stands for direct memory access.

latest ALU operation. For program control, the microprocessor uses a section of RAM as a push-down stack. The stack pointer contains the address of the "top" of this stack. The flag register holds status and flag bits that indicate, among other things, whether the result of the latest ALU operation was zero, positive or negative.

### Timing

The computer understands a few relatively simple instructions: add A to B, move the contents of X to Y, send C to the output device, etc. For the execution of these simple instructions to result in meaningful operations, thousands of instructions must be executed each second. The rate at which instructions are executed and the synchronization of the systems in a microcomputer are controlled by a single clock. Usually, a quartz crystal generates the clock signal. The output of this clock goes to the microprocessor and to any other ICs that need to be synchronized with the microprocessor.

### Summary

The subsystems discussed above may exist in several ICs or a single-chip microcomputer. At the least, a microprocessor *central processing unit* (CPU) contains the control subsystem and the ALU.

### Selecting a Microprocessor

Microprocessors can be classified by the number of bits their accumulators will handle at one time. Four, 8, 12, 16 and 32-bit microprocessors are available. Amateurs usually use 8- or 16-bit microprocessors. Some microcomputers now have both an 8-bit and a 16-bit processor on the same PC board, permitting operation of either processor or simultaneous operation of the two.

One important consideration when selecting a microprocessor is the availability of desirable software for that processor. Familiarity of the designer with programming the microprocessor, or an earlier model with a similar instruction set, may also be an important consideration. Some microprocessors are *upwardly compatible* with older microprocessors of the same family. Upward compatibility means that

programs written for the older microprocessor will run on the newer microprocessor. Upward compatibility eases the transition from one processor to another, and allows a designer to gain the advantages of a new microprocessor without having to replace a complete software library.

Speed is another important consideration in selecting a microprocessor. Clock rates typically run from 1 to 10 MHz, with the 1- to 6-MHz range being suitable for most Amateur Radio applications. The clock frequency defines the duration of the *machine cycle* — the basic unit of time for a microprocessor. In one machine cycle, the microprocessor can perform one basic operation. For example, it might take one machine cycle for the control unit to fetch a number from memory. Each instruction that the microprocessor can execute is made up of several basic operations and will take several machine cycles to execute. Manufacturers' data sheets may refer only to average instruction execution times. For this reason, designers wishing to select the fastest microprocessor for a given job may develop a *benchmark* program to test how fast different microprocessors execute a desired task.

When selecting a microprocessor, it is important to know whether it will be supported by the manufacturer and/or other sources. Microprocessor manufacturers usually offer an entire family of support chips, such as a parallel I/O, serial I/O (UART), DMA controller and timer/counter. It is best to consider the entire chip set before making the decision to select a particular processor.

Documentation is also vital to the designer. Manufacturers may offer an array of data sheets, application notes, programmer's guides and references and other design aids. It will be helpful to know whether the manufacturer will answer technical questions over the phone. Manufacturers may avoid documenting idiosyncracies that could be design hurdles in particular applications. There are quite a few books on how to work with specific microprocessors. Maintaining contact with other designers, either directly or via users' groups, is another way of finding design information and learning about undocumented features.

Power requirements are important in some applications and may be the primary reason for selecting a given microprocessor. Early microprocessors used as many as four voltages, complicating power-supply design. Most designers prefer chip sets that use one voltage, usually +5 V. CMOS microprocessors are normally chosen for satellites and other battery-operated equipment in which power is at a premium. If supply voltage varies widely, the voltage range over which a microcomputer will operate is also important.

Future cost and availability of a microprocessor are difficult to estimate.

Fig. 55 — The backplane of a popular personal computer has several sockets for accessory PC boards such as video adapters, serial and parallel interface cards, or disk-drive controllers.

Nevertheless, there are numerous indicators such as reputation of the manufacturer, the amount of support available and *second sourcing* (arrangements made with other manufacturers to produce the same chip). When a chip is first introduced, its cost may be high, perhaps \$50 or more. If it is used in large-quantity products, the unit price will drop, probably to less than \$10. Many amateurs are simply concerned with the current price of the chips they use. Manufacturers pay less attention to the current cost of a chip and more to their estimate of what it will cost when they have to order production quantities. If you are designing equipment for other amateurs to build (for example, if you plan to write an article for *QST*), try to project cost and availability ahead to the probable publication date. The chips that are cheapest at the moment may be phased out by the time people want to duplicate your circuit.

## MICROCOMPUTER BUSES

Most microprocessors have a single set of data, address and control pins; most of the rest of the microcomputer must be connected, in parallel, to these pins. The address, control and data circuits that connect the subsystems of a microcomputer are called a *bus*. The bus usually also carries power throughout the computer. One popular mechanism for routing the bus to various parts of the microcomputer is to print the bus as a set of parallel PC traces on a PC board called the *mother board*. Multi-conductor connectors, placed at intervals along these traces, are used to connect individual memory, I/O or microprocessor PC boards to the bus (Fig. 55). Common home computers like the Apple II

series and the IBM PC have the microprocessor and some memory on the mother board and several bus connectors, called slots, available for system expansion.

One popular bus was introduced with the Altair 8800 computer in 1975. Because it was a 100-wire bus, it became known as the *S-100* bus. The S-100 bus accommodates PC boards measuring 5 by 10 inches. The S-100 bus is widely supported, and S-100 PC boards for almost every microcomputer function are available. Because of the widespread use of S-100 bus, the Institute of Electrical and Electronics Engineers (IEEE) ultimately developed an S-100 bus standard known as IEEE-696-1983. The S-100 bus computers are popular among radio amateurs who need versatile, expandable computers.

Another bus worthy of note is the IEEE-488-1978 standard. The 488 bus was originated by Hewlett-Packard under the name HPIB and has also been called GPIB. Its main use is for computer control of electronic test equipment, but it can also be used as a microcomputer peripheral bus. Most professional test equipment can be controlled by the 488 bus. Amateur applications of the 488 bus are expected to grow, particularly as bus controllers and test equipment with the 488 bus become available as surplus.

For an overall view of microcomputer buses, see *The S-100 & Other Micro Buses*, by Poe and Goodwin, 2nd Ed., 1981, Howard W. Sams & Co., Inc.

## I/O Transfers

The microcomputer would be useless without I/O. Input and output allow the computer to react to and affect the outside world. Microcomputers transfer data to and from peripheral devices using several techniques.

### Program-Controlled I/O

Under *program-controlled*, or *polled*, I/O, all input and output events are initiated by the program that is running on the microcomputer. The program must wait until the I/O device is ready to accept or deliver data and then execute the instruction that actually sends or receives the data. An example of program-controlled I/O might be a program waiting for a keyboard entry:

Has a key been pressed?

If not, then check again.

If yes, then find out what key was pressed and continue.

One of the disadvantages of program-controlled I/O is that the program must spend its time checking the status of the I/O device. If the program must perform the I/O before it can continue anyway, time spent checking I/O status is not wasted. If, on the other hand, the program could be performing other tasks while waiting for I/O, time spent checking status is wasted. Program-controlled I/O is easily written and debugged. In home computers using the BASIC language, program-

controlled I/O is often the only kind of I/O used.

### Interrupt-Driven I/O

Program-controlled I/O might be understood by imagining a cook returning to the oven every few minutes to see if a meal is ready to be served. In *interrupt-driven I/O*, the cook would go do something else, and the meal would interrupt him when it was ready to come out of the oven. An *interrupt* is a temporary break in the normal execution of a program. Under interrupt-driven I/O, external devices that are ready to accept output or generate input interrupt the program that is executing. When the microprocessor is interrupted, it suspends whatever program it was processing, branches to an *interrupt-service* program, takes care of the device that generated the interrupt and then resumes execution of the interrupted program. The major disadvantage of interrupt-driven I/O is that program flow can get very confusing; what if an interrupt-service program gets interrupted? If a program does not work, is there a problem with the program itself, or is there a problem in an interrupt-service program? These problems are not impossible to solve, and interrupt-driven I/O is common. Programs that rely on interrupt-driven I/O do not have to constantly check the status of I/O devices. Also, each interrupting device can be given a priority, so that I/O events get serviced in order of importance. Interrupt-driven I/O, despite its complexity, is often necessary or desirable in control and communications programs.

### Memory-Mapped I/O

In *memory-mapped I/O*, addresses that are treated like RAM by the microprocessor are actually I/O devices. Thus, a command that would usually be used to read or write to a memory location might actually result in an I/O operation. Memory mapping is an addressing technique and might be used with interrupt-driven or program-controlled I/O.

### Direct-Memory Access (DMA)

DMA is used with I/O devices that need rapid transfer of data, such as magnetic disk drives or high-speed data-communications equipment. When a device that uses DMA is ready to transfer data (either to or from memory), a *DMA controller* makes the transfer directly between memory and the I/O device without interrupting or using the main control unit. Thus, DMA can perform I/O while another program is running, without interrupting that program. Although some microprocessors have built-in DMA controllers, DMA usually requires a special controller IC.

## PERIPHERAL DEVICES

*Peripherals* are devices separate from the central-processing unit that provide additional facilities such as outside communica-

tion. Tape recorders, printers, video-display terminals and modems are common peripherals.

## MOVING MEDIA

The term *moving memory* refers to the mechanical motion of the storage medium past a read or write transducer (often called a *head*). The earliest forms of moving memory used hole patterns punched in paper cards or tapes. Punched cards (also known as IBM<sup>TM</sup> cards), once widely used in the computer industry, have had virtually no application in Amateur Radio. On the other hand, punched tapes have seen Amateur Radio use. The tape format that gained the most popularity among amateur radioteletype operators was the 5-level punched tape, using the Baudot code. The tapes were prepared on a perforator (or reperforator) and read on a transmitter-distributor (TD).

## Magnetic Media

Magnetic tape is widely used for storing digital information. Inexpensive audio cassettes, designed primarily for analog recording, are used by amateurs for digital storage. Most low-end microcomputers use cassettes as an inexpensive magnetic storage medium. Unfortunately, for proprietary reasons, there is little standardization of the tones and data formats used by different microcomputer manufacturers. The Kansas City standard, developed in the mid-70s was an attempt to get all manufacturers to agree on a data rate of 1200 bits per second and the tones 1200 and 2400 Hz. Although it met with little commercial success, the Kansas City standard is now used for data transmission from the UOSAT amateur

satellites and by the Radio Netherlands BASICODE project.

*Streamer* is the term given to a relatively new type of digital magnetic 4-track, 1/4-inch tape-cartridge recorders. These recorders were designed to back up hard disks.

The *floppy disk* (also called *diskette*) is the peripheral most widely used in microcomputers to store large amounts of data. The diskette itself is a paper-thin mylar disk upon which a thin layer of magnetic material has been deposited. This disk, which is like a sheet of magnetic tape, can be 3 to 4, 5 1/4 or 8 inches in diameter. It is enclosed in an envelope that protects the magnetic coating while allowing a read/write head access to the disc (Fig. 56). Floppy disks are read and written by a *disk drive*. The drive spins the disk (within its envelope) much like a record player spins a record. The read/write head may access any spot on the disk by moving to the correct point in the *head-access window* and waiting for the data to spin "into view" (Fig. 57). Because the disk makes several revolutions per second, data on diskette can be accessed much more quickly than data on magnetic tape.

Disks and disk drives may be either *single-sided* (SS) or *double-sided* (DS). Double-sided disks are prepared for reading and writing on both sides, and double-sided drives have read/write heads for both sides of the disk. Depending on the *disk controller* used to access the disk drive, data may be written in either a *single-density* (SD) or *double-density* (DD) format. Using double-density results in nearly twice the storage capacity of single-density but requires higher-quality diskettes. The

Fig. 57 — The read/write head in a disk drive can be positioned over any track on a disk. Disk rotation will then bring the desired sector beneath the head.

initials specifying the number of sides and the density of a disk system are often combined, as in "SSSD," meaning "single sided, single density."

Fig. 56 shows that data is stored on a disk in a number of concentric bands, called *tracks*. Some disks have a track density of 48 tracks per inch (tpi), while others use 96 tpi. Each track is divided into *sectors* — the smallest addressable units of information on a disk. A photoelectric sensor in the disk drive may be used in conjunction with the *index hole* in the disk envelope to sense the radial position of the disk. *Hard-sectored* disks have holes in the disk for each sector. More common *soft-sectored* disks have only one hole. Depending on the number of tracks, sectors, bytes per sector and sides used, a floppy disk can store anywhere from 80 kilobytes to several megabytes.

There is standardization in 8-inch floppy disk formats. The most common format, developed by IBM, has 77 concentric tracks with track 0 on the outside and track 76 inside near the hub. Each track is broken up into 26 equal sectors, each holding 128 bytes. There is a "write-protect" notch on the side of the protective envelope. On 8-inch disks, the disk cannot be written to unless the write-protect notch is covered.

There has not been much standardization of 5 1/4-inch floppy disk formats. The write-protect convention for 5 1/4-inch disks is just the opposite of that for 8-inch disks — expose the notch to the disk.

Standardization efforts are now underway for smaller 3- to 4-inch *microfloppy* disks. The American National Standards Institute (ANSI) X3B8 Microfloppy Industry Committee (MIC) has proposed adoption of a 3 1/2-inch standard with 80 tracks. The unformatted capacity is 500 kbytes for single-sided 3 1/2-inch disks and 1000 for double-sided disks.

It is important to remember that the read/write head is in contact with the surface of the floppy disk, and the disk is rotating at several revolutions per second. Dust and dirt on the disk and the imperfections in the disk surface gradually damage both the disk and the head. This means that disks eventually wear out. When a disk wears out, the data stored on that disk will probably be lost. It is prudent, therefore, to make back-up copies of your disks.

Fig. 56 — Construction of a floppy disk.

Fig. 58 — Typical computer-terminal keyboard layout. Two- and three-letter abbreviations shown at the top of letter and underline keys designate control functions. The CONTROL key must be pressed at the same time as the other keys to enter a control code. The complete ASCII-coded character set is listed in Chapter 19.

Back-up disks, stored in a clean, dry, cool place, will help you avoid disaster when your disks wear out.

In *hard disk* systems, the disk is rigid, and the read/write head does not contact the disk. The absence of friction between the head and the disk allows finer head positioning and higher disk speeds. For these reasons, hard disks hold more data and are accessed more quickly than floppy disks. Hard disks currently used for microcomputers have 5¼- or 8-inch disks capable of storing from 2 to 84 megabytes of data. Although the common Winchester hard disk drives do not, some hard disk drives have removable, interchangeable disks. Hard disk systems are high-precision mechanical devices, and while they do not fail frequently, even one failure can result in the loss of megabytes. To avoid this, you should frequently make back-up copies of your hard disks. Using floppy disks for hard-disk back up can take a lot of diskettes, and streamer tapes (mentioned earlier) make more economical hard-disk back ups.

### Summary

Some type of moving memory is usually included in a general-purpose computer system. Inexpensive home computers use cassette tapes, but floppy disks are more convenient. Advancing technology has been pushing the storage capacity of floppy disks up, while bringing prices down. High-capacity hard disks are also coming within the reach of the amateur budget. Remember, whatever moving medium you use, always make back-up copies of your important data.

### Keyboards

A *keyboard* is an input device consisting of numerous key switches that, when pressed, cause the generation of a particular bit pattern. Most computer keyboards have keys arranged in the QWERTY order, similar to a typewriter keyboard layout. However, the similarity ends with the location of the 26 letters of the Latin alphabet and the 10 Arabic numerals. The placement of punctuation, other printable symbols

and *control keys* varies. A typical computer-terminal keyboard layout is shown in Fig. 58.

Computer keyboards have keys not traditionally found on typewriters. While typewriters have one RETURN key that issues both a carriage return (CR) and a line feed (LF) for a new line, computer keyboards usually have separate CR and LF keys. The CAPS LOCK key on a computer keyboard puts all letters in upper case but preserves the action of the SHIFT key over keys with numerals, punctuation and other symbols. Some keyboards include a special numeric keypad separate from the main keyboard. This keypad makes it easy for operators familiar with calculators or adding machines to enter lists of numbers into the computer. Other special keys often found on computer keyboards include a CONTROL key, an ESCAPE key and perhaps some *function keys*.

Most computer keyboards will generate the entire 128-character ASCII set. (Chapter 19 examines the ASCII characters and their meanings.) Ninety-six of the ASCII characters are numerals, alphabets and printable punctuation marks. These characters are usually generated by single keys or shifted keys. The other 32 characters are *control characters*, and are generated by pressing alphabetic and numeric keys while holding down the CONTROL key. Because control characters are nonprinting, various authors have adopted many different styles to tell the reader to enter a control character. For example, variations on how to hit the BEL character include "CONTROL-G," "CTRL-G," "<control G>," "[G]," or "<^G." Some control characters can be generated by single keystrokes. In particular, the CR character is generated by a key marked RETURN or ENTER. Some keyboards can generate 8-bit *extended ASCII* characters. These characters are generated by a process similar to that used for control keys, except that another special key (sometimes marked ALT) is held down instead of the CONTROL key. Using the CONTROL and the ALT keys, a keyboard with a reasonable number of keys can

generate the complete, 256-character extended ASCII character set.

Software, in conjunction with keys that generate control characters, can create special keyboard effects. When a function key is typed it can be recognized by a special program and expanded to have the effect of several keystrokes. *Escape sequences*, initiated by the ESC character, open up further possibilities. Typing the ESC key alerts software that the next character typed has a special meaning. Unlike the CONTROL key, the ESC key is not held down while the second key is typed. There has been an attempt to standardize the meanings of escape sequences, but there is still a wide variation between manufacturers.

There are many different types of key switches in use. Many provide the travel, acoustic feedback and "feel" of a typewriter keyboard. Some *membrane* keyboards are deficient in this respect but have other special features such as compactness and protection against moisture and dust. With few exceptions, individual keys simply make and break a single electrical contact. Unfortunately, the make is usually not just one clean pulse but a series of disorderly pulses resulting from mechanical contact bounce. Key bounce was a serious problem with some early keyboards. To *debounce* a keyboard, circuits that verify intended key closures and ignore key bounces and noise are added.

Computer keyboards vary from one model of computer to the next. Key placement, the meaning of escape sequences and control characters, and even the availability of specific characters will change if you change computers. The method of entering control characters and escape sequences, however, remains the same.

### Screen Displays

A video display terminal (VDT) consists of a keyboard, as discussed above, and a *monitor*. Most monitors are *cathode-ray tubes*, either video monitors with no RF circuits or standard TV sets. Portable computers often use flat-screen, *liquid-crystal displays* (LCDs).

Whether CRT or LCD, the monitor is usually treated as a dot-matrix display with some number of picture elements (*pixels*) or dots horizontally and some number of pixels vertically. Characters are formed on the display by turning on specific pixels in a *character matrix*. Most CRTs employ *raster scanning*, a method of covering the screen by writing one row of pixels at a time. The electron beam in the CRT writes the top row of pixels first and then continues line-by-line to the bottom of the screen. Then, a *vertical retrace* brings the beam back to the top of the screen to begin again. To display characters on a raster-scanned screen, the electron beam must be turned on and off at precisely the times needed to illuminate the pixels that form the characters.

Fig. 59 — Control signals for turning on every other pixel on a CRT. A shows the ideal square-wave control signal. The signal at B is a sine-wave approximation of the signal at A.

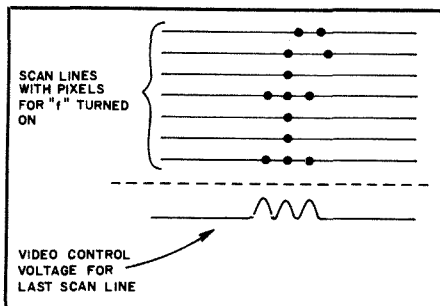

Fig. 60 — Portion of a raster-scanned video display.

Like any other signal, the signal that turns the electron beam on and off occupies bandwidth within the monitor circuits. To calculate the bandwidth needed for a specific display, we must consider the worst-case characteristics of the electron-beam control signal. This worst (highest bandwidth) case is when all of the pixels on the screen are set such that adjacent pixels have different states. The ideal control signal for such a display is shown in Fig. 59A. The frequency (F) of this pulse train can be calculated by

$$F = \frac{(N/2)}{T} \text{ Hz} \quad (\text{Eq. 4})$$

where

N = the number of pixels on the screen  
T = the time taken to complete a whole-screen scan

If the control signal were approximated by a sine wave (Fig. 59B), the bandwidth needed to pass the signal would be equal to the frequency of the sine wave. Unfortunately, the sine wave does not turn the beam on and off abruptly and would produce blurred pixels. To get good definition, components up to the 3rd harmonic of the fundamental square-wave frequency (F) must be accommodated. Thus, a minimum bandwidth of  $3 \times (N/2)/T$  Hz is necessary to scan N pixels in T seconds. Example 1 shows how to calculate the bandwidth needed to display 25 lines, with 80 characters/line and a  $10 \times 7$ -pixel matrix

used for each character.

#### Example 1:

$(10 \times 7 \text{ matrix}) = 70 \text{ pixels/character}$   
Characters/line = 80  
Lines/screen = 25  
Pixels/screen (N) =  $25 \times 80 \times 70$   
= 140,000  
Refresh time (T) =  $1/60$  seconds  
Worst case frequency (F) =  $140,000/2 \times 60 = 4,200,000 \text{ Hz}$   
Bandwidth required =  $3 \times 4.2 \text{ MHz}$   
= 12.6 MHz

Raster scanning is used in television receivers, which may be used for displaying computer text. Television receivers have limited IF bandwidth — on the order of 3.5 MHz for color, 3 MHz or less for black and white. The example above shows that such bandwidth results in a poor display if 25 lines of 80 characters are desired. Computer monitors used to display  $80 \times 25$  screens have a video bandwidth up to 25 MHz. What can be displayed on a TV receiver? Example 2 calculates the bandwidth needed for 16 lines with  $40 \times 9 \times 7$  characters on each line.

#### Example 2:

Pixels/character =  $9 \times 7 = 63$   
Characters/line = 40  
Lines/screen = 16  
Pixels/screen (N) =  $16 \times 40 \times 63$   
= 40320  
Scan time (T) =  $1/60$  seconds  
Worst case frequency (F) =  $40320/2 \times 60 = 1,209,600 \text{ Hz}$   
Necessary bandwidth =  $3 \times 1.2 \text{ MHz}$   
= 3.6 MHz

Thus, this example shows about as much text as can be displayed on a normal TV screen. This screen format ( $40 \times 16$ ) is used by some popular microcomputers to permit use of a TV receiver as an inexpensive display. The individual characters are formed as shown in Fig. 60.

An alternative to raster scanning of a CRT is the *vector mode*. In this mode, the user can draw a straight line by specifying only two points. Vector-mode displays are used primarily for graphics.

#### Character Displays

Rather than having a full screen display, individual characters can be presented on single-character displays. Some of the formats available are shown in Fig. 61. A popular display is the seven-segment version, as shown in Fig. 62, which is an excellent choice for displaying numbers.

Character displays are built using several different manufacturing technologies. LEDs are common because they are easy to read when there is low ambient light. LCDs are now coming into use and are especially useful in low-current-drain battery operation. Unlike the LEDs, LCDs are visible in bright ambient light. However, since LCDs do not emit light, but reflect it, they are not visible in low-light environments. LCDs are also sluggish at low

Fig. 61 — Various character display formats.

Fig. 62 — Segment identification and layout for a seven-segment display.

temperatures. LED and LCD characters are available in several sizes: 0.3, 0.6 inches and larger.

A numeral to be displayed on seven-segment display is usually encoded in BCD form, and a combinational logic circuit activates the proper segments of the display. This logic circuit is called a *decoder*. Various seven-segment decoders are manufactured to drive common-cathode and common-anode displays. One decoder chip available to hobbyists is the 7447A. This is an open-collector TTL device designed to pull down common-anode displays through external current-limiting resistors. A 7447A will also drive common-cathode displays if external transistors are used. Fig. 63 shows the connections for both types of display.

The dc illumination method shown in Fig. 63 is the easiest to implement, but higher light output with lower energy consumption can be obtained by pulsing the display voltage. A pulse rate of 100 Hz is imperceptible because of the persistence of human vision.

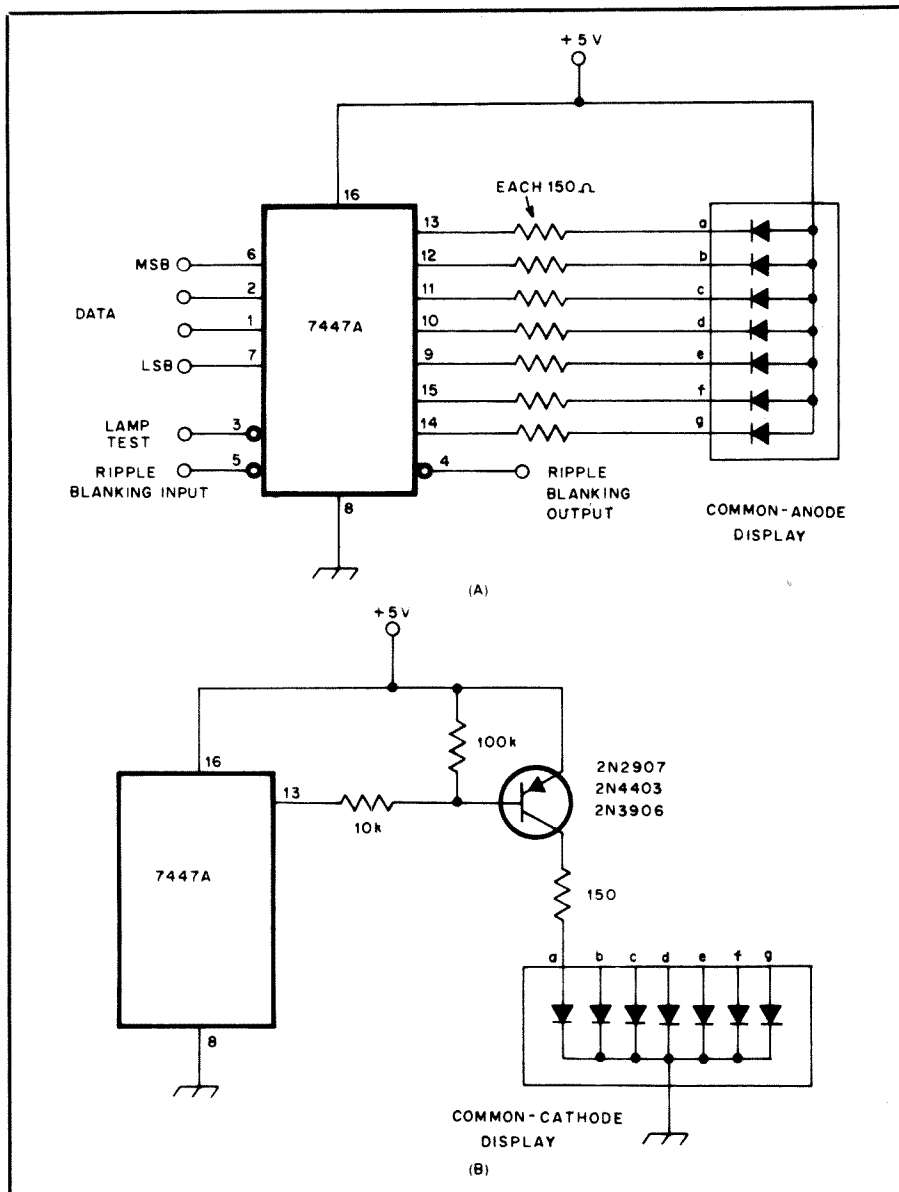

Fig. 63 — A shows a 7447 decoder/driver connected to a common-anode LED display. At B is a method for using the same chip with a common-cathode device.

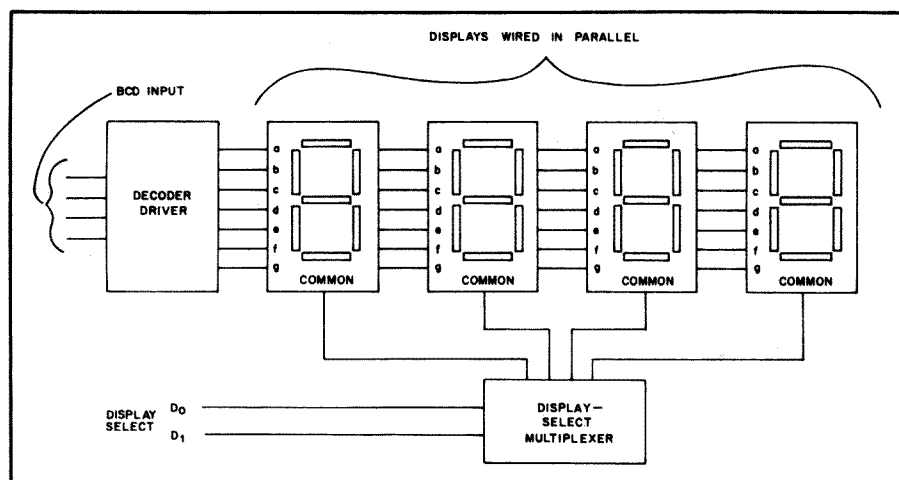

Fig. 64 — Multiplexed character displays. BCD data for a particular display is placed at the input of the decoder/driver, and the desired display is selected by placing its "address" on the inputs to the display-select multiplexer.

As more digits are added to a display, using a decoder/driver for each digit becomes unfeasible from an economic and PC-board real-estate point of view. A technique called *multiplexing* (Fig. 64) allows a single decoder/driver IC to be shared by several digits. The digits are wired in parallel; that is, all of the "a" segments are connected together and so on. The multiplexer logic sends input data for a digit into the decoder and enables the common element of the correct digit. This process is repeated for each digit. Only when both a segment and its associated common lead are selected will that segment be energized. With this system, only one digit is energized at any instant, a factor that greatly reduces power-supply requirements. To maintain the brightness of each digit, the current to each display segment must be increased. When implementing a multiplexed display, you should be sure not to exceed the peak- and average-current specifications for the display.

### Printers

It is often necessary to have a printed copy or "hard copy" of communications, programs or data that are stored in a computer. Printers are used to produce such hard copy. Some printers produce *letter quality* text, with characters that look like they were typed on a typewriter. Other printers produce *data-processing* quality type, used mostly for program listings. Printers are categorized by their printing speed and the quality of type they produce.

In the mid 1970s, a number of amateurs used ITA2 (Baudot) teleprinters as a computer output device. Since these teleprinters had a 5-bit code, they did not print all the characters of ASCII. Certain characters were either ignored or converted to substitutes. These machines operated at speeds in the 45- to 75-baud range (or 6 to 10 char/s) — quite slow by computer standards. ASCII teleprinters, such as the Teletype Corporation Model 33, were only slightly better. These teleprinters operated at 110 bauds or 10 char/s.

Most printers currently used with microcomputers have the full ASCII coded character set. They are called *character printers* because they print only one character at a time, not a whole line at once as *line printers* do. Printers used with personal computers are described below.

*Fully formed character printers* are usually *impact printers*; they print by striking a character-shaped hammer against a ribbon. These printers may use interchangeable type elements (called daisy wheels or thimbles). Many character fonts are available. The characters are fully formed and match those of a typewriter. While characters are printed slowly (less than 80 characters/second), they can be sent to the printer at a much higher rate. The characters are stored in a FIFO buffer, and hardware or software *flow control* (*handshaking*) between the printer input

and the computer output port keeps the computer from overfilling the buffer.

*Dot-matrix* printers print each character as a matrix of dots, much the same way characters are displayed on a raster-scanned monitor. A 5-by-7 matrix (measured 5 dots wide by 7 dots high) is just adequate for the standard ASCII character set. However, such a matrix makes the normal Latin letters look ragged. At least a 7-by-9 matrix is needed to make Latin letters look better and is considered minimum for some foreign alphabets. While dot-matrix printers do not form perfect letters, they are fast (greater than 100 chars/sec), they can print graphics, and they can be used as plotters. Some can print multicolor graphics. Also, dot-matrix printers are generally less expensive than impact printers.

While most printers used on home computers are either dot-matrix or impact printers, several other types of printers are beginning to gain popularity. The *ink-jet* printer has been too expensive for most amateurs, but lower-cost versions are now available. The ink-jet printer has some of the advantages of both letter-quality and dot-matrix printers. *Electrostatic* printers use the process commonly associated with photocopy machines, where a dye is deposited onto charged paper. *Laser* printers are just becoming available for home computers. They are very fast (only several seconds per page), and can produce both graphics and letter quality text.

## SUMMARY

Peripherals allow computers to interact with the outside world. General-purpose computers need both a monitor, to present results to the operator, and a keyboard, to accept commands and data from the operator. Mass storage devices, usually cassette tapes or floppy disks, are used to store programs and data. Printers are used to make hard copies of computer outputs. Peripherals often cost more than the microcomputer to which they are attached; when selecting a microcomputer, pay attention to the availability and price of necessary peripherals.

## COMPUTER LANGUAGES

There are two broad classifications of computer languages: low level and high level. Generally, a low-level language is one that is designed to communicate with a computer in its native tongue, while a high-level language is intended to be more like a widely used human language.

### LOW-LEVEL LANGUAGES

Programmers who wish to converse with a microprocessor directly must do so in *machine language*. The symbols used in machine language are 1s and 0s. Every microprocessor has a built-in instruction set, and each instruction in that set can be represented by a binary word. Few pro-

grammers actually write machine language. When they do, they express machine instructions as octal or hexadecimal numbers rather than as binary numbers. The instruction to move the contents of register B into register A, understood by the microprocessor as "01111000," would be written as "78" in hexadecimal (hex).

Most programmers cannot remember what all the numerical machine-language instructions stand for, so *assembly language* is used to substitute a mnemonic abbreviation for each instruction. In the above example, "78" would become "MOV A,B" in assembly language. Once you get a program written in assembly language, it must be *assembled* to convert it to machine language. This is done with an assembler program that converts commands from mnemonics to binary words, "MOV A,B" would be converted to the byte "01111000." A single assembly-language instruction generates a single machine-language instruction; programming in assembly language creates programs that are as fast and efficient as if they were written in machine language.

Assembly language programs and programs in high-level languages are usually stored as text. Such text is called *source code*, while binary files of machine-language instructions are called *object code*. A single source code instruction, such as "MOV A,B," is called a *statement*.

Both machine and assembly languages are usually different for each microprocessor. However, once you learn assembly-language programming on a particular chip, you can easily work with others in the same family. Even when switching families, you will get the hang of the new mnemonics in no time. Sometimes old habits are hard to break, and you will yearn for your favorite special feature that is not in the new instruction set. In general, you end up doing the same operations but have to learn new mnemonics. A programmer's reference guide or card can help you remember all the mnemonics until they become second nature through repetition.

Many experienced programmers prefer to work in assembly language because it gives them step-by-step control of the processing of data. Programming in assembly language usually results in smaller object code and faster execution than can be achieved with higher-level languages. This is especially useful in high-speed code-conversion and other signal-processing applications.

### HIGH-LEVEL LANGUAGES

High-level languages are oriented toward the user or toward a specific task rather than toward the microprocessor. In order to appear familiar, high-level languages are typically designed to look like a subset of English. Plain-English programming is not yet possible, because English has ambiguities and numerous shades of meaning and

subtleties. We must be content with high-level computer languages in which words have specific meanings (strict *semantics*) and must be used according to rigid rules (*syntax*).

Many high-level languages are extensions of the assembly-language concept — that of substituting something easy to remember for something that is easy to forget. Instead of simply having a few mnemonic letters represent a few numbers, though, high-level languages set up more complex relationships. A single English word (instruction or statement) in a high-level language can cause the generation and execution of several machine-language instructions. Thus, high-level languages provide a way of expressing complex computing processes in notation that is easy to understand and remember.

Like assembly-language source statements, high-level-language statements must be converted to machine language. Conversion is performed by an *interpreter* or a *compiler*. An interpreter translates a statement to machine code and then executes the code immediately. It does not create an object program. A compiler takes an entire high-level source program and translates it into a machine-language object program. The object program may be executed immediately or saved for later execution. If a particular statement is executed several times, an interpreter will translate that statement over and over, while a compiler translates it only once. Thus, compiled programs usually run faster than interpreted programs. However, during program development it is time consuming to recompile a program after every small change is made. In this case, the immediate execution offered by an interpreter can be convenient. Interpreters and compilers each have their advantages and disadvantages. Most home computers are provided with a built-in interpreter for the computer language BASIC, and BASIC compilers can be purchased for some of these computers.

There are hundreds of high-level computer languages. Some are used for specific tasks, some for a wide range of tasks. The languages described below are common or of some specific interest to radio amateurs.

### BASIC

The Beginner's All-purpose Symbolic Instruction Code (BASIC) was developed at Dartmouth College as a language similar to, but easier to learn than, FORTRAN II. BASIC is by far the most common high-level language used by radio amateurs and personal-computer users. Numerous dialects of BASIC exploit the special features of different computers. Many of these dialects implement a common set of BASIC instructions and then add *extensions* that provide new features. Fortunately, many BASIC dialects for different computers were written by the same software

## Glossary of Digital Terms

**Access** — To read or write to memory or an I/O device.

**Accumulator (ACC)** — The register in a computer that holds the result of ALU operations.

**Address** — An expression, either numeric or symbolic, that specifies a memory location.

**Algorithm** — A set of directions describing a way to perform a certain task.

**Architecture** — Organizational structure of a system.

**Arithmetic Logic Unit (ALU)** — The part of a computer that performs mathematical operations.

**Assemble** — To convert a symbolic assembly-language program into machine language.

**Assembly Language** — A symbolic language representing machine language in mnemonic form.

**Asynchronous** — Communication in which data characters are individually synchronized and may be sent at any time.

**Baud** — A bit per second.

**Benchmark** — A program used to compare the performance of two or more computer systems.

**Binary** — The base-two number system, using the numerals 0 and 1.

**Bipolar** — A broad category of semiconductors based on PNP or NPN junction transistors. See MOS.

**Bit** — The basic element of binary information, usually represented by 0 and 1; a contraction of "binary digit."

**Bug** — An error that causes hardware or software to malfunction.

**Byte** — A group of bits, usually 8.

**Central Processing Unit (CPU)** — The part of a computer that interprets and executes instructions.

**Chip** — An integrated circuit.

**Clear** — To make a value or state equal to 0.

**CMOS** — Complementary metal-oxide semiconductor, an integrated-circuit logic subfamily employing both n-channel and p-channel FETs; noted for its low power consumption.

**Compiler** — Software that converts a high-level-language program into a machine- or assembly-language program.

**Cross Assembler** — An assembler that translates code from one machine-language to another.

**Debug** — To remove errors from hardware or software.

**Decimal** — The base-ten number system, using the numerals 0 through 9.

**Display** — Presentation of information in a form to be sensed by humans, usually visual.

**Documentation** — Reference material detailing specifications and technical information on systems, hardware or software.

**ECL** — Emitter-coupled logic, an integrated circuit logic family capable of operating at frequencies above 1.2 GHz.

**Edge-triggered** — A circuit that responds to data or clock transitions, rather than responding to data or clock levels.

**Execute** — To interpret instructions and perform the indicated operations.

**Fan-out** — The number of parallel loads of a given family that can be driven by one output of that family.

**Flip-Flop** — A circuit with two stable states, usually 0 and 1, capable of storing a single bit of information.

**Floppy disk** — A flexible magnetic recording medium for data storage. Also called a diskette.

**Flowchart** — A graphic representation of the structure of a program or process.

**Handshaking** — Exchange of prearranged signals between devices to determine their readiness to establish or maintain communications.

**Hard disk** — A rigid magnetic recording medium for data storage.

**Hardware** — Physical equipment.

**Hexadecimal** — The base-16 number system, using the numerals 0 through 9, and A through F.

**Instruction** — A statement that specifies a computer operation.

**Instruction set** — The repertoire of machine-language instructions for a microprocessor.

**Interface** — The common boundary between two devices or software modules.

**Integrated circuit (IC)** — A miniature electronic module of components and conductors manufactured as a single unit.

**Interpreter** — A program that translates and then immediately executes statements in a high-level language.

**I/O** — Input/output.

**Keyboard** — A set of key-switches used to enter data or commands.

**Label** — One or more characters used to identify a memory location or a statement or an item of data in a computer program.

**Latch** — A flip-flop capable of storing one bit of information. Also used as a verb meaning to hold state.

**LSI** — Large-scale integration, ICs with more than 1000 devices per chip.

**Machine** — A computer.

house, which has had the effect of minimizing unnecessary variations.

Although there is a common core of BASIC that is *transportable* from one computer to another, do not expect to type in a BASIC program listing written for one computer and run it on another without modification. Books like *The Basic Handbook* by David A. Lien discuss translating BASIC from one dialect to another (see the Selected Bibliography at the end of this section).

Here are a few common *commands* and *statements* in BASIC:

**END:** Stops execution of the program.

**LET:** Assigns values to variables. LET is often optional; "LET X = 1" and "X = 1" usually mean the same thing.

**LIST:** Displays the program.

**PRINT:** Means to display whatever follows, such as a variable (X in the line 40 below) or anything enclosed in quotes.

**REM:** Remarks or comments. A computer will ignore lines beginning with REM.

**Example:**

```
20 PRINT "Join the computer revolution."
30 LET X = 1
40 PRINT X
50 END
```

### Pascal

*Pascal* is a structured programming language; structured programs are written

as systems of interacting subprograms. Large programming tasks can be broken into many small tasks, and each of these small tasks can be translated into a Pascal subprogram. (Although BASIC can be used to write such structured programs, it was not designed for easy, efficient structured programming.) Pascal is taught in many engineering courses, since it provides a good basis for understanding other programming languages. Pascal software is available to amateurs for most microcomputers at modest cost.

### C

C is a structured language that, like assembly language, generates compact, fast object programs. Unlike Pascal and many other high-level languages, C allows programs to interact freely with computer hardware. Because of these characteristics, C is becoming popular for Amateur Radio applications.

### IPS

The Interpreter for Process Structure (IPS) is a derivative of the high-level language, FORTH. IPS is a "threaded-code" language written by Karl Meinzer, DJ4ZC, to control the integrated housekeeping unit (IHU) 1802-based computer in the AMSAT-OSCAR Phase III satellites.

## OPERATING SYSTEMS

An *operating system* (OS) is a group of computer programs that supervises the sequencing and processing of other computer programs. The programs supervised by an OS are usually called *applications programs*. Operating systems are also responsible for I/O management — the creation and assignment of files, the maintenance of file directories, and so on. The OS allows applications programs to use I/O devices without knowing the precise characteristics of those devices. In computers that have disk drives, the OS is usually called the disk operating system (DOS). Concurrent or *multi-tasking* operating systems allow several applications programs to share a single CPU. A good OS will provide simple but powerful I/O services to applications programs and an understandable, complete set of commands for human users.

CP/M® is an operating system popular with microcomputer users and manufacturers. CP/M stands for control program/microcomputer, and is a registered trademark of Digital Research Inc. (DRI). CP/M-80 runs on the 8080 family of microprocessors, and CP/M-86 runs on the 8086 family. As supplied by DRI, CP/M must be customized to fit specific microcomputer hardware. CP/M is popular because it provides a well-defined

**Machine Language** — The numeric form of specifying instructions used by a computer.

**Microcomputer (uC)** — A computer having a microprocessor CPU.

**Microprocessor (uP)** — One or a small set of chips capable of performing the functions of a CPU.

**Mnemonic** — A symbol chosen to assist the human memory. The symbolic name used to represent instructions, registers and memory locations.

**Monitor** — A display device, usually a cathode-ray tube. A permanent program resident in a computer to perform basic operations.

**MOS** — Metal-oxide semiconductor. Semiconductors based on field-effect transistors (FETs), rather than bipolar-junction transistors. See bipolar.

**MSI** — Medium-scale integration, ICs with 10 to 100 devices per chip.

**Nyquist rate** — In analog-to-digital conversion, the lowest sampling rate that will result in correct reproduction of the analog signal. This rate is twice that of the highest frequency component in the original analog signal.

**Object program** — A machine-language program.

**Octal** — The base-eight number system, using numerals 0 through 7.

**Open collector** — A TTL output that is not internally pulled up through a resistor or transistor.

**Operating system** — A group of programs that supervise I/O and the execution of other programs in a computer.

**Parallel** — Simultaneous handling of several bits, with a separate channel for each bit. See serial.

**Port** — A set of I/O connections.

**Printer** — An output device that produces a paper copy.

**Program** — A collection of instructions that perform a certain task.

**Program counter (PC)** — A register that specifies the address of the next instruction to be executed.

**Pull-down resistor** — A resistor connected from the input or output of a logic element to ground.

**Pull-up resistor** — A resistor used to connect the input or output of a logic element to a supply voltage.

**Rails** — The positive and negative supply voltages.

**Random-Access Memory (RAM)** — Volatile storage. Storage in which any address can be accessed as easily and quickly as any other.

**Read** — To copy the contents of a memory location or peripheral storage medium.

**Read-Only Memory (ROM)** — Storage that can be easily read but not easily written to; usually nonvolatile.

**RTL** — Resistor-transistor logic, an early bipolar integrated-circuit logic family.

**Schottky** — A TTL manufacturing process that provides high-speed by eliminating transistor saturation.

**Sequential-access memory** — Memory in which the first  $n$  addresses must be accessed in order to access address  $n + 1$ .

**Serial** — A process in which a group of bits are handled one at a time over a single channel.

**Software** — Computer programs.

**SSI** — Small-scale integration, ICs with 10 or fewer devices on a chip.

**Start bit** — The bit transmitted to indicate the beginning of an asynchronous character. See stop bit.

**State** — A mode or condition of a circuit or program.

**State diagram** — A chart showing all states in a device or process and the events leading to and resulting from each state.

**Stop bit** — The bit transmitted at the end of an asynchronous character and between such characters. See start bit.

**Subroutine** — A section of a program used to divide the work of a large program into small segments.

**Synchronous** — A method of communication in which data is sent as a continuous, exactly-timed stream, with special synchronization information sent only at the beginning of long data blocks.

**Totem pole** — A TTL output circuit in which a transistor is used to pull up the collector of another transistor. See open collector.

**TTL** — Transistor-transistor logic, a widely used bipolar IC logic family.

**UART** — Universal asynchronous receiver/transmitter, an IC that converts parallel data into asynchronous serial data, or vice versa.

**USART** — Universal synchronous/asynchronous receiver/transmitter, an integrated circuit that converts parallel data into either synchronous or asynchronous serial data, or vice versa.

**VLSI** — Very-large-scale integration, ICs with 1000 or more devices on a chip.

**Volatile memory** — Storage that does not retain its contents when its power is removed.

**Write** — To place data in memory or peripheral storage.

set of I/O subprograms. Applications programs can use these subprograms without knowing what hardware-specific I/O instructions are actually executed.

Customizing CP/M involves writing a *basic input/output system* (BIOS) that permits the generic I/O subprograms to access existing hardware devices. Once you have a customized BIOS for your computer, you will be able to run all CP/M programs — it is not necessary to customize every application that you wish to run.

Many CP/M programs are in the public domain, meaning that they can be freely copied and used without violating copyrights. A catalog of public-domain software for CP/M is available from NYACC, the New York Amateur Computer Club, Inc., P.O. Box 106, New York, NY 10008.

## MS DOS

MS DOS, written by Microsoft, is quickly becoming as popular as CP/M. A version of this DOS written specifically for the IBM PC is called PC DOS. Because of the prestige of IBM, PC DOS is possibly the fastest-growing microcomputer DOS on the market. Not long after the introduction of the IBM PC, many applications programs written for CP/M and other operating systems became available for PC DOS. A catalog of public-domain software for the

IBM PC is also available from NYACC.

## Other Operating Systems

There are nearly as many microcomputer operating systems as there are microcomputer manufacturers. Some manufacturers supply a proprietary OS with specific computer models. These operating systems are intended to make best use of hardware features or limitations. When you choose a particular personal computer, you will usually not have many operating systems to choose from. You may, however, decide to select a certain computer *because* it uses an OS that you are familiar with.

## NOISE PRECAUTIONS

Noise is an important consideration in designing digital circuits. Noise on a signal or power line may cause logic circuits to perform erratically. Wires and printed-circuit traces may act as antennas that radiate RF noise. These same "antennas" can receive energy, especially when immersed in high RF fields near a radio transmitter.

Pulse rise and fall times determine the frequency of some of the electromagnetic interference radiated or conducted from a digital circuit. You can find the approximate upper frequency of the interference by dividing the constant 0.34 by the time the pulse takes to rise from 10% to 90%

of its full value. For example, a rise time of  $15 \times 10^{-9}$  seconds between 10% and 90% levels would yield RF outputs up to 22.6 MHz. High-speed logic devices may be appealing for certain digital applications but can cause needless RFI because of fast rise and fall times. This can be avoided by using logic that is no faster than necessary.

Digital circuits also produce energy at the repetition rates of the pulses. For example, in digital equipment using a 3.579545-MHz clock, there will be RF energy at that frequency and its harmonics. Whether that energy emanates from the digital equipment and causes interference to radio reception depends largely on the design and construction of the digital equipment.

Designers of *computing devices* for sale in the U.S. are subject to compliance with Part 15 of the FCC rules. A computing device, in the FCC definition, is any electronic system that generates pulses in excess of 10 kHz and uses digital techniques. Class A devices are for commercial or industrial use. Amateurs should be most concerned with Class B devices, which are for use in a residential environment. Class B devices must not radiate more than 100  $\mu\text{V}/\text{m}$  (30-88 MHz), 150  $\mu\text{V}/\text{m}$  (88-216 MHz) or 200  $\mu\text{V}/\text{m}$  (216-1000 MHz) at a distance of 3 meters, nor conduct to the power line more than 250  $\mu\text{V}$  (0.45-30 MHz). These restrictions are suf-

ficient to minimize RFI to neighbors but inadequate to prevent interference to nearby Amateur Radio receivers. Clearly, digital equipment for the shack must be designed to meet more stringent requirements than those of Part 15 of the FCC rules!

Shielding of digital equipment is often neglected. Nonmetallic enclosures may save money initially but can allow unnecessary interference to nearby radio and television receivers. Whenever possible, use a metal enclosure that has solid electrical contact among all of its parts. Paint should be removed where parts meet. To ensure that the entire surface makes contact, you may also need to add some sheet-metal screws or sandwich some copper wire braid between the mating surfaces. Copper or aluminum screen may be used to cover holes without blocking ventilation. If a plastic or wooden enclosure cannot be avoided, it may be possible to add internal shielding using heavy-duty aluminum foil. Otherwise, consider an electrically conductive coating such as nickel-filled acrylic. Coating materials are available in spray cans or may be applied commercially.

Line filters should be used at the ac input of power supplies for digital circuits to minimize interference conducted on the power lines. Three-contact ac-power receptacles of the standard CEE-22 type with built-in line filters are recommended.

All signal and dc-power lines leaving enclosures should be bypassed or filtered. Connectors can be purchased with built-in bypass capacitors on every contact, but they are expensive. The use of individual bypass capacitors (with the shortest possible leads) on all lines capable of causing interference is an economical approach. Large ferrite toroids can be used to decouple cables, and individual wires can be decoupled with ferrite beads.

The wires in cables that carry digital signals between enclosures may act as antennas. One solution to this problem is

to avoid unnecessary external cabling by mounting different digital components in one shielded enclosure. Another way of avoiding the problem is to use optical fibers to transmit digital signals between enclosures. Commercial fiber-optic cabling systems are expensive, but they are expected to come down in price. There is also an opportunity for amateur innovation in inexpensive fiber-optic cabling.

Where external wire cabling is necessary, shielding is recommended. Each conductor may be separately shielded to minimize coupling between signal lines. In long shielded cables with a radiation problem, consider adding toroids along the cable to break up the resonances.

A low-impedance RF ground is as important for digital equipment as it is for radio equipment. Ensure that all digital equipment enclosures, frames, mother boards and cable shields are properly grounded. Use any space left on a PC board for an adequate ground plane.

Take design precautions to avoid power-supply noise from current spikes. Power-supply wiring should be as thick as practical, and wide PC-board power traces should be used to keep the line impedance low. This is particularly true for +5-V lines, which may be the only supply voltage or the one carrying the largest current in a circuit using more than one supply voltage. Ground traces should also be as large possible, since they often carry as much current as power-supply traces. Different voltage traces should be arranged for minimum mutual coupling by keeping them as far apart as possible. Where they cross, try to arrange them at right angles. An on-board voltage regulator is recommended to help isolate noise to and from the rest of the system. Good engineering practice suggests being generous with decoupling capacitors. Typical decoupling practice for +5-V lines includes: a 20- $\mu$ F electrolytic capacitor at the input to the board, a 6.8- $\mu$ F

electrolytic capacitor in parallel with a 0.1- to 1.5- $\mu$ F tantalum capacitor near every 1 to 8 devices and a 0.01- to 0.5- $\mu$ F ceramic capacitor for every 1 or 2 adjacent devices.

Sippl, *Data Communications Dictionary*, Van Nostrand Reinhold Co., 1976.

Soucek, *Microprocessors & Microcomputers*, John Wiley & Sons, Inc., 1976.

Tocci, *Digital Systems*, Prentice-Hall, Inc., Englewood Cliffs, NJ, 1980.

Williams, *Designer's Handbook of Integrated Circuits*, McGraw-Hill, Inc., 1984.

Additional reading material on digital basics and microcomputers is available from a variety of sources. *EDN*, *Electronics Week*, *Computer Design*, *Electronic Engineering Times* and other trade journals regularly print late news of semiconductor development. Semiconductor manufacturers, or their field representatives, are the best sources for data sheets and application notes on specific devices. *Byte* and a number of other magazines cover the general field of personal computers; there are other magazines oriented toward a specific line or type of computer. Amateur computer clubs are excellent sources of hardware and software information. *QST* and *QEX* regularly publish articles on digital subjects.

# Modulation and Demodulation

**M**odulation is the process of varying some characteristic of a *carrier* wave in accordance with a signal to be conveyed. A carrier is a wave having at least one characteristic that can be varied from a known reference by modulation. That known reference is typically a steady sine wave but could be a recurring series of pulses in which no signal is present between pulses. A *modulator* is a circuit or device in which the carrier and modulating signal come together to produce a modulated carrier, or one that processes the modulating signal and presents it to the circuit or device to be modulated. That is, modulation may or may not occur in the modulator, depending how the term is applied in practice. Modulation is normally associated with transmitters. The modulator may be built into the transmitter or exist as a separate unit.

*Demodulation* is the process of deriving the original modulation signal from a modulated carrier wave. But that's not the whole story. The received signal usually contains noise and distortion picked up along the way. For the original modulating signal to be reproduced faithfully, the effects of noise and distortion need to be dealt with effectively during reception and demodulation. Demodulation is part of the receiving process and is performed in a *demodulator*. While a demodulator is a normal part of a radio receiver, external demodulators are used for some types of communications.

The *baseband* is the range of frequencies occupied by the signal before it modulates the carrier wave. The signal in the baseband is usually at frequencies that are substantially lower than that of the carrier. On the low end, the baseband may approach or include dc (0 Hz). The high end depends on the rate at which information occurs as well as the presence of subcarriers or other special signals within the baseband. There is a baseband for all types of signals, whether analog or digital. Also, it should be realized that the term baseband is relative to the specific modulation being considered. There can be more than one baseband in a complete modulation process. For example, to a transmitter, a keyed

tone going into the microphone input is its (analog) baseband; to the tone keyer, the keying pulses are its (digital) baseband.

This chapter presents the fundamentals of the modulation and demodulation processes. Subsequent chapters provide details concerning the generation of modulated signals and demodulation circuitry for types of modulation used in the Amateur Radio Service.

### DESIGNATION OF EMISSIONS

One result of the World Administrative Radio Conference held in 1979 (WARC '79) was the adoption of a new system of designating emissions according to their necessary bandwidth and their classification. These new designations are used throughout this chapter with secondary reference to the pre-WARC '79 designations.

The new designations are not without problems. The new designations take into account the method of generating a signal rather than simply what the signal looks like when transmitted. Thus, the new system would have you use one designation for direct modulation of the main carrier and a different one if you modulate a sub-carrier of a single-sideband suppressed-carrier transmitter. Also, if you key a radioteletype modem with a direct-printing teletypewriter then switch to using a computer to do the same thing, the modulation designation changes under the new system.

On November 27, 1984, the FCC released the Third Report and Order for General Docket No. 80-739 to implement the new emission designators in all radio services, effective January 3, 1985. The appendix amended the Amateur Radio Service rules by deleting the old designations and replacing them with new designations. The amended rules omitted numerous types of emission that were permitted, or implicit, in the rules prior to the change. As this is being written, the FCC is considering a further amendment to either add the missing designators or generalize the wording to allow various types of emission.

### Bandwidth

Whenever a carrier is modulated,

*sidebands* are produced. Sidebands are the frequency bands on both sides of a carrier resulting from the baseband signal varying some characteristic of the carrier. The modulation process creates two sidebands: the *upper* sideband (USB) and the *lower* sideband (LSB). The width of each sideband is generally equal to the highest frequency component in the baseband signal. In some modulation systems, the width of the sidebands may greatly exceed the highest baseband frequency component. The USB and LSB are mirror images of each other and carry identical information. Some modulation systems transmit only one sideband and partially or completely suppress the other in order to conserve bandwidth.

*Occupied bandwidth* is that between lower and upper limits of the signal where the mean power is 0.5% (−23 dB) of the total mean power. In some cases a different relative power level may be specified; for example, −26 dB (0.25%) is used in section 97.69 of the FCC rules governing digital communications. Occupied bandwidth is not always easy for the amateur to determine. It can be measured on a spectrum analyzer — a piece of test equipment that is not generally available to most amateurs. Occupied bandwidth can also be calculated, but these calculations require an understanding of the mathematics of information theory and are not covered in this chapter.

*Necessary bandwidth* is that part of the occupied bandwidth sufficient to ensure transmission of the information at the rate and with the quality required. Formulas used by the International Radio Consultative Committee (CCIR) and the FCC for calculation of necessary bandwidths are included in this chapter's discussion of specific modulation systems.

*Assigned frequency band* is the necessary bandwidth plus twice the absolute frequency tolerance. *Frequency tolerance* (expressed in parts per 10<sup>6</sup>, percentage, or in hertz) is the maximum permissible departure by a frequency from its correct frequency.

Prior to WARC '79, the CCIR and FCC expressed necessary bandwidth in terms of

kilohertz. As examples, 0.1 was used to mean 100 Hz, and 6000 for 6 MHz. Spectrum managers had no taste for ragged computer-generated columns with different numbers of places, so a more elegant technique was clearly needed. The WARC '79 delegates agreed on a new system of expressing necessary bandwidth by three numerals and one letter. The letter occupies the position of the decimal point and represents the unit of bandwidth. The letters H (Hz), K (kHz), M (MHz) and G (GHz) are used, but neither 0 nor K, M nor G may appear in the first character. Numerical values of more than three significant places are rounded off to three places. Some examples taken from the CCIR Radio Regulations are listed in the accompanying table.

## MAJOR MODULATION SYSTEMS

The broadest category of modulation

### Examples of CCIR Necessary Bandwidths

0.002 Hz = H002	6 kHz = 6K00	1.25 MHz = 1M25
0.1 Hz = H100	12.5 kHz = 12K5	2 MHz = 2M00
25.3 Hz = 25H3	180.4 kHz = 180K	10 MHz = 10M0
400 Hz = 400H	180.5 kHz = 181K	202 MHz = 202M
2.4 kHz = 2K40	180.7 kHz = 181K	5.65 GHz = 5G65

systems is how the main carrier is modulated. The major types are amplitude modulation, angle modulation and pulse modulation.

### Amplitude Modulation

Amplitude modulation (AM) covers a class of modulation systems in which the amplitude is the characteristic that is varied. It is possible to amplitude modulate a main carrier or subcarrier. However, in the context of the new emission symbols, it is the modulation of the *main* carrier that determines the first symbol (type of

modulation of the main carrier).

Amplitude modulation is often simplistically described as varying the amplitude of the carrier from a zero power level to a peak power level. This chapter includes some photographs of oscilloscope patterns that seem to prove this notion. In fact the oscilloscope pattern is a composite of the energy produced over a range of frequencies. The carrier itself stays at the same amplitude when modulated by an analog (such as voice) baseband signal. The modulation itself produces sidebands. They are bands of frequencies on both sides of

### Emission Classifications

Emissions are classified by the following basic characteristics:

#### (1) First symbol — type of modulation of the main carrier

(1.1) Emission of an unmodulated carrier	N
(1.2) Emission in which the main carrier is amplitude modulated (including cases where subcarriers are angle modulated)	
(1.2.1) Double sideband	A
(1.2.2) Single sideband, full carrier	H
(1.2.3) Single sideband, reduced or variable-level carrier	R
(1.2.4) Single sideband, suppressed carrier	J
(1.2.5) Independent sidebands	B
(1.2.6) Vestigial sideband	C
(1.3) Emission in which the main carrier is angle modulated	
(1.3.1) Frequency modulation	F
(1.3.2) Phase modulation	G
(1.4) Emission in which the main carrier is amplitude and angle modulated either simultaneously or in a pre-established sequence.	D
(1.5) Emission of pulses <sup>1</sup>	
(1.5.1) Sequence of unmodulated pulses	P
(1.5.2) A sequence of pulses	
(1.5.2.1) modulated in amplitude	K
(1.5.2.2) modulated in width/duration	L
(1.5.2.3) modulated in position/phase	M
(1.5.2.4) in which the carrier is angle modulated during the period of the pulse	Q
(1.5.2.5) which is the combination of the foregoing or is produced by other means	V
(1.6) Cases not covered above, in which an emission consists of the main carrier modulated, either simultaneously or in a pre-established sequence, in a combination of two or more of the following modes: amplitude, angle, pulse	W
(1.7) Cases not otherwise covered	X

#### (2) Second symbol — nature of signal(s) modulating the main carrier

(2.1) No modulating signal	0
(2.2) A single channel containing quantized or digital information without the use of a modulating subcarrier <sup>2</sup>	1
(2.3) A single channel containing quantized or digital information with the use of a modulating subcarrier <sup>2</sup>	2
(2.4) A single channel containing analog information	3
(2.5) Two or more channels containing quantized or digital information	7
(2.6) Two or more channels containing analog information	8
(2.7) Composite system with one or more channels containing quantized or digital information, together with one or more channels containing analog information	9
(2.8) Cases not otherwise covered	X
(3) Third symbol — type of information to be transmitted <sup>3</sup>	
(3.1) No information transmitted	N
(3.2) Telegraphy — for aural reception	A
(3.3) Telegraphy — for automatic reception	B
(3.4) Facsimile	C
(3.5) Data transmission, telemetry, telecommand	D
(3.6) Telephony (including sound broadcasting)	E
(3.7) Television (video)	F
(3.8) Combination of the above	W
(3.9) Cases not otherwise covered	X

The following two optional characteristics may be added for a more complete description of an emission:

#### (4) Fourth symbol — detail of signal(s)

(4.1) Two-condition code with elements of differing numbers and/or durations	A
(4.2) Two-condition code with elements of the same number and duration without error correction	B
(4.3) Two-condition code with elements of the same number and duration with error correction	C

(4.4) Four-condition code in which each condition represents a signal element (of one or more bits)	D
(4.5) Multi-condition code in which each condition represents a signal element (of one or more bits)	E
(4.6) Multi-condition code in which each condition or combination of conditions represents a character	F
(4.7) Sound of broadcasting quality (monophonic)	G
(4.8) Sound of broadcasting quality (stereophonic or quadraphonic)	H
(4.9) Sound of commercial quality (excluding categories K and L below)	J
(4.10) Sound of commercial quality with the use of frequency inversion or band-splitting	K
(4.11) Sound of commercial quality with separate frequency-modulated signals to control the level of demodulated signal	L
(4.12) Monochrome	M
(4.13) Color	N
(4.14) Combination of the above	W
(4.15) Cases not otherwise covered	X

#### (5) Fifth symbol — nature of multiplexing

(5.1) None	N
(5.2) Code-division multiplex	C
(5.3) Frequency-division multiplex	F
(5.4) Time-division multiplex	T
(5.5) Combination of frequency-division multiplex and time-division multiplex	W
(5.6) Other types of multiplexing	X

### Notes

<sup>1</sup>Emissions where the main carrier is directly modulated by a signal that has been coded into quantized form (for example, pulse code modulation) should be designated under (1.2) or (1.3).

<sup>2</sup>This excludes time-division multiplex.

<sup>3</sup>In this context the word "information" does not include information of a constant, unvarying nature such as is provided by standard-frequency emissions, continuous-wave and pulse radars, and so forth.

<sup>4</sup>This includes bandwidth-expansion techniques.

Fig. 1 — A 10-MHz carrier modulated by a 1-kHz sine wave.

Fig. 2 — Graphical representation of frequency modulation. In the unmodulated carrier at A, each RF cycle occupies the same amount of time. When the modulating signal, B, is applied, the radio frequency is increased and decreased according to the amplitude and polarity of the modulating signal.

the carrier frequency. AM is basically a process of heterodyning or nonlinear mixing. As in any mixer, when a carrier and baseband modulation are combined, there are three products in the frequency range of interest: (1) the carrier, (2) the lower sideband (LSB), and (3) the upper sideband (USB). Thus, if a carrier of 10 MHz were modulated by a 1-kHz sine wave, the outputs would be as shown in Fig. 1.

The bandwidth of the modulated signal in this example would be 2 kHz, the difference between the lowest and highest frequencies. In AM, the difference between the carrier and farthest component of the sideband is determined by the highest frequency component contained in the baseband modulating signal.

### Angle Modulation

Two particular forms of angle modulation are *frequency modulation* (FM) and *phase modulation* (PM).

The term frequency modulation is often used to cover various forms of angle modulation. Amateurs use FM when referring to angle-modulated VHF/UHF radios which may use either FM or PM. The pre-WARC '79 emission symbol, F, was used for both FM and PM. However, the post-WARC '79 symbols are F for FM and G for PM.

Frequency and phase modulation are not independent, since the frequency cannot be varied without also varying the phase, and vice versa.

The communications effectiveness of FM and PM depends almost entirely on the receiving methods. If the receiver will respond to frequency and phase changes but is insensitive to amplitude changes, it will discriminate against most forms of noise, particularly impulse noise such as that from ignition systems.

### Frequency Modulation

Fig. 2 is a representation of frequency modulation. When a modulating signal is applied, the carrier frequency is increased during one half cycle of the modulating signal and decreased during the half cycle of the opposite polarity. This is indicated in the drawing by the fact that the RF cycles occupy less time (higher frequency) when the modulating signal is positive, and more time (lower frequency) when the modulating signal is negative.

The change in the carrier frequency (*frequency deviation*) is proportional to the instantaneous amplitude of the modulating signal. Thus, the deviation is small when the instantaneous amplitude of the modulating signal is small, and is greatest when the modulating signal reaches its peak, either positive or negative. The drawing shows the amplitude of the RF signal does not change during modulation. This is an oversimplification and is true only in the overall sense, as the amplitude of both the carrier and sidebands varies with frequency modulation. FM is capable of conveying dc levels, as it can maintain a specific frequency.

### Phase Modulation

In phase modulation, the characteristic varied is the carrier phase from a reference value. In PM systems, the demodulator responds only to instantaneous changes in frequency. PM cannot convey changes in dc levels unless special phase-reference techniques are used. The amount of frequency change, or deviation, is directly proportional to how rapidly the phase is changing and the total amount of the phase change. The rapidity of the phase change is directly proportional to the frequency of the modulating signal and to the instantaneous amplitude of the modulating signal. This means that in a PM system, deviation increases with both the instantaneous amplitude and frequency of the modulating signal. Thus, PM modulators have a built-in *pre-emphasis*, where deviation

increases with modulating frequency. By way of contrast, deviation in FM systems is proportional only to the amplitude of the modulating signal. Apart from this characteristic it is difficult to distinguish between the two.

### Angle-Modulation Sidebands

In AM there is a single set of sidebands above and below the carrier frequency. FM and PM produce many sets of sidebands that occur at integral multiples of the modulating frequency on both sides of the carrier. An angle-modulation signal therefore inherently occupies a wider channel than an AM signal.

In angle modulation, the number of sidebands depends on the relationship between the modulating frequency, frequency deviation and *modulation index*. For angle modulation with a sinusoidal modulating function

$$\chi = \frac{D}{m} = \phi \quad (\text{Eq. 1})$$

where

$\chi$  = modulation index

$D$  = peak deviation (half the difference between the maximum and minimum values of the instantaneous frequency)

$m$  = modulation frequency in hertz

$\phi$  = phase deviation in radians (a radian =  $180/\pi$  or approximately 57.3 degrees)

For example: The peak frequency deviation of an FM transmitter is 3000 Hz either side of the carrier frequency. The modulation index when modulated by a sine wave of 1000 Hz is

$$\text{modulation index} = \frac{3000}{1000} = 3$$

When modulated with a 3000-Hz sine wave at the same deviation the index would be 1; at 100 Hz the index would be 30, and so on.

Given a constant input level to the modulator, in PM the modulation index is constant regardless of the modulating frequency; in FM it varies with the modulating frequency, as shown in the above example. In an FM system the ratio of the *maximum* carrier-frequency deviation to the *highest* modulating frequency is called the *deviation ratio*. Thus

$$\text{deviation ratio} = \frac{D}{M} \quad (\text{Eq. 2})$$

where

$D$  = peak deviation

$M$  = maximum modulation frequency in hertz

For example: The deviation ratio for narrow-band FM is 5000 Hz (peak deviation) divided by 3000 Hz (maximum modulation frequency) and is 1.67.

Fig. 3 — Amplitude variation of the carrier and sideband pairs with modulation index. This is a graphical representation of mathematical functions developed by F. W. Bessel. Note that the carrier completely disappears at modulation indexes of 2.405, 5.52 and 8.654.

Fig. 3 shows how the amplitudes of the carrier and the various sidebands vary with the modulation index. This is for single-tone modulation; the first-order sidebands (a pair, one above and one below the carrier frequency) are displaced from the carrier by an amount equal to the modulating frequency, the second is twice the modulating frequency away from the carrier, and so on. For example, if the modulating frequency is 2000 Hz and the carrier frequency is 29,500 kHz, the first sideband pair is at 29,498 and 29,502 kHz, the second pair is at 29,496 and 29,504 kHz, the third at 29,494 and 29,506 kHz, and so on. The amplitudes of these sidebands depend on the modulation index, not on the frequency deviation.

Note that as shown in Fig. 3, the carrier strength varies with the modulation index. (In amplitude modulation the carrier strength is constant; only the sideband amplitude varies.) At a modulation index of 2.405, the carrier disappears entirely. It then becomes "negative" at a higher index, meaning that its phase is reversed compared to the phase without modulation. In angle modulation, the energy that goes into the sidebands is taken from the carrier, the total power remaining the same regardless of the modulation index.

Since there is no change in total amplitude with modulation, an FM or PM signal can be amplified without distortion by an ordinary class-C amplifier. The modulation can take place in a very low-level stage, and the signal can then be amplified by either frequency multipliers or straight-through amplifiers.

If the modulated signal is passed through one or more frequency multipliers, the modulation index is multiplied by the same factor as the carrier frequency. For example, if modulation is applied at 3.5 MHz and the final output is on 28 MHz, the total frequency multiplication is eight times, so if the frequency deviation is 500 Hz at 3.5 MHz it will be 4000 Hz at 28 MHz.

#### Pulse Modulation

FCC rules restrict pulse modulation to the microwave region. Because of this it is not in common usage among amateurs. Pulse-modulated signals are usually sent as a series of short pulses separated by relatively long stretches of time with no signal being transmitted. (A typical pulse transmission might use 1- $\mu$ s pulses with a 1000-Hz pulse rate. Thus, the peak power of a pulse transmission is usually much greater than its average power.

The pre-WARC '79 emission symbol for

Fig. 4 — The top photo is an oscilloscope pattern of an unmodulated RF carrier. The vertical (Y) axis shows amplitude, and the horizontal (X) axis time. The bottom photo is a spectrum-analyzer display, where amplitude is shown on the Y axis and frequency on the X axis. Notice that there is only one line that represents the amplitude at the carrier frequency.

all pulse-type emissions was P. Since WARC '79, P is used only for a sequence of unmodulated pulses. Other types of pulse modulation are:

- Emission symbol K — pulse-amplitude modulation (PAM)
- Emission symbol L — pulse-width modulation (PWM) or pulse-duration modulation (PDM)
- Emission symbol M — pulse position/phase modulation (PPM)
- Emission symbol Q — angle modulation during the pulse
- Emission symbol V — combination of the above or by other means

### AMATEUR RADIO MODULATION SYSTEMS

Specific modulation systems of general interest to radio amateurs are discussed below. Pre- and post-WARC '79 emission designations and graphic illustrations are included.

#### UNMODULATED CARRIER

Just as number systems include the digit 0, RF carriers have their unmodulated state. The emission symbol for an unmodulated carrier is N0N (formerly A0 or F0). N0N emission is permitted in all amateur bands above 51 MHz. In addition, it is permitted for beacon operation in bands above 28.2 MHz specified by FCC rules. N0N may also be used on any amateur band below 51 MHz for short

Fig. 5 — Voice-modulated AM DSB signal. On top is a dual-trace oscilloscope pattern of amplitude (Y axis) vs. time (X axis). The lower trace is a baseband voice signal. The upper trace is the carrier 100% modulated by the voice signal. The bottom photo is the spectrum-analyzer display of amplitude (Y axis) vs. frequency (X axis).

periods of time when required for authorized remote control purposes or for experimental purposes (such as for transmitter tuning).

The bandwidth of an N0N emission is 0 Hz except for the transient sidebands that occur when the carrier is turned on or off. Fig. 4 shows an oscilloscope amplitude vs. time display and a spectrum analyzer amplitude vs. frequency display of an unmodulated carrier.

## ANALOG TELEPHONY

Modulation systems for transmission of a single analog channel of telephony (including sound broadcasting) are identified by the post-WARC '79 symbols — 3E. The dash is replaced by a letter representing the type of modulation of the main carrier. Types of modulation for speech transmission that are commonly used in the Amateur Radio Service follow.

### Double-Sideband Amplitude-Modulated Telephony

Double-sideband (DSB) amplitude-modulated (AM) telephony is generated by varying the amplitude of the carrier by a voice-frequency analog speech signal. Its post-WARC '79 designation is A3E (formerly A3). The full designation for commercial or amateur quality is 6K00A3EJN, meaning: 6 kHz bandwidth, DSB AM, telephony, sound of commercial quality, no multiplexing. In this case, the highest modulating frequency is 3 kHz,

resulting in 3-kHz sidebands above and below the carrier.

While DSB AM was the primary phone modulation system used in the early days of Amateur Radio, very few amateurs use it today. DSB AM has been virtually replaced by single-sideband amplitude modulation (SSB AM) in the HF bands. Angle (frequency or phase) modulation and SSB telephony are used on the VHF and UHF bands. Nevertheless, the most popular way of producing an SSB signal is to first generate a DSB AM signal and filter out the unwanted sideband.

Fig. 5 shows an oscilloscope amplitude vs. time display and a spectrum-analyzer amplitude vs. frequency display of a voice-modulated AM DSB signal. The signal in Fig. 5 is said to be 100% modulated on peaks, which is the maximum that the FCC permits. Modulation above 100% is unproductive because it adds distortion and generates unwanted sidebands, called *splatter*. Modulation with peaks much below 100% is undesirable because signal-to-noise ratio suffers.

At 100% modulation, voltage of each of the sidebands is half that of the carrier. Therefore, the power in each sideband is  $(\frac{1}{2})^2$  times or  $\frac{1}{4}$  that of the carrier. For a transmitter with a carrier output power of 100 watts, the power in each sideband is 25 watts, and the total sideband power is 50 watts. Fig. 6 illustrates the power in the carrier and sidebands of a 100%-modulated AM DSB signal. However, the same 100-watt AM DSB transmitter produces instantaneous peaks of 400 watts as illustrated in the vector diagram of Fig. 7. The bandwidth of a double-sideband AM telephony signal is calculated

$$B_n = 2M \quad (\text{Eq. 3})$$

where

$B_n$  = necessary bandwidth in hertz

$M$  = maximum modulation frequency in hertz

### Receiving DSB AM Telephony

A double-sideband voice-modulated signal with carrier can be demodulated to audio by means of a half-wave or full-wave rectifier; simply one or more diodes. When the modulated signal passes through a nonlinear device, the carrier mixes with the two sidebands and produces an audio output.

On HF, multipath propagation causes AM DSB signals to fade in amplitude. Fading can be overcome to some extent by using an automatic gain control (AGC) loop circuit to keep the audio output at a constant level. Another multipath effect is selective fading, which has the effect of periodically distorting the demodulated audio. This type of distortion may be virtually eliminated by independent-sideband detection of the upper and lower sidebands and by representing the USB and LSB outputs to separate earphones. Simple elec-

trical combination after detection will reintroduce the distortion.

### Single-Sideband Suppressed-Carrier AM Telephony

As both sidebands of a DSB AM signal convey the same information, a single sideband (SSB) may be transmitted and received. Since the carrier contains no intelligence, it too may be suppressed prior to transmission and reinserted in the receiver. SSB transmission and reception adds complexity and cost to radio equipment. However, SSB has a number of advantages:

- *spectrum conservation* — two SSB signals can occupy the space of one DSB signal.

- *more talk power for a transmitter final stage* — the same transmitter illustrated in Figs. 6 and 7 that ran 100 W carrier, 400 W peak and 50 W of talk power (USB + LSB) in DSB AM service can run 400 W of peak SSB talk power. Thus for a given transmitter power amplifier, SSB is said to have a  $400/50 = 8/1 = 9\text{-dB}$  advantage over DSB AM, considering transmitter peak power alone.

- *elimination of carrier interference* — this eliminates the possibility of a carrier heterodyning with an adjacent signal.

- *reduction in multipath distortion* — SSB does not suffer the audio distortion

Fig. 6 — Example of a carrier 100% modulated by a single 1-kHz tone.

Fig. 7 — Vector diagram of 100% modulation of an AM carrier at the instant when peak conditions exist. The broken vectors show the relationships at an instant when the modulating signal is somewhat below its peak.

Fig. 8 — Single-sideband suppressed-carrier voice modulation. At top is a dual-trace oscilloscope pattern of amplitude (Y axis) vs. time (X axis). The bottom trace is a baseband voice signal. The upper trace is the SSBSC RF telephony signal. The lower photo is the spectrum-analyzer display of amplitude (Y axis) vs. frequency (X axis).

(mushiness) heard when receiving a DSB AM signal where the USB and LSB propagate through separate ionospheric paths.

In the early days of Amateur Radio SSB, a favorite pastime was to calculate the overall effective advantage of SSB over DSB communications. Besides transmitter final amplifier peak power, other considerations are amplifier average power handling capability, the effects of impulse noise on SSB and DSB reception, fading and distortion resulting from multipath propagation, and reception in the presence of different types of interference. However, at risk of resurrecting an old controversy, the overall advantage of SSB over DSB is on the order of 12 dB.

Fig. 8 shows amplitude vs. time and amplitude vs. frequency displays of an SSB suppressed-carrier (SC) signal. The emission symbol is J3E (formerly A3J) for SSBSC. The necessary bandwidth is calculated

$$B_n = M - L \quad (\text{Eq. 4})$$

where

- $B_n$  = necessary bandwidth in hertz
- $M$  = maximum modulation frequency in hertz
- $L$  = lowest modulation frequency in hertz

The full emission designation for an SSBSC telephony signal modulated from

300 to 3000 Hz is 2K70J3EJN. On the end, J means commercial quality, and N signifies no multiplexing.

### Receiving SSBSC Telephony

SSBSC signals can be demodulated by an ordinary AM detector and by using a beat-frequency oscillator to reinsert the carrier within a few hertz of where it should be relative to the sidebands. Better performance can be realized by using a product detector, which is explained in Chapter 18.

### Amplitude-Compandored Single-Sideband Telephony

Amplitude *compression* and limiting are common speech-processing techniques used in most SSB transmission systems to limit peak amplitudes and keep the average speech level high. In some SSB receiving systems, an *expansion* circuit is included to restore the compressed speech to its full dynamic range. A circuit that handles both transmitting compression and receiving expansion is known as a compandor. Unless there is some coordination between the compressor and expander, the expander will not know when and how much to expand. In amplitude-compandored single sideband (ACSSB) the control information is sent as amplitude modulation of a 3.1-kHz pilot tone. ACSSB offers great potential for use in the VHF and UHF amateur bands, and is explained in Chapter 18.

There is no special post-WARC '79 emission symbol for ACSSB. It would fall into the SSBSC category of J3E (formerly A3J), however. The necessary bandwidth would be calculated by

$$B_n = M - L \quad (\text{Eq. 5})$$

where

- $B_n$  = necessary bandwidth in hertz.
- $M$  = maximum modulation frequency in hertz, which in this case is that of the pilot tone
- $L$  = lowest modulation frequency in hertz.

### Single-Sideband Full-Carrier Telephony

This type of modulation is the same as SSBSC except that a full carrier has been added. It is also known as *compatible AM* (CAM) because it can be received on an ordinary AM receiver with no beat-frequency oscillator. CAM has a number of additional advantages:

- receiver tuning is less critical than for SSBSC.
- bandwidth is half that of DSB AM.
- it is easy to generate using an SSBSC transmitter by the simple insertion of the carrier.

Disadvantages are:

- transmission of the full carrier reduces the peak power available for the intelligence-bearing sideband.
- carriers produce unnecessary beat notes in the phone bands.

Fig. 9 — Displays of a single-sideband, full-carrier telephony, or compatible-AM (CAM), signal. At top is a dual-trace oscilloscope pattern of amplitude (Y axis) vs. time (X axis). The bottom trace is a baseband voice signal. The upper trace is the CAM RF signal. The lower photo is the spectrum-analyzer display of amplitude (Y axis) vs. frequency (X axis).

• reception with an ordinary DSB AM receiver will be less effective than a receiver designed for SSB reception.

The post-WARC '79 emission symbol for single-sideband full-carrier telephony is H3E (formerly A3H). The full CCIR emission designation 3K00H3EJN would mean a bandwidth of 3 kHz, full-carrier, single-sideband telephony, commercial quality and no multiplexing. Necessary bandwidth is calculated by

$$B_n = M \quad (\text{Eq. 6})$$

where

- $B_n$  = necessary bandwidth in hertz
- $M$  = maximum modulation frequency in hertz

Fig. 9 shows oscilloscope and spectrum-analyzer displays of a sample CAM signal.

### Angle-Modulated Telephony

Below 29.0 MHz, FCC rules limit the bandwidth of frequency- or phase-modulated telephony to that of an AM transmission having the same audio characteristics. The full emission designation for such a signal would be 6K00F3EJN for frequency modulation and 6K00G3EJN for phase modulation. These designations break into: 6-kHz bandwidth, F for frequency modulation or G for phase modulation, single-channel analog, telephony, sound of commercial quality and no multiplexing.

Because of the limitation not to exceed the bandwidth of an AM transmission of the same characteristics, the bandwidth is restricted to 2M (twice the maximum modulation frequency) or  $2 \times 3000 = 6000$  Hz. You cannot use 5-kHz or even 3-kHz deviation without greatly exceeding the 6-kHz bandwidth limit. In fact, the usual FM bandwidth formulas will not work in this case, and it is necessary to examine the power in the second pair of sidebands and limit it to about 1% of the total. If this were done assuming sinusoidal modulation at 3000 Hz, the highest modulation index would be 0.4, and deviation would be limited to 1.2 kHz. In practice, however, the energy distribution in a complex (voice) wave is such that the modulation index for any one frequency component is reduced as compared to the index with a sine wave having the same peak amplitude as the voice wave. Thus, for voice, a modulation index of 0.6 and a 1.8-kHz deviation will ensure that the second pair of sidebands will be 27 dB below the unmodulated carrier level.

To obtain the benefits of this mode, a good FM receiver is required. As shown in Fig. 3, at an index of 0.6 the amplitude of the first pair of sidebands is about 25 percent of the unmodulated-carrier amplitude; this compares with a sideband amplitude of an AM transmitter modulated 100 percent.

Above 29.0 MHz, the standard FM deviation is 5 kHz. The formula for necessary bandwidth is

$$B_n = 2M + 2DK \quad (\text{Eq. 7})$$

where

- $B_n$  = necessary bandwidth in hertz
- $M$  = maximum modulation frequency in hertz
- $D$  = peak deviation in hertz
- $K = 1$

For a maximum modulation frequency of 3000 Hz and a peak deviation of 5000 Hz, the necessary bandwidth is 16,000 Hz. The emission designation would be 16K0F3EJN for 16-kHz bandwidth, frequency modulation, analog, telephony, commercial quality, and no multiplexing. In the case of phase modulation, the designation would be 16K0G3EJN.

In the early 1970s, 15-kHz deviation was used extensively by amateurs. Using Eq. 7, the bandwidth would be 36 kHz, and the emission designations would be 36K0F3EJN and 36K0G3EJN for frequency modulation and phase modulation, respectively. Currently, 15-kHz deviation is used mostly on frequencies above 450 MHz. One exception is that some fast-scan ATV groups apply 15-kHz FM audio modulation to the video carrier on repeater input frequencies.

#### TV Sound

The sound channel for U.S. TV broadcasting has a maximum modulation fre-

quency of 15 kHz and uses a peak deviation of 25 kHz. Using Eq. 7, necessary bandwidth is calculated to be  $2M + 2DK = (2 \times 15) + (2 \times 25 \times 1) = 80$  kHz. The emission designation would be 80K0F3EJN, meaning: 80-kHz necessary bandwidth, frequency modulation, analog, telephony, sound of broadcasting quality (monophonic) and no multiplexing. This is of interest to amateurs who transmit ATV for reception by ordinary TV receivers. Amateurs may not be interested in transmitting the full 50- to 15,000-Hz audio range and can reproduce high-quality speech with a 250- to 6000-Hz audio passband. In this case, the necessary bandwidth would be reduced to 62 kHz. If the maximum modulation frequency were reduced to 3000 Hz, the necessary bandwidth would be 56 kHz.

#### FM Broadcasting

The characteristics of FM sound broadcasting are of interest to amateurs for special applications. Chapter 32 illustrates the use of an FM broadcast receiver as a demodulator in a Gunnplexer<sup>TM</sup> microwave communication system.

FM sound broadcasting uses a peak deviation of 75 kHz and a maximum modulation frequency of 15 kHz. Again using Eq. 7, the necessary bandwidth is  $2M + 2DK = 2 \times 15 + 2 \times 75 \times 1 = 180$  kHz. The emission designation is 180K0F3EJN, which breaks down to: 180-kHz necessary bandwidth, frequency modulation, analog, telephony, sound of broadcasting quality (monophonic), and no multiplexing. For stereophonic or quadrasonic sound, the G would be replaced by H. N would become F to indicate frequency-division multiplexing.

#### AMATEUR IMAGE COMMUNICATIONS MODULATION

Image communications systems used in the Amateur Radio Service are outlined in Chapter 20. Below is a discussion of the most popular modulation systems for these modes.

#### Fast-Scan Television

Two types of amplitude modulation are presently in use by Amateur Radio fast-scan television (FSTV) operators. One is double-sideband, and the other is vestigial sideband. Although most FSTV is in color, some monochrome (black and white) FSTV is still in use.

The simplest way to transmit FSTV is monochrome DSB AM. In this case, the necessary bandwidth can be calculated from

$$B_n = 2M \quad (\text{Eq. 8})$$

where

- $B_n$  = necessary bandwidth in hertz
- $M$  = maximum modulation frequency in hertz

Typically, monochrome FSTV has a video bandwidth ( $M$  in Eq. 8) of 2.5 MHz. The complete CCIR emission designation would be 5M00A3FMN for: 5-MHz necessary bandwidth, double-sideband AM, single-channel analog information, television, monochrome, and no multiplexing. This emission designation does not account for any audio channel — the possibilities include sending the audio independently or multiplexing it with the video transmission.

Using the NTSC color system, the video bandwidth needs to be about 4 MHz. Again using Eq. 8, the DSB AM necessary bandwidth would be 8 MHz. The emission designation becomes 8M00A3FNM, which stands for: an 8-MHz necessary bandwidth, double sideband AM, single-channel analog information, television, color and no multiplexing. Again, no audio channel is included.

Double-sideband AM transmission of either monochrome or color TV occupies a considerable amount of spectrum. So, it is desirable to use vestigial-sideband (VSB) transmission wherever possible for FSTV to reduce bandwidth. This is particularly important for FSTV repeater outputs because repeaters are generally well sited for wide-area coverage and may run several hundred watts of power. For vestigial-sideband FSTV, the necessary bandwidth of the visual transmission can be calculated from

$$B_n = M + V \quad (\text{Eq. 9})$$

where

- $B_n$  = necessary bandwidth in hertz
- $M$  = maximum modulation frequency in hertz
- $V$  = bandwidth of the vestigial sideband (typically 1.25 MHz)

For example, the full emission designation for a VSB color TV transmission might be 5M25C3FNN, meaning: 5.25-MHz necessary bandwidth, vestigial-sideband AM, single-channel analog information, television, color, and no multiplexing. For monochrome VSB TV, the emission designation might be 4M00C3FMN, meaning: 4-MHz necessary bandwidth, vestigial-sideband AM, single-channel analog, television, monochrome and no multiplexing. Neither of these designations includes an audio channel which would most likely be 4.5 MHz above the video carrier and use 80K0F3EJN emission as discussed earlier in this chapter.

#### Analog Slow-Scan Television or Facsimile

Slow-scan television (SSTV) or facsimile (FAX) is typically transmitted by frequency modulating an audio oscillator and feeding that into a single-sideband suppressed-carrier transmitter. The bandwidth has to take into account both the frequency range over which the oscillator frequency is swung (such as from 1200 to

2300 Hz) and the number of picture elements (pixels) transmitted per second. The necessary bandwidth can be calculated from

$$B_n = 2M + 2DK \quad (\text{Eq. 10})$$

where

$B_n$  = necessary bandwidth in hertz  
 $M = N/2$   
 $N$  = number of pixels per second  
 $K = 1.1$  (typically)  
 $D$  = peak deviation (half the difference between the maximum and minimum values of the instantaneous frequency)

For example, with a tone that can be swung from 1200 to 2300 Hz (a difference of 1100 Hz),  $D$  = half the difference, or 550 Hz. If the horizontal sweep rate is 15 Hz and there are 100 pixels per line,  $N = (15 \times 100) = 1500$  pixels/s, and  $M = 1500/2 = 750$ . Pouring these numbers in Eq. 10,  $B_n = (2 \times 750) + (2 \times 550 \times 1.1) = 1500 + 1210 = 2710$  Hz. If this were an SSTV transmission, the emission designator could be 2K71J3FMN, for: 2.71-kHz necessary bandwidth, single-sideband suppressed-carrier, single-channel analog information, monochrome and no multiplexing. For facsimile, it would be 2K71J3CMN — the C designating facsimile. Note that it is the SSBSC modulation of the main carrier that determines the basic type of emission (J), not the fact that the subcarrier is frequency modulated. On the other hand, if you directly frequency-modulate the main carrier, the J in the above designators would change to F.

### Quantized Slow-Scan Television or Facsimile

Many amateurs are now using computers to generate *quantized* (rather than continuously varying signals). The bandwidth of quantized SSTV or FAX may be calculated using Eq. 15 provided that the transitions between quantized steps are smooth. For abrupt transitions between steps where image contouring is to be preserved, larger values of  $K$  should be used. If the modulation system is as described under Analog Slow-Scan Television or Facsimile, above, the emission designators for quantized SSTV or FAX would be changed by substituting the digit 2 (meaning quantized modulation of a tone) for the digit 3 (analog) in the third symbol.

### TELEGRAPHY

These modulation systems include telegraphy for aural reception (Morse code) and telegraphy for automatic reception (radioteletype).

#### Continuous-Wave Morse Telegraphy

Telegraphy by *on-off keying* (OOK) of a carrier is the oldest radio modulation system. It is also known as CW (for continuous wave). While CW is used by

Fig. 10 — Shaping and timing in CW keying systems.

amateurs and other communicators to mean OOK telegraphy by Morse code, parts of the electronics industry use CW to signify an unmodulated carrier. OOK telegraphy is also known as *amplitude-shift keying* (ASK).

The emission symbol for Morse OOK of the main carrier is A1A (formerly A1). The first letter is A because keying a carrier on and off produces double (upper and lower) sidebands corresponding to the frequency components of the keying pulse. The amplitude of the RF signal rises from zero to full strength some time after the key is closed, and returns to zero some time after the key is opened. The lengths of these transition intervals and their wave shapes determine the bandwidth occupied by the signal.

In Fig. 10, the envelope rises from zero to full amplitude in 5 ms. The waveform during the rise time resembles 90 degrees of sine wave having a period of 20 ms, or a frequency of 50 Hz. Amplitude-modulation theory tells us that the occupied bandwidth will be 100 Hz; that is, 50 Hz for the lower sideband (LSB) and 50 Hz for the upper sideband (USB). If the waveform deviates from sinusoidal, harmonics are present, and the bandwidth will be some integral multiple of 100 Hz. The fall time is just as important as the rise time; whichever is shorter or has the greatest harmonic content will determine the bandwidth of the emission.

League publications have long promoted 5-ms rise and fall times for CW keying envelopes. This figure was not chosen arbitrarily. Appendix 6 of the CCIR Radio Regulations and section 2.202 of the FCC rules define the bandwidth for an A1A emission as

$$B_n = BK \quad (\text{Eq. 11})$$

where

$B_n$  = necessary bandwidth in hertz  
 $B$  = telegraph speed in bauds  
 $K$  = an overall numerical factor that varies according to the emission and that depends on the allowable signal distortion.

The CCIR and FCC recommend  $K = 3$  for nonfading circuits and  $K = 5$  for fading circuits when using telegraphy for aural reception. If  $K = 3$  is chosen, that means the frequency of the keying envelope rise is the third harmonic of the keying frequency.  $K = 3$  is the minimum needed for aural reception because a  $K = 1$  (although useful for machine recognition) sounds like the keying is too soft.  $K = 5$  is more appropriate for fading circuits because the faster rise time helps the ear sense the transitions. Further,  $K = 5$  says that the third and fifth harmonic of the keying pulses are present in both sidebands. Thus, if any of these harmonics are lost through *selective fading* caused by *multipath* propagation, the rest of the signal stands a good chance of getting through and being interpreted correctly by the receiving operator. Selective fading isn't usually a problem on HF at speeds below 50 bauds because the upper and lower sidebands are fairly close in frequency and are usually *correlated* (they fade together). Every now and then you can hear the exception, which sounds like the signal is in a barrel.

In Morse telegraphy a dot occupies one unit of time, as does a space. For a string of dots having a duration of 20 ms, there will be 25 such dots in a second, and the keying speed will be 50 bauds. We are more accustomed to words per minute (WPM)

Fig. 11 — Curves for determining 23-dB bandwidths and maximum telegraph speeds for various keying rise and fall times.

than bauds when dealing with Morse code, so let's apply the following formulas.

$$\text{WPM} = 2.4 \times \text{dot/s}$$

$$\text{WPM} = 1.2 \text{ B}$$

where

WPM = telegraph speed in words per minute

2.4 = a constant calculated by comparing dots per second with plain-language Morse code sending the word PARIS

1.2 = a constant calculated by comparing the signaling rate in bauds with plain-language Morse code sending the word PARIS

B = telegraph speed in bauds

Thus a keying speed of 25 dot/s or 50 bauds is equal to 60 WPM. Returning to Eq. 11, on a nonfading circuit the necessary bandwidth will be  $50 \times 3 = 150 \text{ Hz}$ . This value differs from the 100 Hz derived earlier because the formula is based on a larger energy spectrum and recognizes that the keying waveform isn't likely to be purely sinusoidal. Also, we defined the rise and fall times to include the complete transition interval for ease of illustration. Measuring the rise and fall times according to the 10% to 90% convention shortens the times somewhat and tends to further reconcile the two bandwidth values. Given a 150-Hz bandwidth, how fast can we communicate over a fading path? Setting  $B_n = 150$  and  $K = 5$ , and solving Eq. 11 for B produces a telegraph speed of

30 bauds, which is 36 WPM (PARIS). You may conclude that 5-ms rise and fall times are suitable for up to 36 WPM on fading circuits and 60 WPM on nonfading circuits. These numbers can be scaled up or down according to your needs as shown in Fig. 11.

Fig. 12 shows an oscilloscope amplitude vs. time display and a spectrum-analyzer amplitude vs. frequency display of an OOK signal.

To complete the picture, the full CCIR emission designation for the Morse code keying just discussed is 150HA1AAN. The figure 150 is the necessary bandwidth in hertz (H); A = double-sideband amplitude modulation; 1 = a single channel containing quantized or digital information without the use of a modulating subcarrier; the second A = telegraphy — for aural reception; the third A = two-condition code with elements of differing numbers and/or durations; and N = no multiplexing.

#### Receiving Morse Telegraphy

Proper reception of a Morse-code transmission requires that the receiver bandwidth be at least that of the necessary bandwidth plus any frequency error. Thus, if you have 150-Hz receiver bandwidth, it would be necessary for you to carefully tune your receiver to receive a 150-Hz-bandwidth transmission. Or, if you want to have a fixed-frequency receiver, probably one that's crystal controlled, you will need to increase the 150-Hz bandwidth

Fig. 12 — Displays of a CW OOK signal. At top is a dual-trace oscilloscope pattern of amplitude (Y axis) vs. time (X axis). The bottom trace is the CW keying input before shaping at 25 dots/s. The upper trace is the keyed RF carrier after keying has been shaped for approximately 5-ms rise and fall times. The bottom photo is the spectrum-analyzer display of amplitude (Y axis) vs. frequency (X axis) for the same signal.

by the combined error of both the transmitter and receiver frequencies.

For aural reception, a Morse-code OOK radio signal is not completely demodulated to its original dc pulse, since only thumping would be heard. Instead, it consists of simply heterodyning the RF signal down to an AF signal somewhere in the vicinity of 700 Hz. If the IF bandwidth is much greater than 150 Hz, the overall bandwidth can be reduced by adding an audio filter in the receiver AF circuits. These concepts and practical circuits are developed in Chapter 28.

#### Single-Sideband Suppressed Carrier Tone-Modulated Morse

Rather than keying a main carrier on and off, many modern transmitters generate a CW signal by keying an audio tone of about 700 or 800 Hz and feeding it to an SSBSC transmitter. The transmitter output looks just the same as though the main carrier had been keyed except for the suppressed carrier 700 or 800 Hz away. In fact, the carrier is so well suppressed that it cannot be heard any appreciable distance away from the transmitter. "If it looks like a duck, walks like a duck and quacks like a duck..." Well, not in this case. The transmitted signal is not classified as A1A but as J2A (formerly A2J). Eq. 11 can still be used to calculate bandwidth. Using the 5-ms rise-time example discussed under continuous-wave Morse telegraphy, the bandwidth would remain 150 Hz. Thus, the

## Glossary Of Modulation, Multiplexing And Demodulation Terms

**ACSB\*** — Amplitude-compandored single sideband; registered trademark of Sideband Technology Inc. (See ACSB.)

**ACSSB** — Amplitude-compandored single sideband.

**ADM** — Adaptive delta modulation.

**AFSK** — Audio-frequency-shift keying.

**AM** — Amplitude modulation.

**Analog** — Information in continuously variable quantities. (Opposite digital. Also see quantized.)

**ANBFM** — Adaptive narrow-band frequency modulation.

**Apparent carrier** — The frequency,  $f_0$ , at which the signal maximum appears.

**APK** — Amplitude phase keying. (Same as QAM.)

**APCM** — Adaptive pulse-code modulation.

**ASK** — Amplitude-shift keying.

**AWGN** — Additive white Gaussian noise.

**Baseband** — The band of frequencies of a signal (a) prior to modulation of the main carrier or (b) after demodulation of the main carrier.

**Baud (Bd)** — A unit of signaling speed equal to the number of discrete conditions or events per second. (If the duration of a pulse is 20 ms, the signaling rate is 50 bauds or the reciprocal of 0.02.)

**Bit/s** — A measure of the number of bits of data transmitted per second. (The prefixes k, M, or G may be added to denote higher speeds; for example 1 kbit/s is 1000 bits per second.)

**BPSK** — Binary phase-shift keying.

**Carrier** — A continuous radio frequency capable of being modulated by a baseband signal or subcarrier.

**CDM** — Companded delta modulation.

**CDMA** — Code-division multiple access.

**CFSK** — Coherent frequency-shift keying.

**C/N** — Carrier-to-noise ratio. (Expressed in dB.)

**Compandor** — A contraction of compressor-expander.

**CPFSK** — Continuous-phase frequency-shift keying.

**CPM** — Continuous-phase modulation.

**CVSD** — Continuously variable slope delta modulation. (Used to convert analog speech into compressed digital form.)

**CW** — Continuous wave. (In Amateur Radio, CW usually means a continuous carrier wave keyed on and off by Morse code.)

**DAV** — Data above voice.

**DBPSK** — Differentially binary phase-shift keying.

**DCPSK** — Differentially coherent phase-shift keying.

**Demodulation** — The process of deriving the original modulation signal from a modulated carrier wave.

**DEBPSK** — Differentially encoded binary phase-shift keying, with carrier recovery.

**DECPSK** — Differential encoded coherent phase-shift keying.

**DFSK** — Double frequency-shift keying.

**Dibit** — A group of two bits. (The possible states are 00, 01, 10 and 11. In phase modulation each dibit translates to one of four specific phases or transitions.)

**Digital** — Information in discrete states. (Opposite analog.)

**DIV** — Data in voice.

**DLL** — Delay-locked loop

**DPCM** — Differential pulse-code modulation.

**DPMM** — Digitally processed multimode modulation.

**DPSK** — Differential phase-shift keying.

**DS** — Direct sequence. (A technique used in spread spectrum.)

**DSB** — Double sideband.

**DSBSC** — Double-sideband suppressed carrier.

**DUV** — Data under voice.

**Envelope delay** — The propagation time of the envelope of a wave.

**Equalizer** — A circuit with fixed or variable parameters for correction of amplitude or phase distortion.

**Eye diagram** — (Also called eye pattern). An oscilloscope display of a digital signal stream, triggered at the transmission bit rate, to show the received waveform. (The displayed waveform resembles an eye.)

**FAX** — Facsimile.

**FDM** — Frequency-division multiplexing. (Typically used to transmit a number of sub-carriers [each having its own frequency] over one carrier.)

**FDMA** — Frequency-division multiple access.

**FFSK** — Fast frequency-shift keying. (Same as MSK.)

**FH** — Frequency hopping. (A modulation technique used in spread spectrum.)

**FM** — Frequency modulation.

**FSK** — Frequency-shift keying.

**FSTV** — Fast-scan television.

**GMSK** — Gaussian-filtered minimum-shift keying.

**Group delay** — The rate of change with frequency of the phase shift during propagation from one point to another.

**ICW** — Interrupted continuous wave.

**ISB** — Independent sideband.

**Isochronous distortion** — The peak-to-peak phase jitter, which may be expressed in percentage of the unit interval.

**Intersymbol interface (ISI)** — Pulse stretching of one pulse into the next pulse.

**Jitter** — The peak-to-peak time difference between the ideal time and the actual time for a pulse transition.

**LPC** — Linear predictive coding. (A technique for converting analog speech to digital form using a small number of bits.)

**LSB** — Lower sideband.

complete emission designation would be 150HJ2AAN.

### Amplitude Tone-Modulated Morse Telegraphy

This type of modulation, often called *modulated CW (MCW)*, was lumped under an ambiguous pre-WARC '79 emission symbol of A2. MCW or A2 meant that a Morse-keyed tone modulated a double-sideband AM transmitter. The ambiguity was whether only the sidebands were keyed or the sidebands and the carrier. Carrier-keyed MCW is permitted in the Amateur Radio Service only on frequencies between 50.1 and 54 MHz and above 144.1 MHz. MCW produced by keying the tone but not the carrier can be operated on the frequencies just mentioned and as specified in §97.65(b) of the FCC rules: "Whenever code practice, in accordance with §97.91 (d), is conducted in bands authorized for A3 emission tone modulation of the radio telephone transmitter may be utilized when interspersed with appropriate voice instructions."

The post-WARC '79 emission symbol for MCW is A2A. Again, no distinction is made in the emission symbol to tell whether the carrier is keyed. The formula for necessary bandwidth is

$$B_n = BK + 2M \quad (\text{Eq. 12})$$

where

$B_n$  = necessary bandwidth in hertz

$B$  = modulation rate in bauds

$M$  = maximum modulation frequency in hertz

$K$  = 5 for fading circuits, 3 for non-fading circuits

For a 25-WPM ( $B = 20$ ) transmission with  $M = 1000$  and  $K = 5$ , the bandwidth will be 2.1 kHz. The full emission designation in this case will be 2K10A2AAN. Broken down, the designation stands for: 2.1 kHz bandwidth, double-sideband AM, a single channel containing quantized or digital information, telegraphy for aural reception, two-condition code with elements of differing numbers and/or durations, and no multiplexing.

### Frequency-Shift-Keyed Telegraphy

On-off keying is effective for aurally received Morse-code transmissions because the ear is able to recognize the difference between the presence of a signal and noise (the absence of signal). Demodulators for teletypewriters and computers do much better with two positive conditions, each representing a specific logic state (1 or 0).

Frequency-shift keying (FSK) provides

the two positive states just mentioned. The transmitter shifts between two predetermined frequencies, called *mark* (1) and *space* (0). In Amateur Radio Baudot and AMTOR systems, the standard shift is now 170 Hz. Deviation (usually abbreviated D) is measured from an imaginary center frequency and the mark or space frequencies, and is half the shift. Thus a 170-Hz shift equals a deviation of 85 Hz.

Sometimes you will see the abbreviation CP used in front of FSK. CP, meaning *continuous phase*, says that the mark and space frequencies as well as the dc pulses that switch between them are clocked in a way that ensures a continuous sinusoidal function. This avoids generating unwanted sidebands that would have resulted from waveform discontinuities.

To date, virtually all amateur FSK has been NCFSK, the NC standing for *non-coherent*. You can tell this quickly by looking at the signaling rate (in bauds) and the shift: If one is not an integral multiple of the other, the FSK will be noncoherent. For example, a 170-Hz-shift FSK system keyed at 45.45 bauds is noncoherent because 170 divided by 45.45 equals 3.740374 — far from a round number. Unless special design precautions are taken, an NCFSK signal could contain many unwanted sideband components (key clicks),

**MAP** — Maximum a posteriori probability. (A mathematical estimative technique used in data demodulation. See ML.)  
**Mark** — The presence of a signal. (See space.)  
**M-ary** — M is a variable representing the number of states (in modulation).  
**MCW** — Modulated continuous wave. (In Amateur Radio, MCW usually means a tone-modulated carrier keyed on and off by Morse code.)  
**MASK** — Multiple amplitude-shift keying.  
**MFSK** — Multiple frequency-shift keying.  
**ML** — Maximum likelihood. (A mathematical estimative technique used in data demodulation. See MAP.)  
**MPSK** — Multiple phase-shift keying.  
**Modem** — Modulator-demodulator.  
**Modulation** — The process of varying some characteristic of a carrier wave to convey intelligence.  
**Modulation index** — In frequency modulation, the number of sideband pairs for a given modulating frequency.  
**MSK** — Minimum-shift keying. (Same as FFSK.)  
**MSTV** — Medium-scan television.  
**MUX** — Multiplex; multiplexer.  
**NBFM** — Narrow-band frequency modulation.  
**NBPSK** — Narrow-band phase-shift keying.  
**NCSK** — Noncoherent frequency-shift keying.  
**Necessary bandwidth** — The bandwidth just sufficient to ensure the transmission of information at the rate and with the quality required.  
**NLA-QAM** — Nonlinear amplified QAM.  
**NLF-OQPSK** — Nonlinearly filtered QPSK; also known as Feher's QPSK.  
**Occupied bandwidth** — The bandwidth the upper and lower limits of which have mean powers equal to a specified percentage (0.5% unless otherwise specified) of the total mean power.

**OOK** — On-off keying.  
**OQPSK** — Offset (or staggered) quadrature phase-shift keying.  
**PAM** — Pulse-amplitude modulation.  
**PCM** — Pulse-code modulation.  
**PDM** — Pulse-duration modulation. (Same as PWM.)  
**PFM** — Pulse-frequency modulation.  
**PLL** — Phase-locked loop.  
**PM** — Phase modulation.  
**PSK** — Phase-shift keying.  
**Pulse spreading** — Elongation of a received pulse as a result of multipath propagation.  
**PWM** — Pulse-width modulation. (Same as PDM.)  
**QAM** — Quadrature amplitude modulation. (Same as APK.)  
**QASK** — Quadrature amplitude-shift keying.  
**Q-M/PSK** — Quadrature suppressed-carrier AM added to quadrature carrier and hard limited.  
**QPPM** — Quantized pulse-position modulation.  
**QPRS** — Quadrature-partial-response modulation system.  
**QPSK** — Quadrature phase-shift keying (quadrature phase).  
**Quadbit** — A group of 4 bits. In phase modulation each quadbit translates to one of 16 specific phases or transitions.)  
**Quantize** — To divide the range of variables into a finite number of specific values or steps.  
**Raised cosine (RC)** — A method of shaping a keying waveform to reduce bandwidth by following the cosine function with the negative peak of the wave raised (or biased) to 0-V dc.  
**Reduced carrier (RC)** — A method of transmission wherein the carrier is reduced by a predetermined number of decibels.  
**SCPC** — Single channel per carrier.  
**Sideband** — The group of frequencies above or below the main carrier frequency which contain the product of modulation.  
**S/N** — Signal-to-noise ratio. (Expressed in dB.)  
**Space** — The absence of a signal. (See mark.)  
**Splatter** — Generation of unnecessary sidebands by exceeding 100% modulation in an AM system or by flat-topping.  
**SQAM** — Staggered (or offset) quadrature amplitude modulation.  
**SQPSK** — Staggered (or offset) quaternary phase-shift keying.  
**SSB** — Single sideband.  
**SSBSC** — Single-sideband suppressed carrier.  
**SSMA** — Spread-spectrum multiple access.  
**SSTV** — Slow-scan television.  
**Suppressed carrier (SC)** — A method of transmission wherein the carrier is greatly attenuated.  
**TADI** — Time assignment digital interpolation. (A technique for sending bursts of data during pauses in speech.)  
**TDM** — Time-division multiplexing.  
**TDMA** — Time-division multiple access.  
**TFM** — Tamed frequency modulation.  
**TH** — Time hopping. (A technique used in spread spectrum.)  
**Unit interval** — The duration of the shortest signal element. (Expressed in seconds, the unit interval is the reciprocal of the signaling speed in bauds.)  
**USB** — Upper sideband.  
**VF** — Voice frequencies.  
**VFCT** — Voice-frequency carrier telegraphy. (A technique for combining multiple telegraph channels in the frequency spectrum normally occupied by one voice channel.)  
**VSB** — Vestigial sideband.  
**VSDM** — Variable-slope delta modulation.  
**WBFM** — Wideband frequency modulation.  
**WGN** — White Gaussian noise.  
**WPM** — Words per minute. (A unit of speed in telegraph systems.)  
**8PSK** — Eight-ary or octal phase-shift keying.

which would interfere with nearby channels.

The pre-WARC '79 emission symbol for FSK was F1. The new designation still begins with F1 but includes a third letter (and the fourth and fifth letters if you care to add them). For conventional 170-Hz FSK 45.45-baud Baudot RTTY, the short-form emission symbol is F1B, the B standing for telegraphy — for automatic reception. The complete emission designation would be 249HF1BBN. The optional fourth letter means a two-condition code with elements of the same number and duration without error correction; the fifth letter N is for no multiplexing. For Baudot RTTY, the necessary bandwidth is calculated

$$B_n = B + 2DK \quad (\text{Eq. 13})$$

where

$B_n$  = necessary bandwidth

$B$  = modulation rate in bauds

$D$  = peak deviation (half the frequency shift) in hertz

$K$  = 1.2 (typically)

The complete emission designation for AMTOR FSK RTTY is 304HF1BCN. The bandwidth 304H is calculated using Eq. 13, above; in this case,  $B$  is 100 bauds. The optional fourth and fifth letters are: C for

two-condition code with elements of the same number and duration with error correction and N for no multiplexing.

For both Baudot and AMTOR RTTY, the third letter B, meaning telegraphy for automatic reception, implies *direct-printing* telegraphy. In CCIR lingo, direct-printing describes the traditional teletypewriter-to-teletypewriter circuit where what you type on one end comes out on a typewriter-like printer on the other end. However, when you depart from direct-printing telegraphy and enter the world of computers to generate FSK, you are entering the "twilight zone" of CCIR terminology. Thus, if you are transmitting ASCII from teletypewriter to teletypewriter, you are transmitting FIB emission. If, on the other hand, you are transmitting *data* (in this case loosely meaning that a computer generates it and it is probably received by a computer-like device at the other end), then the emission symbol is FID. We suggest using the third symbol B for all narrow-band direct-printing telegraphy whether sent by a teletypewriter or a computer.

#### Audio-Frequency-Shift-Keyed Telegraphy

Audio-frequency-shift keying (AFSK) is more popular than direct FSK of the main carrier for both direct-printing telegraphy and data transmission in the Amateur

Radio Service. AFSK into an SSBSC transmitter is common for both the HF bands and via satellite. For Baudot and AMTOR, the emission designations of AFSK-generated signals would be 249HJ2BBN and 304HJ2BCN, respectively, using the same parameters as in the FSK examples given earlier.

Above 50 MHz, radioteletype transmissions are often sent by frequency-shift keying an audio tone and feeding the AFSK tone into the microphone input of an FM transmitter. Necessary bandwidth calculations get a bit tricky because of the double modulation. First, let us determine the baseband bandwidth of the frequency-shifted tones. That is done by using Eq. 13, which will yield bandwidths of 249 Hz for 45-baud Baudot, as calculated above. If the AFSK tones used are 2125 and 2295 Hz, you can determine the highest modulation frequency by finding the center frequency and adding half the bandwidth to that. As 2125 and 2295 Hz differ by 170 Hz, the center frequency is 2210 Hz. Half the 249-Hz bandwidth is 125 Hz (124.5 Hz rounded up), so  $2210 + 125 = 2335$ . Thus the highest modulation frequency is 2335 Hz. To complete the bandwidth calculation, we then use the general necessary bandwidth formula for the main FM carrier

Fig. 13 — Power spectral density of BPSK, QPSK, MSK, GMSK and TFM relative to the mean power of the total emission. (After CCIR Rep. 767-1 and Steber, March 1984)

$B_bT$  = normalized bandwidth of premodulation  
Gaussian band-pass filter (GMSK)  
 $f_c$  = center frequency  
 $f_b$  = bandwidth (Hz)  
 $P$  = spectral density (W/Hz)

$$B_n = 2M + 2DK \quad (\text{Eq. 10})$$

where

$B_n$  = necessary bandwidth in hertz  
 $M$  = maximum modulation frequency in hertz  
 $D$  = peak deviation in hertz  
 $K$  = 1

Thus, if a frequency deviation of 5 kHz is used,  $B_n = (2 \times 2335) + (2 \times 5000 \times 1) = 4670 + 10,000 = 14,670$  Hz.

## DATA, TELEMETRY AND TELECOMMAND

Data, telemetry and telecommand are identified by D as the third symbol of the emission designator. Included in this category are computer-to-computer data transfers, packet radio, telemetry from satellites, and remote control of models and other objects. Excluded from this category is narrow-band direct-printing telegraphy (conventional radioteletype).

### Efficient Data Communications

A measure of data communication efficiency is the number of hertz or frequency shift (in an FSK system) per baud (Hz/Bd) — this is nothing more than FM modulation index. Narrow-band direct-printing RTTY transmissions use low signaling rates and small frequency shifts in absolute terms (Hz). Typically an RTTY signal uses a frequency shift of 170 hertz and signals at a rate of 45 bauds. This amounts to

170 Hz/45 Bd, which reduces to a modulation index of 3.78 (Hz/Bd). If we were to use the same modulation index for a 1200-baud data transmission, the frequency shift would be  $3.78 \times 1200 = 4536$  Hz. Further, applying Eq. 13, the necessary bandwidth would be

$$B_n = B + 2DK = 1200 + (4536 \times 1.2) = 1200 + 5443 = 6643 \text{ Hz.}$$

Clearly, it would not be good spectrum efficiency to use more than 6 kHz of bandwidth when existing technology permits transmission of a 1200-baud data signal in a much smaller bandwidth. Through this analysis, we have established that conventional RTTY, while not occupying much spectrum in absolute terms, is spectrally inefficient with respect to its signaling rate. Also, it can be concluded that data transmission at higher speeds must use spectrally efficient modulation techniques in order to find room in crowded Amateur Radio bands.

The FCC recognized this matter of spectrum efficiency in the rules, which state: "the ... frequency shift (difference between the frequency for the "mark" signal and that for the "space" signal), as appropriate, shall not exceed 1000 Hz. When these emissions are used on frequencies above 50 MHz, the frequency shift, in hertz, shall not exceed the sending speed, in baud(s), of the transmission, or 1000 Hz, whichever is greater." The frequency shift

Fig. 14 — Wide spectral displays of 1200-baud data transmissions. At top is a display of amplitude (Y axis) vs. frequency (X axis) of a 1200-baud signal produced by a Bell 202 modulator, which has a frequency shift of 1000 Hz. At center is a similar display of the output of a minimum-shift-keying (MSK) modulator, which has a shift of 600 Hz. At bottom is a display of a binary-phase-shift-keying (BPSK) modulator. Note that the top and bottom displays have spans of 20 kHz, while the center display span is 5 kHz.

(in Hz) not exceeding the sending speed (in Bd) means a limit of 1 Hz/Bd (a modulation index of 1) for signaling rates of 1000 Bd or more.

For 1200-Bd packet radio, it is common to use surplus Bell 202 compatible modems. As Bell 202 tones (1200 and 2200 Hz) shift 1000 Hz, the result is 1000/1200 or a modulation index of 0.83 (Hz/Bd). On HF packet radio, there is activity using Bell 103 tones (originate tones of 1070 and 1270 Hz or answer tones of 2025 and 2225 Hz) at a signaling speed of 300 bauds. This amounts to a modulation index of  $(200/300) = 0.67$  (Hz/Bd). A frequency shift of 600 Hz at a signaling speed of 1200 bauds would give a modulation index of

Fig. 15 — Close-in spectral displays of same types of modulation as in Fig. 14. Bell 202 FSK (1000-Hz shift) at top; MSK (600-Hz shift) at center; and BPSK (180° phase shift) at bottom.

$(600/1200) = 0.5$  and would be called *minimum-shift keying* (MSK) or, less frequently, *fast frequency-shift keying* (FFSK).

Eq. 13 is considered a good rule of thumb for modulation indexes greater than 1. For modulation indexes below 1, Eq. 13 is inaccurate and yields excessively large necessary bandwidth figures. In such cases, we recommend either a literature search for

the specific type of modulation or actual measurement with a spectrum analyzer to determine occupied bandwidth. For your convenience, Fig. 13 summarizes the spectral densities of a number of digital modulation schemes.

### Multilevel Modulation

It is now commonplace to use more than one modulation system to generate a radio signal. As an example, you can use a digital stream to frequency modulate an audio tone that frequency-modulates the transmitter carrier. This technique is used for transmission of RTTY at VHF. In some texts, this complex modulation technique is abbreviated FM-FM (or FM/FM). The first term is the modulation applied to the subcarrier, while the second is the modulation of the main carrier.

Here are some examples of double modulation systems used in the Amateur Radio Service:

**AFSK-SSB** — A digital stream (Baudot, AMTOR, packet radio) modulating an audio-frequency-shift-keyed tone that modulates a single-sideband transmitter. (Emission designation: J2B or J2D.)

**FM-SSB** — A signal frequency modulating a subcarrier that modulates a single-sideband transmitter. (This is commonly used for SSTV and FAX on high-frequency transmitters; emission designations would be J3F and J3C, respectively.)

**FM-VSB** — A signal frequency modulating a subcarrier that modulates a vestigial-sideband transmitter. (Example: The aural subcarrier injected into a UHF fast-scan TV transmitter.)

# Radio Frequency Oscillators and Synthesizers

**R**F oscillators and synthesizers are fundamental building blocks used in radio equipment of all kinds. The first stage in almost all simple transmitters is an oscillator. This stage determines on what particular frequency the transmitter will operate. In a similar manner, the various oscillators used in a superheterodyne communications receiver determine the frequency the receiver is tuned to. The simplest transmitter is a crystal-controlled oscillator. A full-feature transceiver may use a microprocessor-controlled frequency synthesizer to determine transmit and receive frequencies.

An oscillator is actually a special type of amplifier. The transistor or other active device used in the oscillator amplifies the signal applied to its input just as any amplifier circuit does. The basic difference is that a portion of the output from the device is fed back to the input of the amplifier so that it aids the applied signal. This is called positive feedback or regeneration. An example of this is the howling that sometimes occurs in a public-address system. Negative feedback or degeneration tends to oppose the input signal.

## Crystal Oscillators

A crystal-controlled oscillator uses a piece of quartz that has been ground to a particular thickness, length and width. For the most part, the thickness determines the frequency at which the crystal oscillates, irrespective of the stray capacitance in the immediate circuit of the crystal. Stray capacitance has some effect on the operating frequency, but overall the effect is minor. The maximum power available from such an oscillator is restricted by the heat (caused by circulating RF current) the crystal can withstand before fracturing. The circulating current is determined by the amount of feedback required to ensure excitation. Excessive heating of the crystal causes frequency drift. The extent of the drift is related to the manner in which the quartz crystal is cut. It is for these reasons that the amount of feedback used should be held to only that level which provides quick oscillator starting and reliable opera-

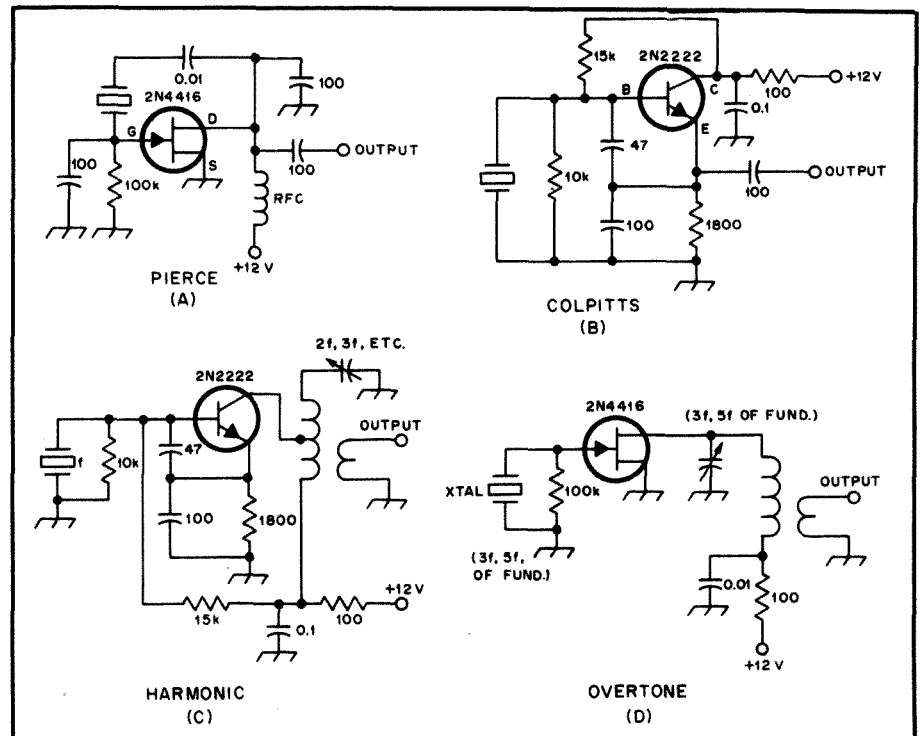

Fig 1—Four types of popular solid-state crystal oscillators.

tion under load. The power necessary to excite a successive stage properly can be built up inexpensively by low-level amplifiers.

Although a wide variety of crystal-controlled oscillator circuits can provide acceptable performance in amateur equipment, only a few of the popular ones will be highlighted here. In the circuits offered as illustrations, the feedback must be sufficient to assure quick starting of the oscillator. Some circuits function well without the addition of external feedback components (internal capacitance within the transistor or tube being adequate). Other circuits need external feedback capacitors. Poor-quality (sluggish) crystals generally require larger amounts of feedback to provide operation comparable to that of lively crystals. Some surplus crystals are sluggish, as can be the case with those

which have been reground or etched for a different operating frequency. Therefore, some experimentation with feedback voltage may be necessary when optimizing a given circuit. As a rule of thumb it is necessary to use one-fourth of the oscillator output power as feedback power to ensure oscillation.

The active element in an oscillator can be a tube, transistor or IC. Some common examples of solid-state oscillators are shown in Fig 1. A Pierce oscillator that employs a JFET is illustrated at A. A bipolar transistor is used at B to form a Colpitts oscillator. The example in Fig 1C shows how to extract the harmonic of a crystal by tuning the collector circuit to the desired harmonic. Unless a band-pass filter is used after the tuned circuit, various harmonics of the crystal frequency will appear

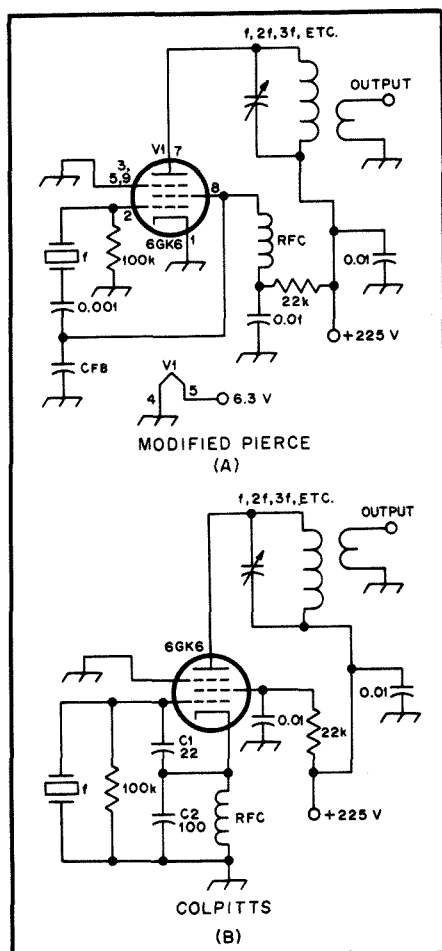

Fig 2—Two common tube types of crystal oscillators.

in the output. Therefore, if good spectral purity is desired it is necessary to use a double-tuned collector tank to obtain a band-pass characteristic, or to employ the tank circuit shown and follow it with a harmonic filter.

An overtone oscillator is depicted in Fig 1 at D. The crystal oscillates near an odd multiple of the fundamental cut—usually the third or fifth harmonic. In this example the drain tank is tuned approximately to the desired overtone. Oscillation will begin when the tank is tuned slightly above the overtone frequency. A high-Q tuned circuit is necessary.

Vacuum-tube crystal oscillators are presented in Fig 2. A modified Pierce oscillator is shown at A. In this case the screen grid of VI functions as the plate of a triode tube. Feedback is between the screen and control grids.  $C_{fb}$  will range from 10 to 100 pF for oscillators operating from 1.8 to 20 MHz. At lower frequencies the feedback capacitor may require a higher value.

A Colpitts style of tube oscillator is illustrated in Fig 2B. The feedback occurs between the grid and cathode by means of a capacitive divider (C1 and C2). The plate tank can be tuned to the crystal frequency or its harmonics. In the interest of good

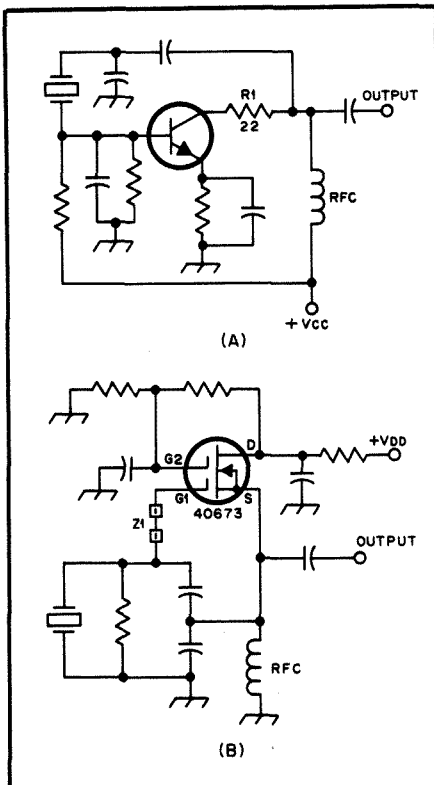

Fig 3—Two methods for suppressing VHF and UHF parasitic oscillations. R1 at A damps the parasitics and Z1 at B (ferrite beads) serves that purpose.

oscillator stability, the supply voltage to the circuits of Figs 1 and 2 should be regulated. This is especially significant in the case of harmonic or overtone oscillators where small amounts of drift are multiplied by the chosen harmonic factor.

The usual cause of erratic oscillation, or no oscillation at all, is excessive loading on the oscillator output by the succeeding stage of circuit, insufficient feedback or a sluggish crystal. Concerning the latter, a crystal not ground to a uniform thickness and feathered carefully around the edges may be difficult to make oscillate. Attempts by amateurs inexperienced in grinding their own crystals may lead to this condition.

Some crystal oscillators develop unwanted VHF self-oscillation (parasitics) even though the circuits may be functioning normally otherwise. The result will be a VHF waveform when the RF voltage is viewed by means of an oscilloscope. Parasitics can cause TVI and specific problems elsewhere in the circuit in which the oscillator is used. Two simple methods for preventing VHF parasitics are shown in Fig 3. The technique at A calls for the insertion of a low-value resistance (R1) in the collector lead as close to the transistor body as possible. Typical resistance values are 10 to 27 ohms. The damping action of the resistor inhibits VHF oscillation. An alternative to the use of resistance for swamping VHF oscillation is illustrated at B in Fig 3. One or two high- $\mu$  miniature

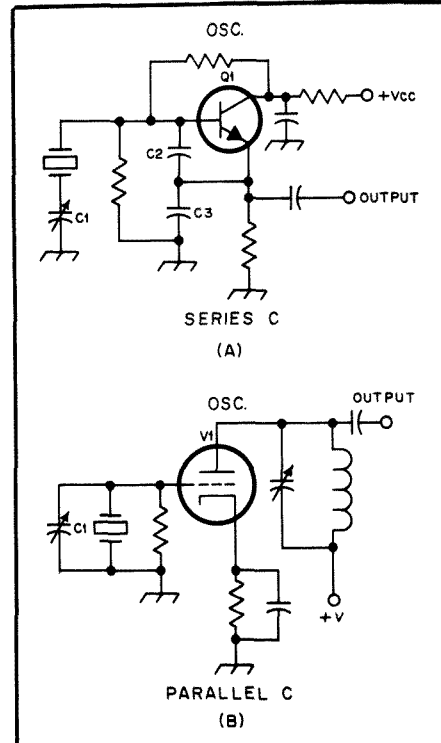

Fig 4—The crystal-oscillator operating frequency can be shifted slightly by means of trimmer capacitors as shown at A and B. A series hookup (A) is used with transistors to help compensate for the relatively high input capacitance of the transistor.

ferrite beads ( $\mu_r = 950$ ) are placed near the transistor body in the lead to gate 1. The beads can be used in the drain lead when a tuned circuit or RF choke is used in that part of the circuit. Ferrite beads can be used in the base or collector lead of the circuit of Fig 3A, rather than employing R1. Similarly, R1 can be used at gate 1 of the oscillator.

### Adjusting Frequency

It is necessary in some crystal oscillator applications to ensure spot accuracy of the operating frequency. Various reactances are present in most oscillator circuits, causing the operating frequency to differ somewhat from that marked on the crystal case. Addition of a trimmer capacitor will permit "rubbering" the crystal to a specified frequency within its range. This procedure is sometimes referred to as "netting" a crystal.

Fig 4 shows two circuits in which a trimmer capacitor might be used to compensate for differences in the operating frequency of the oscillator. At A the series capacitor (C1) is connected between the side of the crystal and ground. The series hookup is used to help offset the high input capacitance of the oscillator. The input capacitance consists of the series value of feedback capacitors C2 and C3 plus the input capacitance ( $C_{in}$ ) of Q1. Conversely, the input capacitance of the circuit at B in Fig 4 is quite low because a triode tube is

employed. In this kind of circuit the trimmer capacitor is connected in parallel. The choice between series and parallel trimming will depend on the active device used and the amount of input capacitance present. This rule applies to tube oscillators as well as those which use transistors.

Fig 5 shows four practical oscillator circuits of this type. CI is included for adjusting the crystal to the frequency for which it has been ground. In circuits where considerable shunt capacitance is present (Fig 5A and C) the trimmer is usually connected in series with the crystal. When there is minimal parallel capacitance (approximately 6 pF in the circuits at B and D, Fig 5) the netting trimmer can be placed in parallel with the crystal. Whether a series or parallel trimmer is used will depend also on the type of crystal used (load capacitance and other factors).

Feedback capacitance ( $C_{fb}$ ) for the circuit at B in Fig 5 must be found experimentally. Generally, a value of 100 pF will suffice for operation from 3.5 to 20 MHz. As the operating frequency is lowered it may require additional capacitance. The drain RF choke should be self-resonant below the operating frequency.

A third-overtone crystal is illustrated at Fig 5D. Satisfactory operation can be had by inserting the crystal as shown by the dashed lines. This method is especially useful when low-activity crystals are used in the overtone circuit. However, CI will have little effect if the crystal is connected from gate to drain, as shown. C2-L1 is adjusted slightly above the desired overtone frequency to ensure fast starting of the oscillator. The circuits shown in Fig 5 can be used with dual-gate MOSFETs also, assuming that gate 2 is biased with a positive 3 to 4 volts.

### Crystal Switching

Although several crystals for a single oscillator can be selected by mechanical means, a switch must be contained in the RF path. This can impose severe restrictions on the layout of a piece of equipment. Furthermore, mechanical switches normally require that they be operated from the front panel of the transmitter or receiver. That restriction complicates the remote operation of such a unit. Also, the switch leads can introduce unwanted reactances in the crystal circuit. A better technique is illustrated in Fig 6, where D1 through D3—high-speed silicon switching diodes—are used to select one of three or more crystals from some remote point. As operating voltage is applied to one of the diodes by means of S1, it is forward biased into "hard" conduction, thereby completing the circuit between the crystal trimmer and ground. Some schemes actually call for reverse-biasing the unused diodes when they are not activated. This ensures almost complete cutoff, which may not be easy to achieve in the circuit shown because

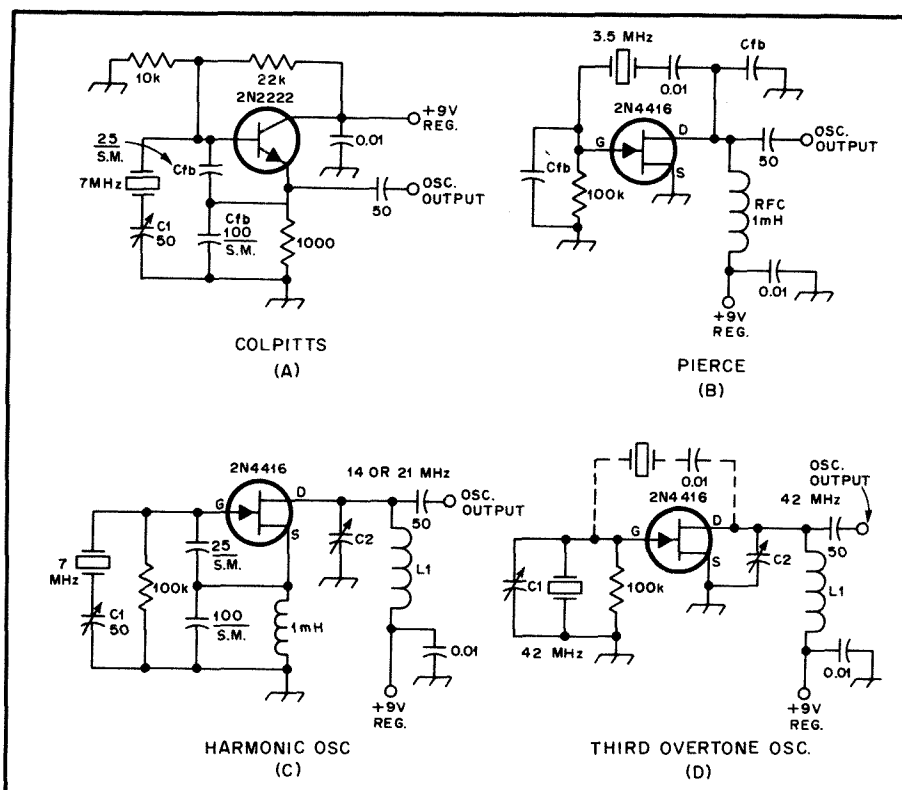

Fig 5—Practical examples of crystal-controlled oscillators that can be frequency trimmed.

Fig 6—Method for changing crystals by means of diode switching.

of the existing RF voltage on the diode anodes.

### VXO Circuits

Variable-frequency crystal oscillators (VXOs) are useful in place of conventional crystal oscillators when it is necessary to "rubber" the crystal frequency a few kilohertz. AT-cut crystals in HC-6/U type holders seem to provide the greatest frequency change when used in a VXO. To obtain maximum frequency shift it is vital to reduce stray circuit capacitance to the

smallest possible amount. This calls for low-capacitance switches, low minimum-capacitance variable capacitors, and the avoidance of crystal sockets. The crystals should be spaced well away from nearby metal surfaces and circuit components to further reduce capacitance effects. The higher the crystal fundamental frequency, the greater the available frequency swing. For example, a 3.5-MHz crystal might be moved a total of 3 kHz, whereas a 7-MHz crystal could be shifted 10 kHz. Although shifts as great as 50 kHz at 7 MHz may be possible, they should be avoided. Under those conditions, the high-stability traits of a crystal oscillator are lost.

Fig 7 contains a simple VXO circuit at A. By adjusting  $X_1$  the operator can shift the crystal frequency. The range will start at the frequency for which the crystal is cut and move lower. In both circuits, D1 is included to stabilize the FET bias and reduce the transistor junction capacitance during the peak of the positive RF-voltage swing. It acts as a clamp, thereby limiting the transistor  $g_m$  at peak-voltage periods. This lowers the junction capacitance and provides greater VXO swing. D1 also reduces harmonic output from the VXO by restricting the nonlinear change in transistor junction capacitance—a contributing factor to the generation of harmonic currents. Clamp diodes are used for the same purpose in conventional FET VFOs. The circuit of Fig 7A will provide a swing of approximately 5 kHz at 7 MHz.

An improved type of VXO is presented

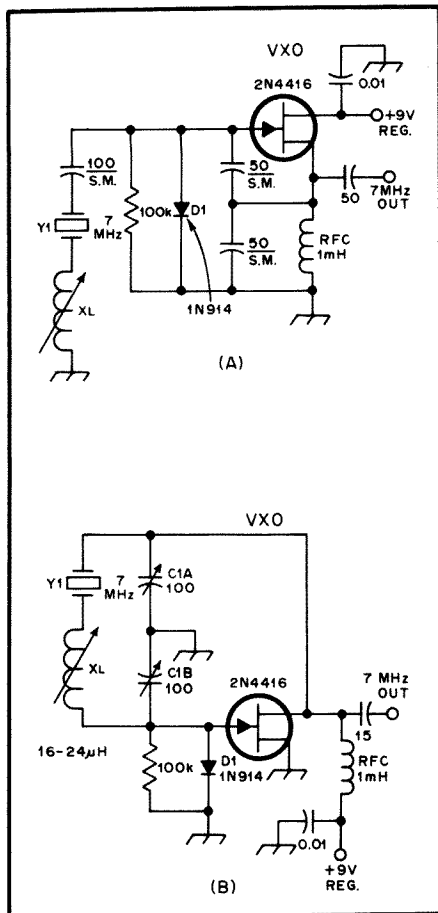

Fig 7—Circuits for two types of VXOs.

at B in Fig 7. Depending on the exact characteristics of the crystal used at Y1, swings as great as 15 kHz are possible at 7 MHz.  $X_L$  is set initially for a reactance value that will provide the maximum possible frequency shift when C1 is tuned through its range. The frequency shift should be only that which corresponds to true VXO control, even though greater range can be had after the circuit ceases to be a highly stable one.  $X_L$  is not adjusted again. A buffer stage should be used after either of the VXO circuits to prevent frequency pulling during load changes.

VXOs of this general type are useful in portable transmitters and receivers when full band coverage is sacrificed in exchange for stability and simplicity. Output from VXOs can be multiplied several times to provide LO energy for VHF and UHF receivers and transmitters. When that is done it is possible to realize 100 kHz or more of frequency change at 144 MHz.

#### VFO Circuits

Variable-frequency oscillators are similar to VXOs. The essential difference is that greater frequency coverage is possible, and no crystals are used. The practical upper frequency limits for good CW or SSB stability is between 7 and 10 MHz. For operation at higher frequencies, it is better

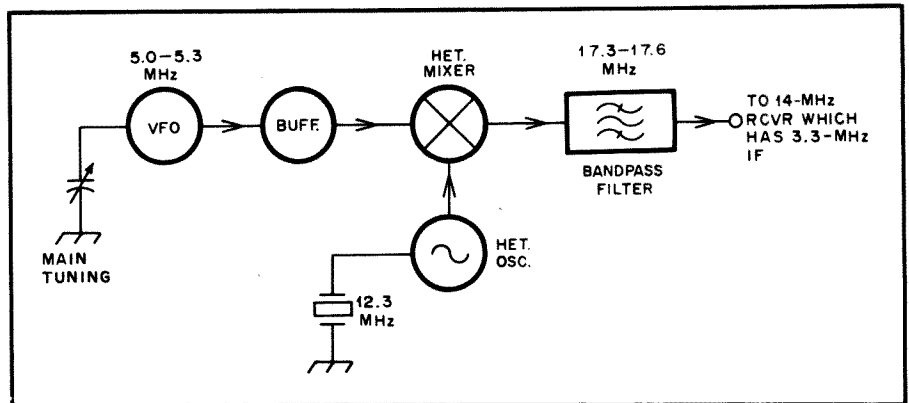

Fig 8—Technique for heterodyne frequency generation in a receiver.

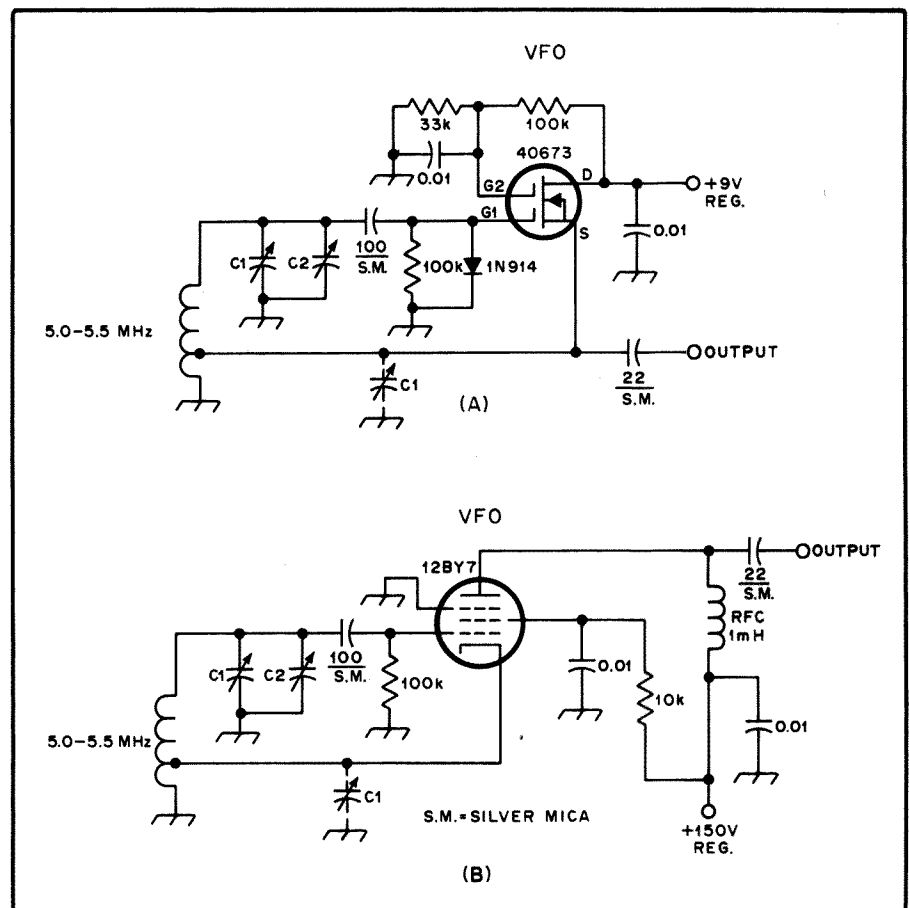

Fig 9—Examples of Hartley VFOs. A MOSFET version is shown at A; a vacuum-tube type at B.

to employ a heterodyne-type VFO. This calls for a VFO operating at, say, 5 MHz. The VFO output is heterodyned in a mixer with energy from a crystal-controlled oscillator. This provides a resultant or difference frequency at the desired LO-chain output frequency. A block diagram is given at Fig 8 to illustrate the concept as it might appear in a receiver. The same scheme could be used in a transmitter. The heterodyne oscillator has a crystal for each amateur band accommodated by the receiver. The crystals and appropriate

band-pass filters are switched by a panel-mounted control. The band-pass filter (Fig 8) is desirable to prevent 5- and 12.3-MHz energy from reaching the receiver mixer. A doubly balanced mixer is recommended if minimum unwanted energy is desired at the mixer output.

Some typical VFOs are shown in Figs. 9 and 10. A vacuum-tube Hartley is compared to a similar one that utilizes a dual-gate MOSFET in Fig 9. The capacitor shown in dashed lines (C1) can be used in that part of the circuit rather than at the

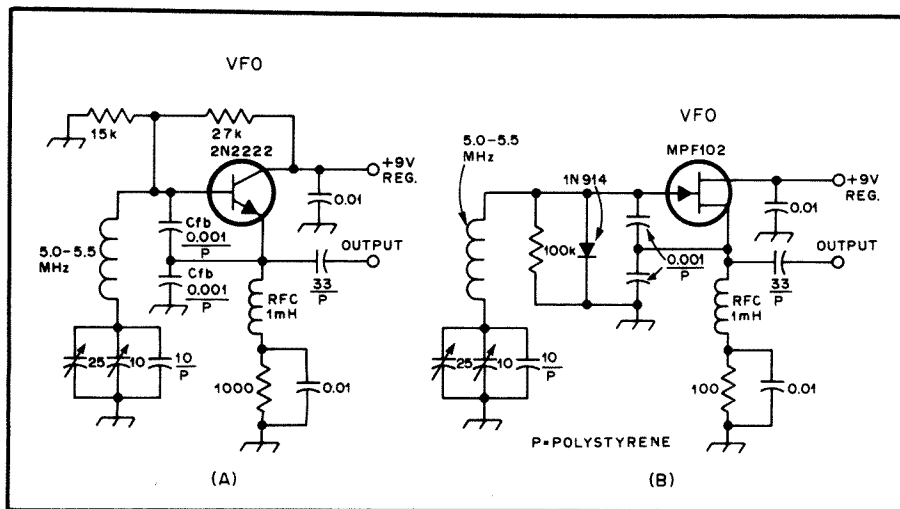

Fig 10—Colpitts VFOs. A bipolar transistor type is seen at A, while an FET version is given at B.

low end of the tank coil if greater band-spread is desired. C1 is the main-tuning capacitor and C2 is the padder for calibrating the oscillator. The coil tap is approximately 25 percent of the total number of turns for proper feedback.

A comparison is drawn in Fig 10 between a bipolar transistor and JFET version of a series-tuned Colpitts oscillator (sometimes called a "series-tuned Clapp"). These VFO circuits can be scaled to other operating frequencies by using the values shown to determine the reactances of the capacitors. This information will enable the designer to select approximate values in picofarads for other frequencies.

#### Fundamental Stability Considerations

There are some specific measures that must be taken when designing a VFO. The form on which the VFO coil is wound is of special significance with regard to stability. Ideally, the use of metallic core material should be avoided. Therefore, powdered iron, brass, copper and ferrite slugs, or toroid cores for that matter, are not recommended when high stability is required. The reason is that the properties of such core materials are affected by changes in temperature and can cause a dramatic shift in the value of inductance that might not occur if an air-core coil was used. Furthermore, some styles of slug-tuned inductors are subject to mechanical instability in the presence of vibration. This can cause severe frequency jumping and a need for frequent recalibration of the VFO readout.

Regardless of the format selected for the VFO coil, the finished product should be coated with two or three applications of polystyrene cement (Q dope) or similar low-loss dopant. This will keep the coil turns secured in a permanent position—an aid to mechanical stability.

The VFO coil should be mounted well away from nearby conducting objects (cabinet walls, shield cans, and so on) to prevent frequency shifts which are likely to occur if the chassis or cabinet are stressed during routine handling or mobile operation. Movement of the chassis, cabinet walls and other nearby conductive objects can (if the coil is close by) change the coil inductance. Furthermore, the proximity effects of the conductive objects present an undefined value of capacitance between the coil and these objects. Changes in spacing will alter that capacitance, causing frequency shifts of an abrupt nature.

It follows that all forms of mechanical stability are of paramount importance if the VFO is to be of "solid" design. Thus, the trimmer or padder capacitors used in the circuit should be capable of remaining at their preset values despite temperature changes and vibration. For this reason it is not wise to use ceramic or mica trimmers. Air-dielectric variable capacitors of the PC-board-mount subminiature type are recommended.

The main tuning element (capacitor or permeability tuner) needs to have substantial rigidity; it should be mounted in a secure manner. Variable capacitors used as main-tuning elements should be of the double-bearing variety. They should rotate easily (minimum torque) to minimize mechanical stress of the VFO assembly when they are adjusted. Variable capacitors with plated brass plates are preferred over those with aluminum plates. Compared with brass, aluminum is more subject to physical changes in the presence of temperature variations. The VFO tuning-capacitor rotor must be grounded at both ends as a preventive measure against instability. Some designers have found that a 1/8- to 1/4-inch-thick piece of aluminum or steel plate serves as an excellent base for the

VFO assembly. It greatly reduces instability that can be caused by stress on the main chassis of the equipment. The VFO module can be installed on shock mounts to enhance stability during mobile operation.

#### Electrical Stability

Apart from the mechanical considerations just discussed, the relative quality of the components used in a VFO circuit is of great importance. Fig 11 contains three illustrations of basic solid-state tunable oscillators suggested for amateur applications. The numbered components have a direct bearing on the short- and long-term stability of the VFO. That is, the type of component used at each specified circuit point must be selected with stability foremost in mind. The fixed-value capacitors, except for the drain bypass, should be temperature-stable types. NP0 ceramic capacitors are recommended for frequencies up to approximately 10 MHz. A second choice is the silver-mica capacitor (dipped or plain versions). Silver micas tend to have some unusual drift characteristics when subjected to changes in ambient temperature. Some increase in value while others decrease. Still others are relatively stable.

It is often necessary to experiment with several units of a given capacitance value in an effort to select a group of capacitors that are suitably temperature stable. The same is not true of polystyrene capacitors. When they are used with the commonly available slug-tuned coils, the temperature characteristics of the polystyrene capacitors and those of the inductor tend to cancel each other. This results in excellent frequency stability. If toroidal cores are used, they should be made of SF-type powdered iron material (Amidon mix 6). This material has a low temperature coefficient and when used with NP0-type ceramic capacitors produces very low drift oscillators. Ordinary disc-ceramic capacitors are unsuitable for use in stable VFOs. Those with specified temperature characteristics (N750 and similar) are useful, however, in compensating for drift.

The circuit of Fig 11A is capable of very stable operation if polystyrene capacitors are used at C3 through C8. A test model for 1.8 to 2.0 MHz exhibited only 1 Hz of drift from a cold start to a period some two hours later. Ambient temperature was 25° C. Q1 can be any high- $g_m$  JFET for use at VHF or UHF. Capacitors C1 through C4 are used in parallel as means of distributing the RF current among them.

A single fixed-value capacitor in that part of the circuit would tend to change value because of the RF heating within it. Therefore, a distinct advantage exists when several capacitors can be used in parallel at such points in a VFO circuit. The same concept is generally true of C5, C6 and C7. In the interest of stability, C5 should be the smallest value that will permit reliable oscillation. Feedback capacitors C6 and C7

are typically the same value and have an  $X_C$  of roughly  $60\ \Omega$ . Therefore, a suitable value for a 1.9-MHz VFO would be 1500 pF.

C8 of Fig 11A should be the smallest capacitance value practical with respect to ample oscillator drive to the succeeding stage. The smaller the value of C8, the less the chance for oscillator pulling during load changes. D1 is a gate-clamping diode for controlling the bias of the FET. Basically, it limits the positive swing of the sine wave. This action restricts the change in Q1 junction capacitance to minimize harmonic generation and changes in the amount of C associated with L1.

The reactance of RFC can be on the order of 10 k $\Omega$ . The drain bypass, C9, should have a maximum  $X_C$  of 10 ohms to ensure effective bypassing at the operating frequency. Ideally, an  $X_C$  of 1 ohm would be used (0.1  $\mu$ F at 1.5 MHz). D2 is used to provide 9.1 volts, regulated, at the drain of Q1. Lower operating voltages aid stability through reduced RF-current heating, but at the expense of reduced oscillator output.

A Hartley oscillator is shown in Fig 11B. This circuit offers good stability also, and is one of the better circuits to use when the tank is parallel tuned. The tap on L1 is usually between 10 and 25 percent of the total coil turns, tapped above the grounded end. This ensures adequate feedback for reliable oscillation. The higher the FET  $g_m$ , the lower the feedback needed. Only that amount of feedback necessary to provide oscillation should be used: Excessive feedback will cause instability and prohibitive RF heating of the components. Most of the rules for the circuit of Fig 11A apply to the oscillator in Fig 11B.

Parallel tuning of the kind used in Fig 11B and C are suitable for use below 6 MHz, although the circuit at B can be used successfully into the VHF region. However, the Colpitts oscillators of A and C in Fig 11 have large amounts of shunt capacitance caused by C6 and C7 of A, and C5 and C6 of C. The smaller the coupling capacitor between L1 and the gate, the less pronounced is this effect. The net result is a relatively small value of inductance at L1, especially with respect to Fig 11C, which lowers the tank impedance and may prevent oscillation (high C-to-L ratio). The series-tuned circuit of Fig 11A solves the shunt-C problem nicely by requiring considerably greater inductance at L1 than would be acceptable in the circuit of Fig 11C. The circuit at A resembles the popular "Clapp" circuit of the early 1950s.

A suitable transistor for Q1 of Fig 11C is an RCA 40673. The Texas Instruments 3N211 is also ideal, as it has an extremely high  $g_m$ —approximately 30,000 microsiemens ( $\mu$ S). Dual-gate MOSFETs are suitable for the circuits of Fig 11A and B if biased as shown at C. Also, they can be used as single-gate FETs by simply connecting gates 1 and 2 together. No

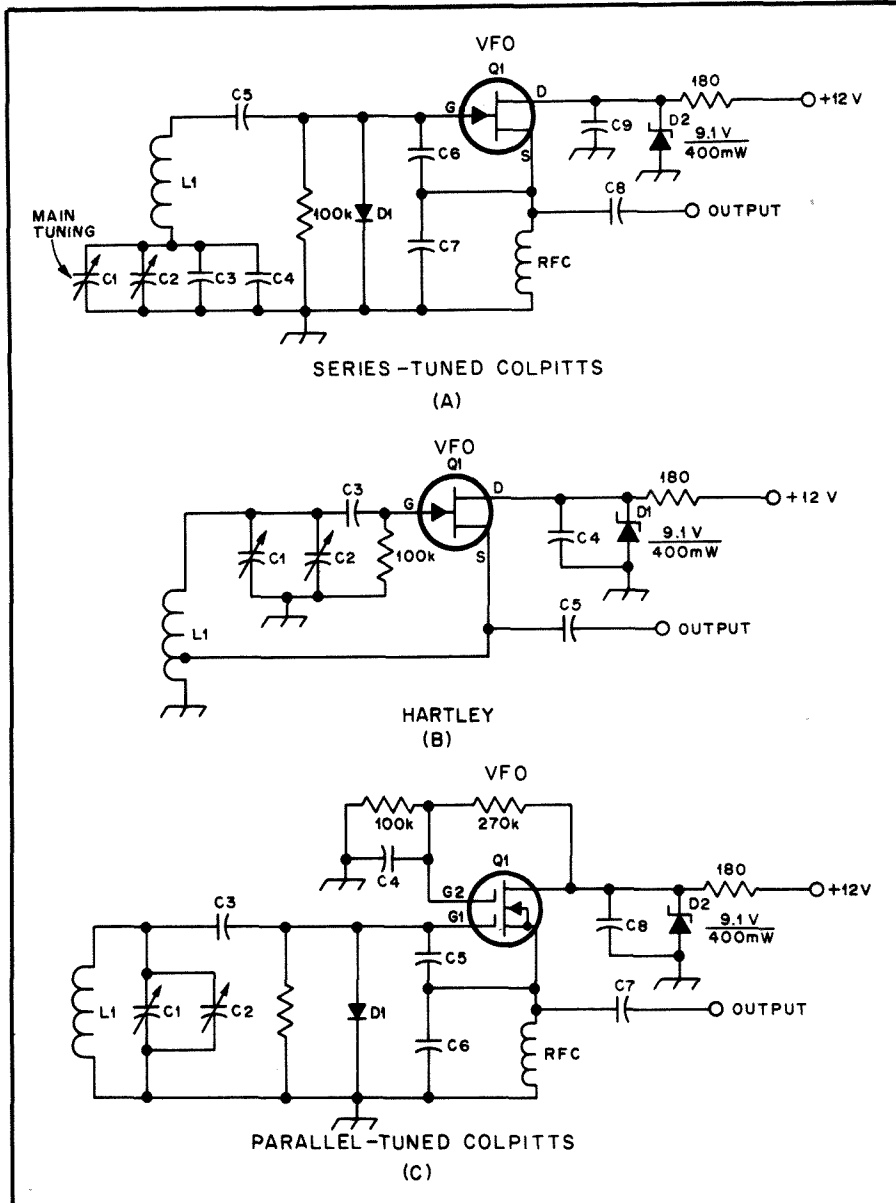

Fig 11—Three common types of VFOs for use in receivers and transmitters.

external bias is required if this is done. Gate 2 of Q1 (Fig 11C) should be bypassed with a low-reactance capacitor (C4), as is the rule for the drain bypassing of all three examples given in Fig 11.

Bipolar transistors are satisfactory for use in the three VFOs just discussed. The principal disadvantage of bipolars in these circuits is the low base impedance and higher device input capacitance. Most FETs exhibit an input C of approximately 5 pF, but many bipolar transistors have a substantially higher capacitance, which tends to complicate a VFO design for the higher operating frequencies. The UHF small-signal transistors, such as the 2N5179, are best suited to the circuits under discussion.

#### Load Isolation for VFOs

Load changes after the oscillator have a pronounced effect on the operating frequency. Therefore, it is imperative to provide some form of buffering (isolating stage

or stages) between the oscillator and the circuit to which it will be interfaced. The net effect of load changes, however minor, is a change in reactance which causes phase shifts. The latter affects the operating frequency to a considerable degree. Therefore, the more isolating stages which follow the oscillator (up to a practical number, of course), the less likelihood of load shifts being reflected back to the oscillator.

Buffer stages can perform double duty by affording a measure of RF amplification, as needed. But, care must be taken to avoid introducing narrow-band networks in the buffer/amplifier chain if considerable frequency range is planned, for example, 5.0 to 5.5 MHz. If suitable broadband characteristics are not inherent in the design, the oscillator-chain output will not be constant across the desired tuning range. This could seriously affect the conversion gain and dynamic range of a receiver mixer, or lower the output of a

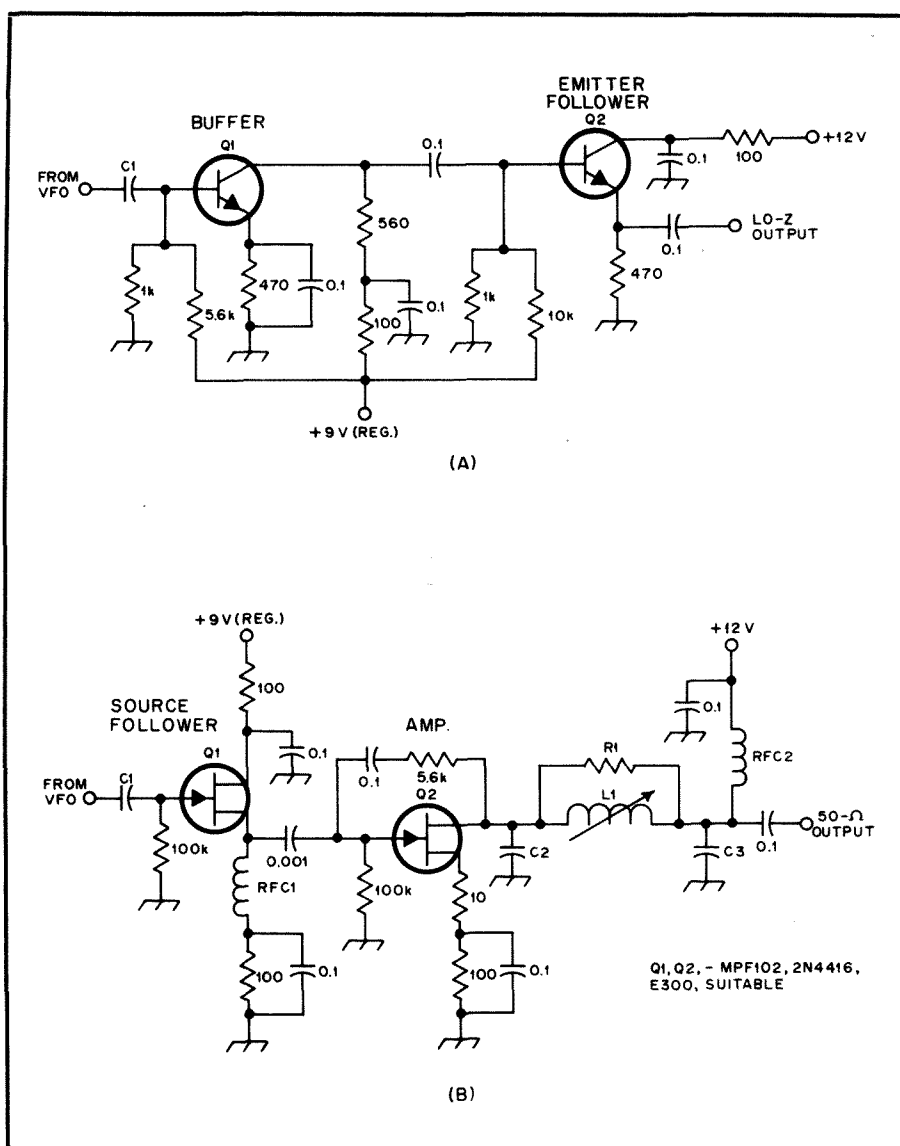

Fig 12A illustrates a typical RC coupled VFO buffer with broadband response. C1 is selected for minimum coupling to the oscillator, consistent with adequate drive to Q1. Q1 and Q2 should have high  $f_T$  and medium beta to ensure a slight RF-voltage gain. Devices such as the 2N2222A and 2N5179 are suggested.

A better circuit is offered in Fig 12B. Q1 is a JFET that has a high input impedance (1 M $\Omega$  or greater) by virtue of the FET-device characteristic. This minimizes loading of the oscillator. RFC1 is chosen to resonate broadly with the stray circuit capacitance (roughly 10 pF) at the mid-range frequency of the LO chain. Although this does not introduce significant selectivity, it does provide a rising characteristic in the RF-voltage level at the source of Q1.

Q2 functions as a fed-back amplifier with shunt feedback and source degeneration. The feedback stabilizes the amplifier and makes it broadband. The drain tank is designed as a pi network with a loaded Q of 3. The transformation ratio is on the order of 20:1 (1000-ohm drain to 50-ohm load). R1 is placed across L1 to further broaden the network response. The 50-ohm output level is recommended in the interest of immunity to load changes: The higher the output impedance of a buffer chain the greater the chance for oscillator pulling with load changes. P-P output across C3 should be on the order of 3 volts when using the oscillator of Fig 11A.

Fig 13 illustrates a composite VFO that

**Fig 12—VFO buffer and buffer/amplifier sections, which provide isolation between the oscillator and the VFO-chain load. The circuit at B is recommended for most applications.**

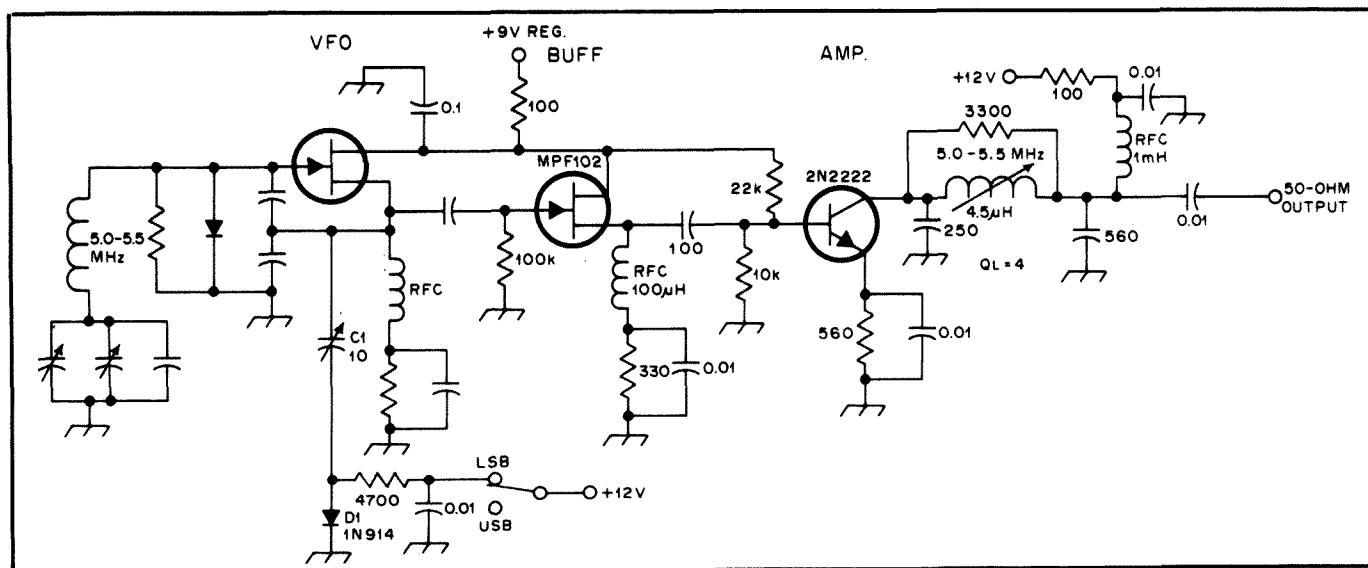

Fig 13—Suggested circuit for a stable series-tuned Colpitts VFO. Buffering follows the oscillator to increase the output level and provide load isolation.

has a buffer stage followed by an amplifier. D1 can be included to provide the necessary frequency offset when switching the receiver from upper to lower sideband. This is necessary to eliminate the need to re-adjust the calibration dial when changing sidebands. C1 is adjusted for the desired offset amount. The pi-network output from the amplifier stage is designed to transform 500 ohms to 50 ohms. The low-impedance output is desirable in the interest of minimum frequency pulling from load changes. A 3300 ohm swamping resistor is used across the pi-network inductor to broadband the tuned circuit and to prevent any tendency toward instability when a high-impedance load is attached to the circuit. Long-term drift measurements with this type of circuit at the frequency specified indicated a maximum shift of 60 Hz over a three-hour period. Output was measured at approximately 1 volt RMS across 50 ohms.

### Other VFO Criteria

Apart from the stability considerations just treated, purity of emissions from VFOs

is vital to most designers. It is prudent to minimize the harmonic output of a VFO chain and to ensure that VHF parasitic energy is not being generated within the LO system.

The pi-network output circuit of Fig 12B helps reduce harmonics because it is a low-pass network. Additional filtering can be added at the VFO-chain output by inserting a half-wave filter with a loaded Q of 1 ( $X_L$  and  $X_C = 50$  for a 50- $\Omega$  line).

VHF parasitics are not uncommon in the oscillator or its buffer stages, especially when high  $f_T$  transistors are employed. The best preventive measures are keeping the signal leads as short as possible and adding parasitic suppressors as required. The parasitic energy can be seen as a superimposed sine wave riding on the VFO output waveform when a high-frequency scope is used.

A low-value resistor (10 to 22 ohms) can be placed directly at the gate or base of the oscillator transistor to stop parasitic oscillations. Alternatively, one or two ferrite beads (950  $\mu_i$ ) can be slipped over the gate or base lead to resolve the problem. If VHF oscillations occur in the buffer stages, the

same preventive measures can be taken.

VFO noise should be minimized as much as possible. A high-Q oscillator tank will normally limit the noise bandwidth adequately. Resistances placed in the signal path will often cause circuit noise. Therefore, it is best to avoid the temptation to control the RF excitation to a given LO stage by inserting a series resistor. The better method is to use small-value coupling capacitors.

A Hartley VFO circuit is shown in Fig 14. Operating frequency range with the components shown is 5.0 to 5.5 MHz, but the circuit will function well from 2.5 to 10 MHz. The design guidelines offered in the previous section will be useful for altering the circuit for other frequency ranges. More information about this VFO circuit can be found in the High-Performance Communications Receiver project in Chapter 30, and another practical VFO circuit is shown in the Band-Imaging Receiver project in Chapter 30. Other VFO circuits and design information appear in the ARRL publication *Solid-State Design for the Radio Amateur*.

# Radio Frequency Synthesizers

Frequency synthesis has become a feature in almost every type of amateur equipment. The first amateur application was in 2-meter FM transceivers. The frequency accuracy and stability required by repeaters rules out VFOs; they tend to fall short in stability and frequency display accuracy. When 2-meter FM activity became heavy, the cost of crystals to fully use a 2-meter transceiver became prohibitive, and synthesizers began appearing.

The frequency synthesizer can be viewed as a simple system or, as it is often called in the electrical engineering world, a "black box." This black box is designed to provide an output signal at some convenient level on some desired frequency. The desired output signal frequency is an input to the black box. That input may come from electrical logic signals or mechanical switches.

The range of frequencies available from a synthesizer could span from a few percent to several decades depending on the application. The smallest frequency change that can be accommodated by a frequency synthesizer is called the resolution. This can vary from a few hertz to several megahertz again depending on the application. Usually the resolution is a power of 10, that is 1, 10 or 100 Hz, etc.

Another basic characteristic of a synthesizer is the lock-up time. This is the amount of time from the instant that a new frequency is called for until the output has assumed that frequency. Lock-up time can vary from less than one cycle of the current output frequency to several seconds or even minutes for highly accurate synthesizers and frequency standards. This is a critical characteristic when it is necessary to change frequencies very quickly—such as when the same synthesizer is used to control both the receiver and the transmitter frequency. When changing from receive to transmit, the synthesizer must provide the proper output frequency quickly.

A synthesizer should produce a single output frequency without distortion or other spectral impurity. Harmonics and other far-removed signals are not usually a problem in most systems; they can be easily removed with a low-pass filter. Spectral components close to the desired signal are not easily removed by simple filtering.

One type of close-in spectral impurity is known as phase noise. This is residual random variation of the phase difference between the synthesizer output and a perfect sine wave of the same frequency. Phase noise tends to reduce the ability of a receiver to separate nearby signals in spite of a good IF filter because it tends to "spread" the local oscillator signal. This phenomenon is known as reciprocal mix-

(A)

(B)

Fig 15—Spectrum analyzer photographs of a VCO. The VCO is disconnected from the phase-locked loop at A. The reduction of noise sidebands provided by the loop is shown at B.

ing. A receiver that has good selectivity, sensitivity and dynamic range can be destroyed by a local oscillator with excessive phase noise. Likewise, a transmitted signal will appear "broad" if the frequency control system has excessive phase noise.

Phase noise is generated within the oscillators of the synthesizer. A crystal oscillator has little phase-noise. Synthesizers that use only crystal oscillators usually have excellent phase-noise characteristics. Some synthesizers use voltage-controlled oscillators (VCOs). VCOs have considerably higher amounts of phase noise. VCO phase noise can be reduced in a properly designed synthesizer. Fig 15 shows a spectrum analyzer display of a typical VCO before and after reduction of phase noise. Just how much phase noise can be tolerated depends on the type of operation intended. Narrow-band modes require better phase-noise characteristics than wider modes. Phase noise is measured as the power contained in a specific bandwidth at a frequency removed from the carrier. For example, synthesizer phase noise could be specified as  $-90$  dB from

the carrier in a 10-Hz bandwidth 1 kHz from the carrier. A more detailed discussion of phase noise appears later in this chapter.

Frequency accuracy can be an important requirement in some synthesizer applications. Accuracy and resolution should not be confused. Just because a synthesizer displays a lot of digits and has very narrow frequency resolution does not mean that the actual frequency is the one displayed to the last digit. Frequency inaccuracy is the difference between actual and displayed frequency.

An attribute of frequency synthesizers is stability. Generally, frequency synthesizers are in some fashion or another locked to the frequency of a crystal oscillator. In that case, the stability of the synthesizer is the stability of the crystal oscillator. There are some designs where more than one crystal oscillator or other non-crystal-controlled oscillators are used. In these cases, the stability of the synthesizer is a function of the oscillators involved.

Another important characteristic is the amount of signal radiated from the synthesizer. Most systems have numerous internal signals of various frequencies. It would be nearly impossible for all of these frequencies to never cause any harmful interference. Therefore, careful shielding is important in the design of any frequency synthesizer. Typically all programming, power and other control lines are well bypassed and shielded. The output of the synthesizer is usually band-pass filtered to eliminate the escape of any internal signals.

## DIRECT NUMERICAL SYNTHESIS

A common technique for producing sine waves from digital sources is to construct the sine wave from a series of samples, as shown in Fig 16. In this example, a sine wave is constructed from 16 samples. The wave is divided into 16 equally-spaced samples, resulting in an approximation of the actual sine wave. The raggedness of the sine wave reconstructed from the samples can be smoothed by low-pass filtering; the result is shown at C in Fig 16.

The output frequency of the digitally generated sine wave is the rate at which the samples are generated divided by the number of samples for a complete sine wave. For example, for the sine wave in Fig 16, 16 samples are generated per cycle at a 16 kHz rate. This means we are producing a 1-kHz sine wave.

An interesting twist on this method of sine wave generation is to supply only every second, third, fourth (or  $N$ th sample where  $N$  is any integer). This is done by making the next sample the current sample plus  $N$ . For example, for  $N$  equal to 4, if the first

Fig 16—A sine wave can be created digitally using discrete samples. If the sine wave shown at A is sampled at each point on the curve, the samples can be used to recreate the wave; this is shown at B. The roughness in the recreated wave can be smoothed out by low-pass filtering, resulting in the smooth curve shown at C.

sample is number zero, the next would be 4, then 8, then 12 and so on. When  $N$  is greater than one, fewer samples are used to produce a complete sine wave than the total number of samples available; the number of samples used per cycle is equal to the total number of available samples divided by  $N$ . The output frequency is still the rate at which samples are generated

divided by the number of samples per complete sine wave. To use the previous example, for  $N$  equal to 4, only four of the available 16 samples are used per cycle, but these samples are produced at one-fourth the 16 kHz sampling rate, again resulting in a 1-kHz sine wave.

The actual number of samples used to generate the sine wave is the total number of available samples divided by  $N$ . The actual output frequency is the rate at which the samples are generated divided by the number of samples used for each output cycle:

$$F_{\text{out}} = f_{\text{clock}} / P \times N$$

where  $P$  is the total number of samples available.

If  $f_{\text{clock}} / P$  is selected to be a convenient number, such as 1 Hz, the output frequency is directly proportional to  $N$  in steps of 1 Hz. The lower limit to the number of samples is two; the familiar Nyquist sampling limit states that the sample rate must be at least twice the maximum frequency to be sampled.

Fig 17 shows a block diagram of a direct numerical synthesizer. The values of the samples are stored in a read-only memory (ROM) which drives a D/A converter to create an analog output equal to the value of the sample. A latch holds the address of the ROM until the next sample is desired. The value of the following sample is determined by adding a fixed number to the current ROM address. This is done with an adder using the programmed input frequency under control of the clock.

The synthesized sine-wave output is not perfect; there are several factors that contribute to the distortion of the sine wave. First, the number of bits employed in the A/D converter will limit just how accurate the samples used for the sine function can be. This means that the samples can be close but not always precise. The fact that the sine wave is sampled at finite intervals will cause distortion in spite of the fact that most of the distortion can be removed with low-pass filtering.

Another type of distortion arises because the number of samples used to generate the

sine function does not have to be an integer. In the previous example 16 samples were used with an  $N$  of 4. This resulted in exactly 4 samples per output cycle. If  $N$  is 5, there will be 3.2 samples per output cycle. This means that the points on the sine wave where the sampling occurs are at different points on the following cycle. Using the example of  $N$  equal to 5, if the first sample is at 0 degrees, the second occurs at 75 degrees, then 150, 225 and 300 degrees. The first sample of the next output cycle will be at 15 degrees. This sort of thing will continue until the fifth cycle when the sampling is back to 0, 75, 150 and so on again. This produces some low-level sidebands that have complex relationships to the programmed frequency.

This method of frequency synthesis is used mostly for the generation of audio frequency signals and RF signals in the lower HF region. The method offers excellent resolution without high cost. Using high-quality components, the level of the complex sidebands can be kept low enough for many applications.

When this technique is used at HF and higher, very fast logic, ROMs and D/A converters are required. The sidebands become more difficult to control and the simplicity of the system is overshadowed by the relative cost of the components. Improved components are making the technique more attractive, however.

### Indirect Synthesis: Phase-Locked Loop

The two synthesizers described earlier are examples of "direct" synthesis. Their output frequency is derived directly from one or more oscillators. Another method of frequency synthesis, perhaps the most widely used method, is called the "indirect" method. This method uses the phase-locked loop (PLL). The description "indirect" refers to the fact that the output frequency is generated by stabilizing a voltage-controlled oscillator (VCO).

A simple phase-locked loop synthesizer block diagram is shown in Fig 18. Five elements make up the simple loop; a VCO, a programmable divider, a phase detector, a loop filter and a reference frequency source.

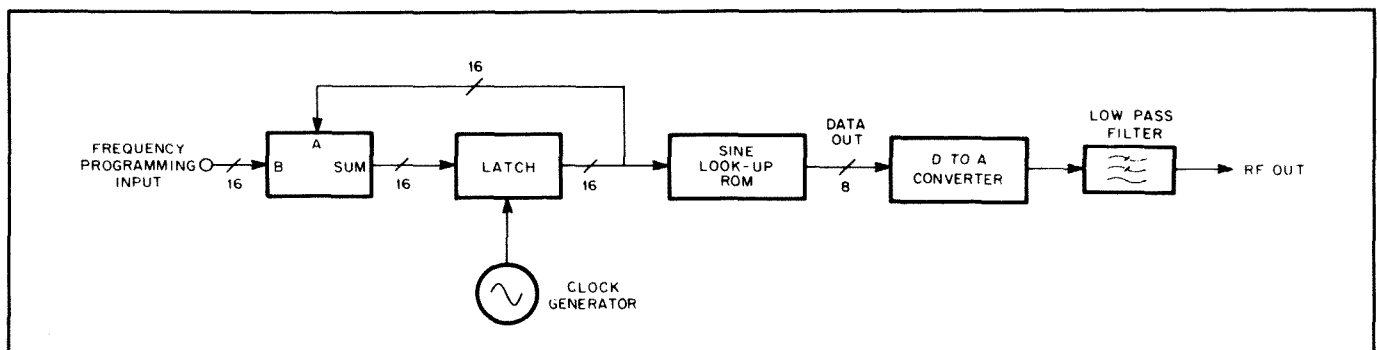

Fig 17—A block diagram of a direct numerical synthesizer. See text for details.

The purpose of the PLL synthesizer is to take a signal from a VCO, divide the frequency by an integer, and compare that result to a precise and stable reference frequency in a phase detector. The phase detector produces an electrical output that indicates positive or negative phase difference. The phase detector output is fed back to the VCO through a filter. The loop works to adjust the output of the phase detector to zero automatically. That means the output of the programmable divider is precisely on the same frequency as the reference. This can be described mathematically as:

$$F = NFr$$

where  $F$  is the output frequency,  $N$  is the value of the programmable divider, which is always an integer, and  $Fr$  is the reference frequency.

Depending on the reference frequency, phase comparison can take place at great speed. Frequency corrections can be made at such a rate that small and rapid deviations in frequency such as phase noise can be corrected. A control voltage correction can only be made once every cycle of the reference frequency. Therefore, the correction at the output of the phase detector is not a continuous function but rather a sampled function. The sample frequency is equal to the reference frequency. This signal is filtered to remove some of the energy at the reference frequency. Not all of the reference frequency energy can be removed; what remains is applied to the VCO control voltage. Any variation of the control voltage frequency modulates the VCO. This modulation causes sidebands to be generated. These sidebands appear not only at frequencies removed from the carrier by the reference frequency, but also at harmonics of the reference frequency. The amount of reference energy that is applied to the VCO is a function of the loop filter and the phase detector.

The loop filter has an effect not only on the reference sidebands of the PLL synthesizer, but also on the time and nature of the lock up. Fig 19 shows the three basic paths for PLL frequency change. In the first path the loop changes from the original to the new frequency directly without overshoot and in minimum time. This is called critically damped and is the usual path chosen in synthesizer design, especially if the frequency must change between transmit and receive. Curve B in Fig 19 shows the frequency rapidly changing to the desired frequency, overshooting the mark and continuing to oscillate around the desired frequency before becoming stable. This characteristic is called underdamped.

It may appear that this transient characteristic has no value in the design of synthesizers. A certain amount of underdamping can make the loop filter design easier for realizing low sideband levels in the system; this approach may be used

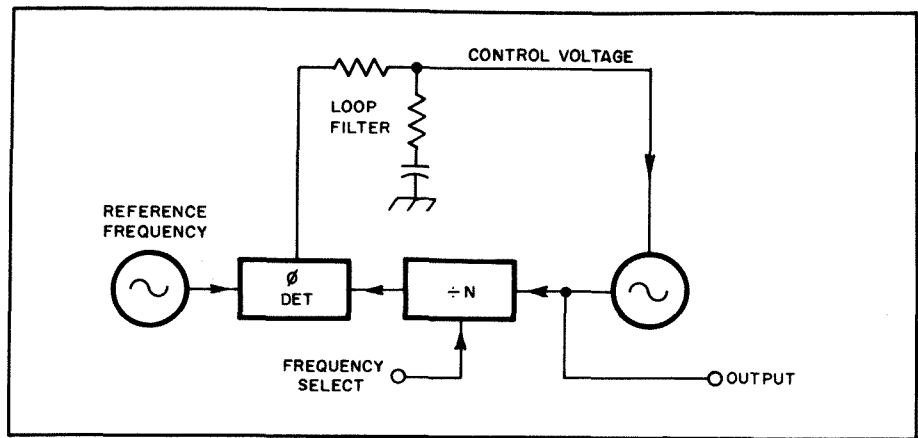

Fig 18—A simple single-loop PLL synthesizer.

Fig 19—Three transient frequency-change characteristics: critically damped at A, underdamped at B, overdamped at C.

Fig 20—Exclusive-OR type phase detector.

when the synthesizer is not required to change frequency rapidly. Curve C in Fig 19 shows the overdamped case. In this case the frequency changes from the old frequency to the new frequency without overshoot, but the time required is considerably longer than in the critically damped case.

Several varieties of phase detectors are suitable for use in PLL systems. One very simple type of phase detector is the exclusive-OR circuit shown in Fig 20. The signals presented to the exclusive-OR phase detector must have exactly 50 percent duty cycle—a condition not difficult to generate when using IC dividers.

Fig 21 shows the input and output waveforms found in the exclusive-OR phase detector. When the phase angle between the two inputs is 90 degrees (Fig 21B), the average value of the output is 50 percent. When the phase angle is less, the average value of the output changes depending on which input is leading. Furthermore, the output is a pulse train with a frequency equal to twice the input frequency. It is important when using the simple exclusive-OR phase detector that the loop filter have sufficient rejection of the phase detector output frequency.

The exclusive-OR phase detector has one serious drawback that limits its use in certain types of frequency synthesizers: If

there is any harmonic relationship between the two inputs to the phase detector, the output will allow the loop to lock up on an incorrect output frequency. This can be used to advantage for PLL systems where harmonics are desired. In a PLL where only one frequency is desired, however, this possibility must be eliminated. There would be no problem if the frequency range of the VCO were limited to a ratio of less than 2 to 1. This limitation would preclude the VCO from ever locking on a harmonic because the VCO cannot generate the fundamental and the harmonic of any frequency.

A phase detector specifically designed for phase-locked loops is shown in Fig 22. This phase detector is not susceptible to harmonically related inputs; for that reason it is more accurately called a phase/frequency detector. The phase/frequency detector also has a three-state output. If the phase or frequency difference is such that a positive output is required, the upper (P-channel) FET conducts supplying a current path from  $V_{DD}$  to the output. If the input phase relationship is such that a negative output is required, the lower (N-channel) FET conducts and provides a current path from the output to  $V_{SS}$ . If the phase angle is very close neither FET conducts and the output floats. Because the output has the capability of two "on"

Fig 21—Waveforms associated with an exclusive-OR phase detector. Variable and reference are in phase at A. Variable leads reference by 90° at B. At C, variable and reference are 180° out of phase.

states as well as an "off" state, the amount of reference ripple in the output is much lower than with the exclusive-OR phase detector. The only significant disadvantage of this phase detector is the definition of where the phase angle between the two inputs is small enough for both output transistors to be off. In operation the loop will "bounce" between the two on states and cause a low frequency noise that can be objectionable. The usual solution to this problem is to inject a small amount of current at the phase detector to force the phase detector out of this "dead zone."

### Programmable Dividers

Programmable dividers are generally constructed from IC counters. The counter can be binary or decade depending on the source of programming information. Binary counters are suited to microprocessor programming where there is a binary output. For simple systems, where information is accepted from mechanical switches, binary-coded-decimal programming (BCD) is required. Therefore, both binary and BCD programmable dividers are used in synthesizer systems.

Fig 23 shows a programmable divider using ripple BCD counters as the dividers.

Fig 22—A phase/frequency detector specifically designed for phase-locked loop synthesizers.

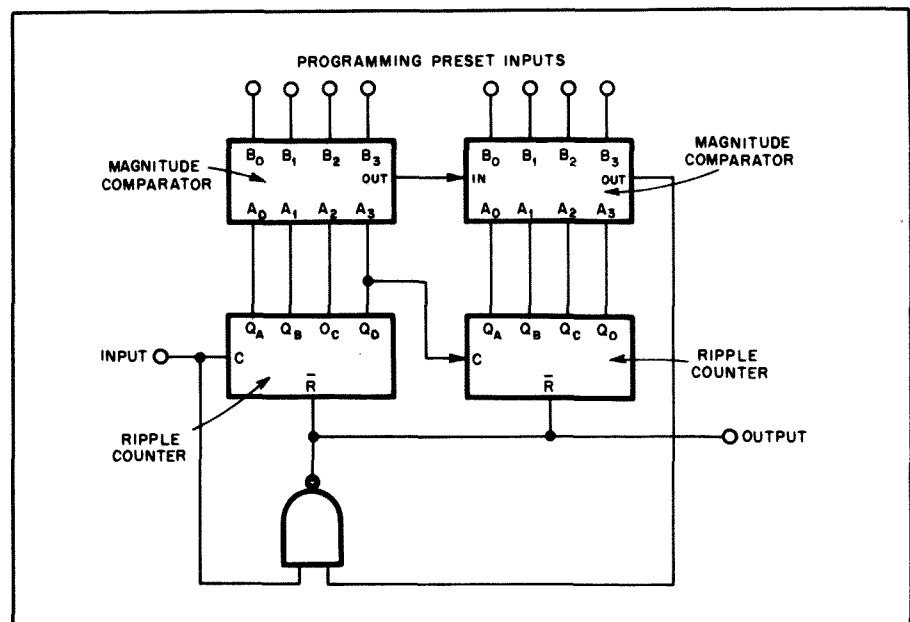

Fig 23—A programmable divider based on a ripple counter.

A magnitude comparator accepts information from the programming switches and compares this input to the state of the counter. When the counter reaches the selected state, the "equals" output of the magnitude comparator provides a reset pulse to the counter. This type of programmable divider is frequency limited to only a few megahertz.

A higher frequency alternative is to use a synchronous counter with internal zero detect as shown in Fig 24. This programmable divider is preset to a number and then counts down to a value of one and then is preset to the same number. Normally, IC counters are provided with internal zero detection for the purpose of cascading counters. For use as a programmable divider, however, the detection of

the count of one is required. This can be done simply by detecting the zero state for all of the cascaded counters except the least significant digit that detects the count of one.

The advantage of this type of programmable divider is a significant increase in operating speed. First, the propagation delay within the counter is much less than that of a ripple counter. Second, only one state of the counter must be decoded, a value of one, and the magnitude decoder required for that task is simpler and therefore, faster than a full-function magnitude comparator. A typical TTL programmable divider using synchronous down-counters can operate reliably at 15 MHz.

There are special programmable dividers using CMOS technology with special look-

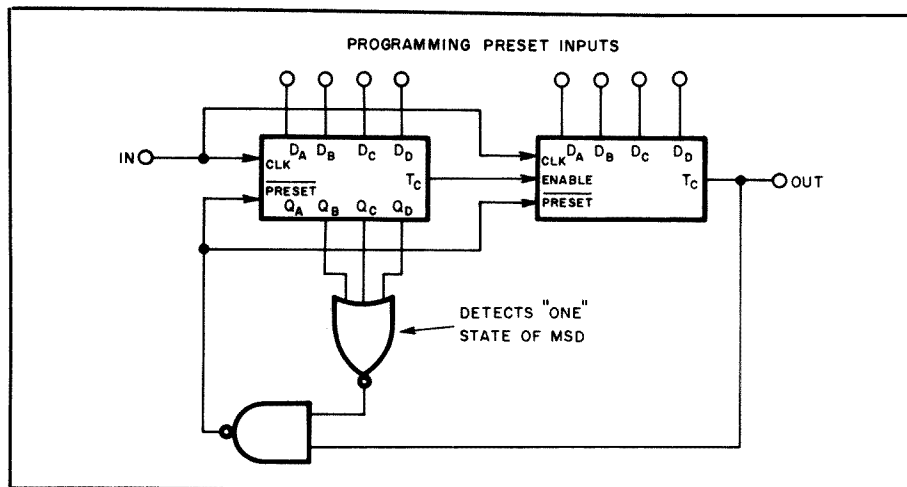

Fig 24—A programmable divider based on a synchronous down counter.

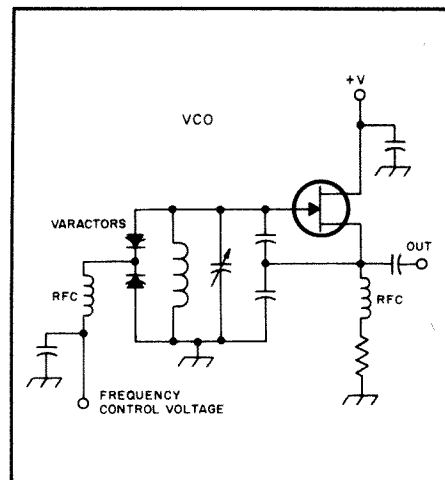

Fig 25—A Colpitts oscillator with varactor tuning suitable for use as a VCO.

ahead decoding that can further increase the speed to a point where CMOS logic speed can approach that of TTL. These specialized circuits are typically used in synthesizer LSI chips.

### Voltage-Controlled Oscillators

The VCO used for a PLL can be practically any one of the standard oscillator circuits with a varactor diode in the tuned circuit to allow voltage tuning. Fig 25 shows a Colpitts oscillator that has a varactor diode. The VCO must not only provide the output from the synthesizer, but also must provide drive for the programmable divider. Usually several buffer amplifier stages are used to isolate the VCO from the output of the synthesizer as well as the programmable divider. Changes in the VCO load can cause the generation of unwanted phase noise.

The noise level of a synthesizer will depend to a great extent on the design of the VCO. One method of reducing VCO phase noise is to use two varactor diodes back to back, as shown in Fig 25. This prevents the RF voltage at the VCO tuned circuit from being rectified in the varactor diode and changing the tuning voltage.

### SYNTHESIZERS FOR HIGH-FREQUENCY COMMUNICATIONS SYSTEMS

The synthesizer required for high frequency communications systems presents several design problems. First, the operating frequency span is large, from 3 to 30 MHz for general coverage. Also, the frequency resolution must be fine; and 100 Hz is considered the absolute maximum for SSB or CW operation and then only if a clarifier or receiver-incremental tuning (RIT) control is provided for SSB operation. For RTTY operation or SSB without the use of a clarifier control even better resolution is required, typically on the order of 25 Hz or less. Because 25-Hz steps are not easily displayed by the frequency dis-

play, some designs use 10-Hz resolution, which is sufficiently small to accommodate any type of operation. Narrow resolution and wide frequency coverage are two characteristics that are not complementary. That is, it would be easy to design a phase-locked loop with a narrow frequency range and narrow resolution. It is difficult to design a synthesizer that has a broad frequency range and narrow frequency resolution, while maintaining good noise performance and quick lock-up time.

Typical amateur HF operation involves continuous tuning for signals, as opposed to VHF FM where operation takes place on well-defined frequencies. Therefore, the time it takes the synthesizer to lock on the proper frequency is an important parameter and must be taken into account in the design of a high-frequency synthesizer. All of these requirements taken together dictate a system more complicated than a single-loop synthesizer.

The modern trend in receiver (and transceiver) design is up conversion, a scheme in which the first IF is higher than the highest received frequency. For coverage to 30 MHz, the minimum IF must be above 30 MHz. That places the local oscillator at 30.1 to 60 MHz for a 0.1- to 30-MHz input. In practice the first IF is 45 MHz, or higher, which dictates first local-oscillator coverage from 45 to 75 MHz—a span of less than an octave.

A ratio of two to one between the highest and the lowest frequency generated, or an octave, is about the maximum range that can be covered reliably by a single VCO. Greater frequency ratios are obtained by using several VCOs or band-switching the VCO with transistors or PIN diodes. It is especially important to minimize the VCO frequency range in the design of low-noise synthesizers. As previously mentioned, the exclusive-OR phase detector requires an input range of less than two to one. Essentially, a simple synthesizer cannot operate with a maximum to minimum frequency ratio of more than two to one.

For a frequency resolution of 50 Hz (the maximum acceptable for tuning SSB) a conventional, single-loop synthesizer requires a 50-Hz reference. The loop bandwidth must be considerably less than 50 Hz, in order to reduce the level of reference sidebands. Lock up time in this case would be too slow for manual tuning of amateur bands. Any frequency excursion of more than a few kilohertz would find the loop dragging behind the frequency display. To counteract this, multiple loop synthesizers are used. The output frequency of these synthesizers is a function of two phase-locked loops.

### Two-Loop Synthesizers

Fig 26 shows an example of a two-loop synthesizer for use with an up-converting receiver or transceiver with a 45-MHz first IF. In this example, a coarse-tune PLL provides an output at 50 to 80 MHz. This loop has a reference frequency of 100 kHz and a fast lock-up time. Because of the high reference frequency, this loop can provide a very clean output signal. The coarse-tune VCO output is mixed with the main VCO output. The output of the mixer is tuned to 5 MHz. For each frequency of the coarse-tune synthesizer, there are two possible frequencies of the main VCO that will provide a 5-MHz output; the sum and the difference.

To prevent the VCO from operating at the wrong frequency, a coarse-tune voltage is applied to the main VCO. This voltage sets the VCO to approximately the correct frequency. The mixer output is phase compared to the fine-tune PLL synthesizer output. The output of this phase detector is fed through a loop amplifier to the main VCO. Thus, the frequency difference between the coarse tune loop and the main VCO is precisely equal to the output frequency of the fine-tune loop.

To avoid the lock-up time problems, the fine-tune loop does not operate in the 5-MHz range, but at 50 times that

frequency, or 250 MHz. The required output frequency is 5.0000 MHz to 4.90005 MHz. This frequency variation is the reverse from the programming information; as the programming data is increased in value the frequency of the fine-tune VCO is decreased. This can be handled either by a microprocessor or with logic within the fine-tune synthesizer as shown in Fig 27.

Because the loop operates at 50 times the desired output frequency, the reference frequency is 50 times the desired frequency resolution—2500 Hz for 50-Hz resolution. It is not difficult to achieve a lock time of a few ms with a 2500-Hz reference. In addition, the noise and reference sidebands at 250 MHz are reduced 33 dB because of the frequency division.

Practically any division factor can be used for the fine-tune loop. For example, a standard ECL divide-by-40 chip could be used. The VCO would operate in the 200-MHz region; the reference would be 2000 Hz. Lock-up time would be slightly longer, but the programmable divider ratios would remain exactly the same as in the previous example.

General-coverage receivers and transceivers increase the need for frequency synthesis in HF equipment. A typical amateur-band-only transceiver of a few years ago used a crystal oscillator in conjunction with a conventional VFO. The VFO operated in the megahertz region and the crystal oscillator operated in the low-VHF region. This scheme provides reasonable noise and stability performance. When more than a few frequency bands are covered, however, the cost of the required crystals becomes prohibitive. For a general-coverage receiver with the range divided into 500-kHz bands, approximately 59 crystals are required; that is totally unacceptable.

### Partial Synthesis

One solution to the crystal problem is the partially synthesized transceiver (see Fig 28). Partially synthesized means that the operating frequency is set by both a synthesizer and a free-running VFO. This synthesizer consists of a single PLL. The 500-kHz reference frequency ensures that phase noise will be sufficiently low for SSB, RTTY and CW operation; the VFO ensures that the resolution is nearly infinite.

A VCO (actually three separate switchable oscillators) is the first local oscillator. It operates 48.05 MHz above the input frequency. The output of this VCO is mixed with a 45.05- to 45.55-MHz signal to produce a 3.0- to 33.0-MHz output. This output feeds the programmable divider. The 45.05- to 45.55-MHz signal is generated by mixing a 40-MHz oscillator with a 5.05- to 5.55-MHz VFO.

Output from the programmable divider feeds a phase detector, which also receives a 500-kHz reference frequency. The programmable divider works in a range

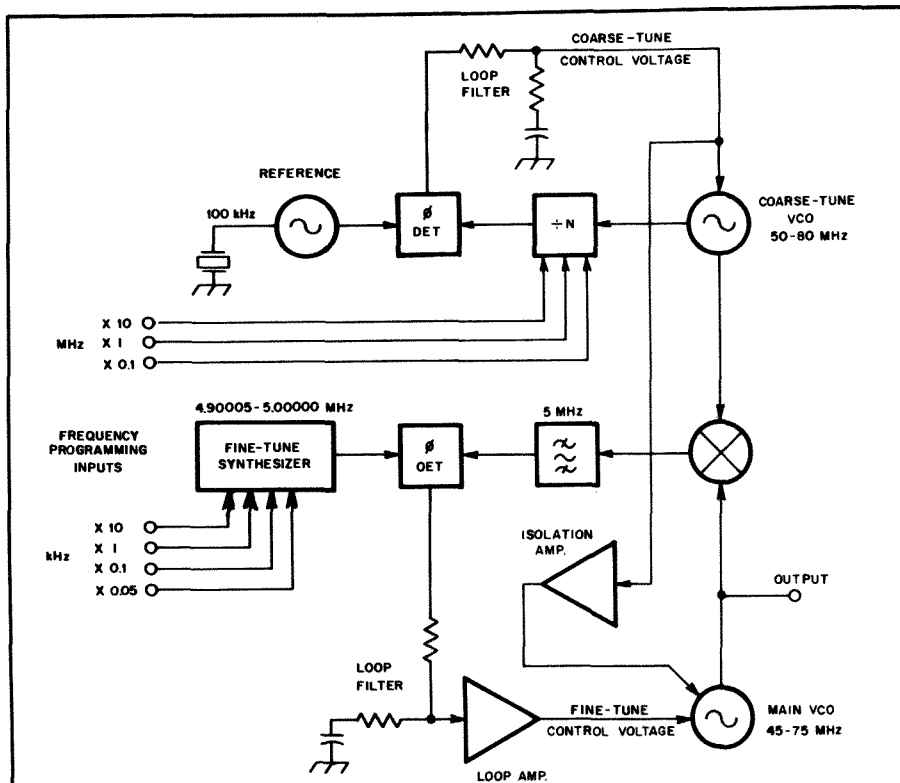

Fig 26—A two-loop synthesizer used in a high-frequency receiver or transceiver with a 45-MHz IF.

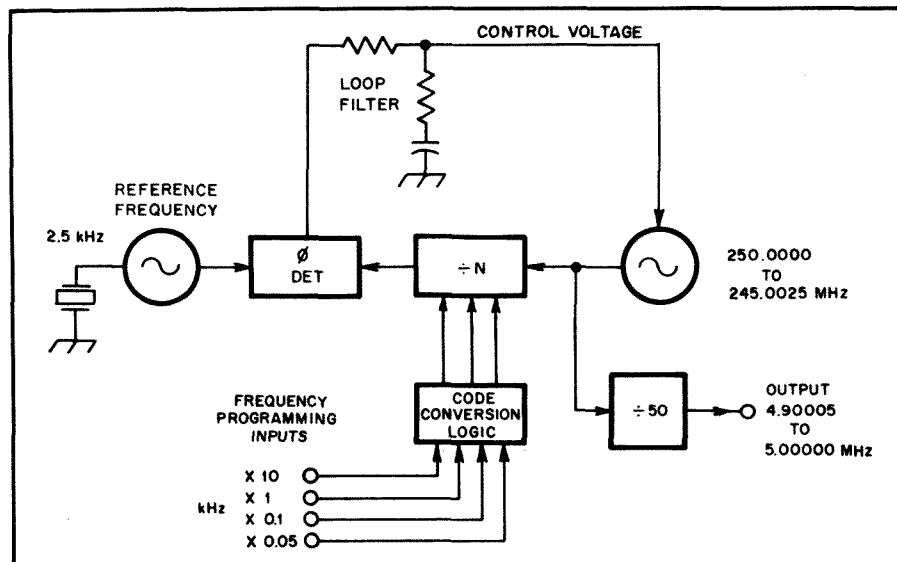

Fig 27—Logic circuit for use with the fine-tune synthesizer within the system shown in Fig 26.

from 6 to 65; that corresponds to frequency coverage from 0 to 29.5 MHz. The programmable divider sets the operating frequency of the transceiver in 500-kHz steps while the VFO adds from 0 to 500 kHz to the basic synthesizer frequency.

There are some significant disadvantages to this type of system. First, the frequency cannot be fully programmed externally. Because of the mechanically tuned VFO, only the 500-kHz bands can be programmed. Second, the frequency stability is not better than that of the VFO. Because the VFO is operating in the low MHz

region, however, the stability will be acceptable for all but the most demanding operation. Finally, the frequency readout is a combination of digital inputs to the synthesizer and the dial of a VFO. This can be improved by using a frequency counter to display the frequency electronically.

### VHF SYNTHESIZER APPLICATIONS

The requirements of a frequency synthesizer for VHF operation are generally less stringent than those for HF. Normally the synthesizer covers only one amateur band. That means a span that is a small

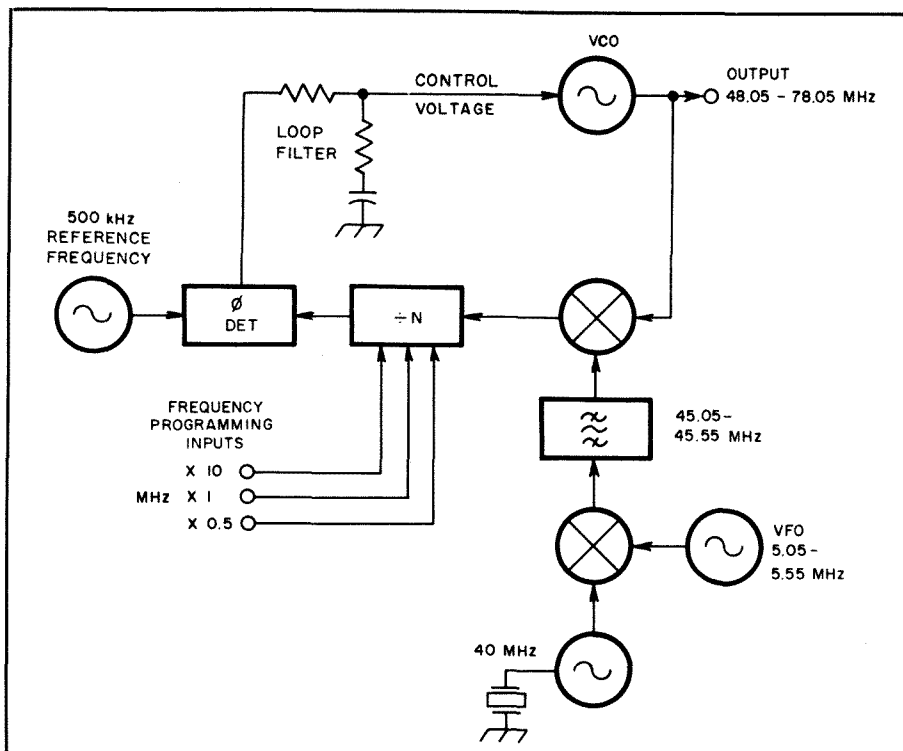

Fig 28—Frequency control for a partially synthesized transceiver for high-frequency operation.

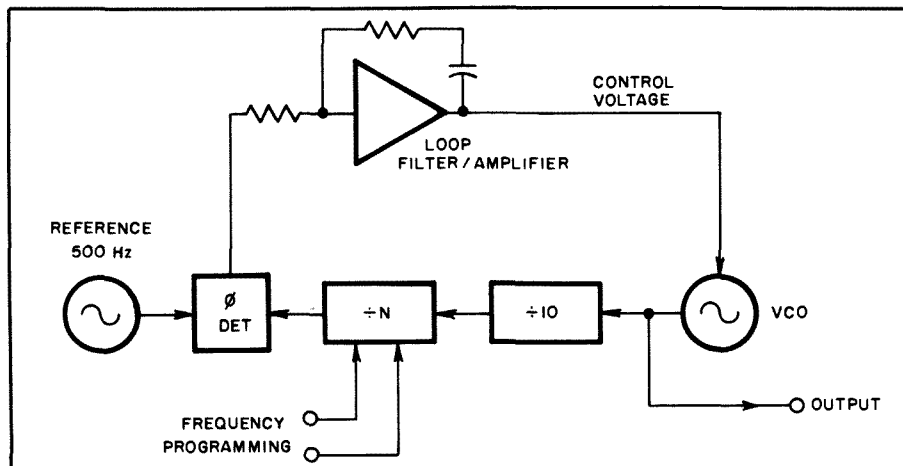

Fig 29—VHF synthesizer using a fixed-modulus prescaler.

percentage of the operating frequency. Resolution or channel separation is typically 5 or 10 kHz for FM operation and perhaps 100 Hz for SSB operation. A simple synthesizer would appear to suit the VHF transceiver. The problem is that conventional logic cannot operate at frequencies of 150 MHz. Even emitter-coupled logic (ECL) with propagation delays as short as a few nanoseconds cannot be used to construct programmable dividers to operate at 150 MHz.

One method of constructing a VHF PLL synthesizer is shown in Fig 29. In this example, the VCO output is divided by 10 in an ECL prescaler. ECL logic is fast enough to operate as a fixed divider at 150 MHz, but fails as a conventional programmable divider.

The major disadvantage of this syn-

thesizer design method is that the loop reference frequency must be reduced by the same factor as the fixed-modulus divider. As an example, if a synthesizer for a 2-meter transceiver were designed with 5-kHz channel resolution using a simple phase-locked loop, a 5-kHz reference frequency could be used. If a fixed-modulus prescaler with a division of 10 were placed between the VCO and the programmable divider, the reference frequency would have to be reduced to 500 Hz.

It is important that the highest reference frequency possible be used in a PLL synthesizer for best noise performance and lowest reference sidebands. In this example, the output of the prescaler can be used to drive relatively low-speed logic in the programmable divider. However, even 15 MHz requires fast logic in a program-

mable divider. Fixed-modulus prescaler divisions of more than 10 are typically required with some low-power logic families. This means a less than 500-Hz reference frequency in the 2-meter synthesizer example. That would greatly compromise the synthesizer performance.

### Dual-Modulus Programmable Dividers

One technique used in VHF synthesizers with conventional logic without reducing the reference to an unacceptable frequency is the dual-modulus programmable divider. The heart of the divider is the dual-modulus prescaler shown in Fig 30. This ECL chip can divide by two factors that differ by 1. The dual-modulus prescaler shown in Fig 30 can divide by either 10 or 11, depending on the state of the modulus control input. The 10/11 ratio has important applications in BCD-programmed synthesizers. They are available in a variety of frequency capabilities up to more than 500 MHz. Some standard ratios are: 5/6, 8/9, 15/16, 20/21, 32/33, 40/41 and 80/81. Other ratios can be created with one of these chips and some external logic.

The dual-modulus programmable divider consists of three parts: the main counter, the auxiliary counter and the dual-modulus prescaler (see Fig 31). Both the main and auxiliary counters are presettable; they are often down counters. At the beginning of the divider cycle both the main and auxiliary counters are preset to the respective programmed value. Both counters are clocked together from the output of the dual-modulus prescaler. If the auxiliary counter is preset to a value other than zero, the dual-modulus prescaler starts counting by the larger of its two divisors ( $N + 1$ ) at the beginning of the divider cycle. When the auxiliary counter reaches zero, the mode of the dual-modulus prescaler is changed to the smaller of the two divisors ( $N$ ). The main counter continues to count toward zero, while the auxiliary counter stops counting. When the main counter reaches zero both the main and auxiliary counters are preset, and the divider cycle starts anew.

The total number of VCO cycles required for a complete divider cycle can be calculated in the following manner. Assume the main counter is preset to the value,  $M$ , and the auxiliary counter is set to the value of  $A$ . Because the dual-modulus prescaler divides by  $N + 1$  until the auxiliary counter reaches zero,  $(N + 1)A$  VCO cycles are required to reach this point. The mode is then switched and the dual-modulus prescaler divides by  $N$  until the main counter reaches zero. The main counter requires  $(M - A)$  counts or  $N(M - A)$  VCO cycles to reach zero. The total cycles of the VCO required for the complete divider cycle is:

$$(N + 1)A + N(M - A) = NM + A$$

From the equation, it can be seen that  $M$  has more effect on the division value of the dual-modulus divider than  $A$ . In the

case of a 10/11 prescaler, the effect of  $M$  is 10 times that of  $A$ . That ratio is an important advantage of the 10/11 prescaler. In BCD-programmed synthesizers such as those programmed directly from switches, some of the switches can program the main counter while others are used to program the auxiliary counter.

There are some restrictions on the possible values of  $M$  and  $A$ . Because the auxiliary counter must reach zero before or concurrent with the main counter, the value of  $M$  must be equal to or greater than  $A$ . There is also a limit on the minimum division factor. That limit is equal to  $N(N-1)$ . For example, the minimum division factor for a dual-modulus divider using a 10/11 prescaler is 90. As a proof, try to determine what numbers must be set into the main and auxiliary counters to create a division of 89. It is not possible to find two numbers that will work and satisfy the requirement that  $M$  be equal to or greater than  $A$ . This minimum does not usually cause any problems in VHF synthesizers in which the minimum division factor is usually quite high.

### Integrated Circuits

One significant advancement in synthesizer design is the LSI chip made specifically for dual-modulus synthesizers. Chips such as the Motorola MC145156 and MC145152, when used with suitable prescalers, allow two-chip synthesizer designs to operate at more than 500 MHz. A block diagram of a Motorola chip is shown in Fig 32. This chip is unique; the frequency-programming information is entered into the chip serially to reduce the package size. This could be a disadvantage in some systems, but it can be handled easily by a microprocessor. The MC145152 is a parallel entry version of the MC145156; the '145152 is housed in a 24-pin package, while a 16-pin package serves for the '145156.

Another important advance in dual-modulus VHF synthesizer design came when low power ECL prescalers became available. Perhaps the most significant disadvantage of the divider was the cost and the power requirements of the dual-modulus prescaler. An early 150-MHz ECL dual-modulus prescaler required as much as 100 mA at 5 volts; the power requirement for a modern prescaler is as low as 7 mA. This makes the dual-modulus prescaler a possible contender for portable, battery-operated equipment.

### Frequency Modulation

FM is accomplished in a PLL by modulating the oscillator control voltage. The loop normally will tend to remove any frequency variation. To prevent removing all of the applied modulation, the response of the loop is restricted to frequencies below the voice-frequency band or approximately 300 Hz. Unfortunately, this prevents the loop from removing mechanically induced FM of the VCO known as

Fig 30—Block diagram of a dual-modulus prescaler suitable for VHF synthesizers.

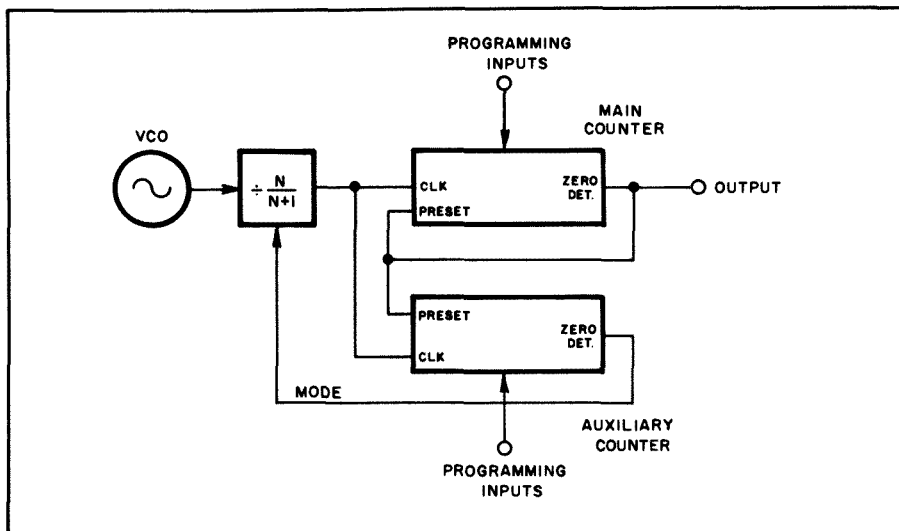

Fig 31—Block diagram of a dual-modulus divider.

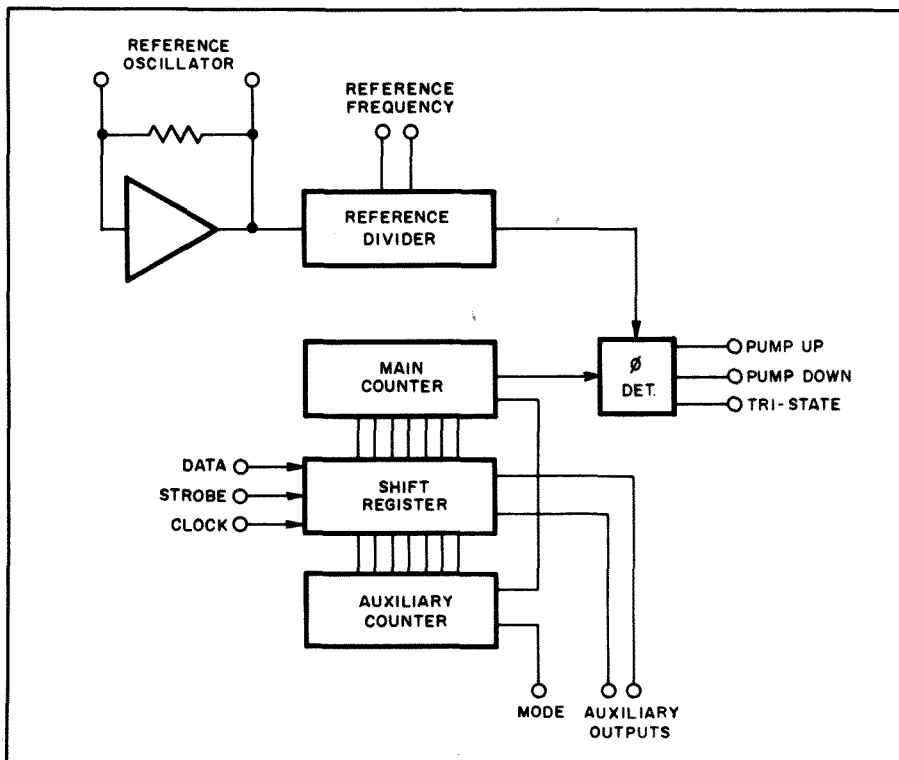

Fig 32—Block diagram of a Motorola LSI synthesizer chip.

microphonics. When the loop frequency response is so limited, the VCO must have few microphonics. This requires rigid shields and components secured with adhesives or potting compounds.

When modulation is applied to the VCO control voltage the amount of frequency deviation depends on the VCO constant. In VHF synthesizers where the bandwidth is a small percentage of the operating frequency, the variation in VCO constant versus operating frequency is small. When the VCO frequency range is large compared to the operating frequency, such as the 4-MHz span of the 50-MHz band, VCO constant can be a significant problem.

### Mixing in VHF Synthesizers

VHF synthesizers can also use some form of mixing. Mixing can achieve two goals simultaneously. It can reduce the VCO frequency to a value that can be handled by conventional logic. Mixing can also perform some of the synthesizer arithmetic such as providing the IF offset for receive.

Fig 33 shows a block diagram of a VHF synthesizer using a mixing technique. In this example, the VCO operates in two bands, 133.3 to 137.3 MHz which is the receiver local-oscillator range, and the transmitter range from 144 MHz to 147.995 MHz. The same VCO serves as the receiver local oscillator and the transmitter oscillator. The VCO is mixed with a 125.3-MHz oscillator for receive and a 136-MHz oscillator for simplex transmit. In Fig 33, the programmable divider division factor goes from 1600 at 144 MHz to 2399 at 147.995 MHz. No special code conversion is required for this synthesizer, and Fig 34 shows the logic diagram of the programmable divider. On simplex, the VCO frequency is changed by 10.7 MHz between transmit and receive, by switching crystals in the offset oscillator. For repeater operation, the crystal oscillator is changed to provide a transmit frequency 600 kHz up or down from the receive frequency. More crystals are required to operate with other splits. The disadvantage of this synthesizer is the number of required crystals. A 2-meter synthesizer with simplex, 600-kHz positive and negative repeater offsets and 1-MHz repeater split requires seven crystals including the reference-oscillator crystal. The output frequency is directly dependent on each crystal, unlike the dual-modulus synthesizer, in which frequency accuracy depends on only one crystal.

The VCO must shift approximately 10 MHz between transmit and receive. This requires the synthesizer to lock up quickly. The transmitter must be inhibited while the synthesizer is out of lock. To facilitate the frequency shift, a fixed capacitor can be switched in and out of the VCO tank circuit.

A variation of this synthesizer uses only two crystal oscillators, including the 5-kHz reference. VCO shifts, transmit/receive switching and repeater offsets are con-

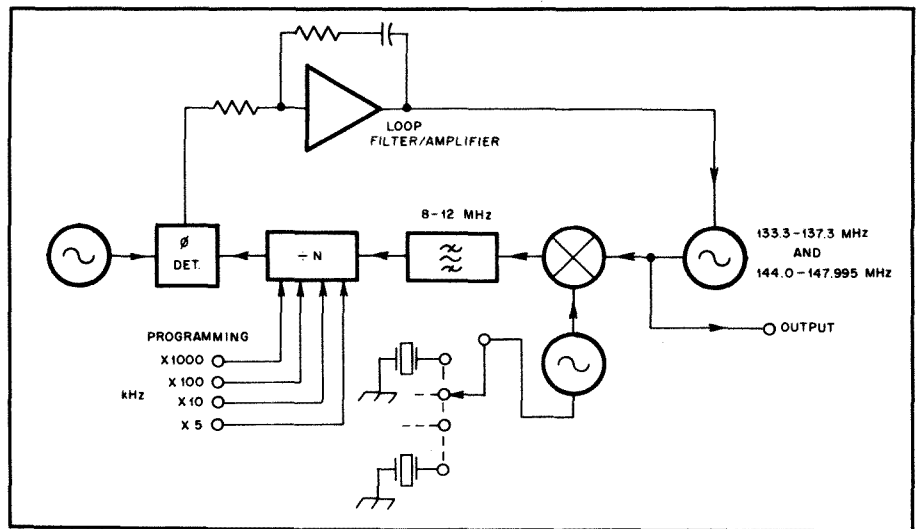

Fig 33—Block diagram of a VHF synthesizer using mixing techniques.

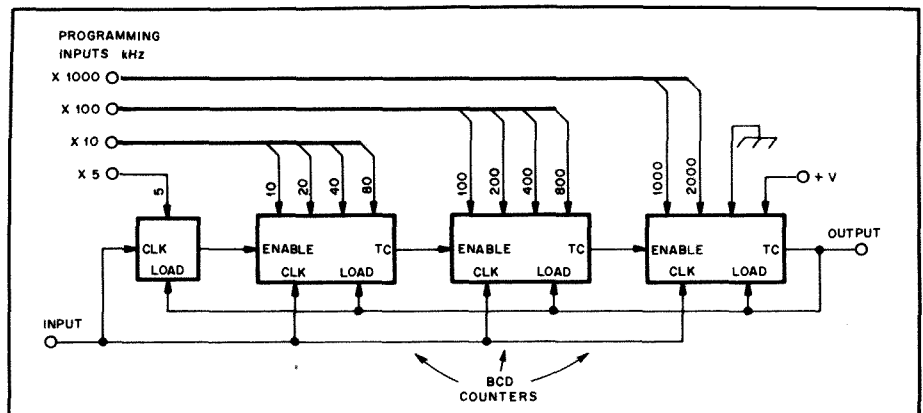

Fig 34—Logic diagram of the programmable divider for the synthesizer shown in Fig 33.

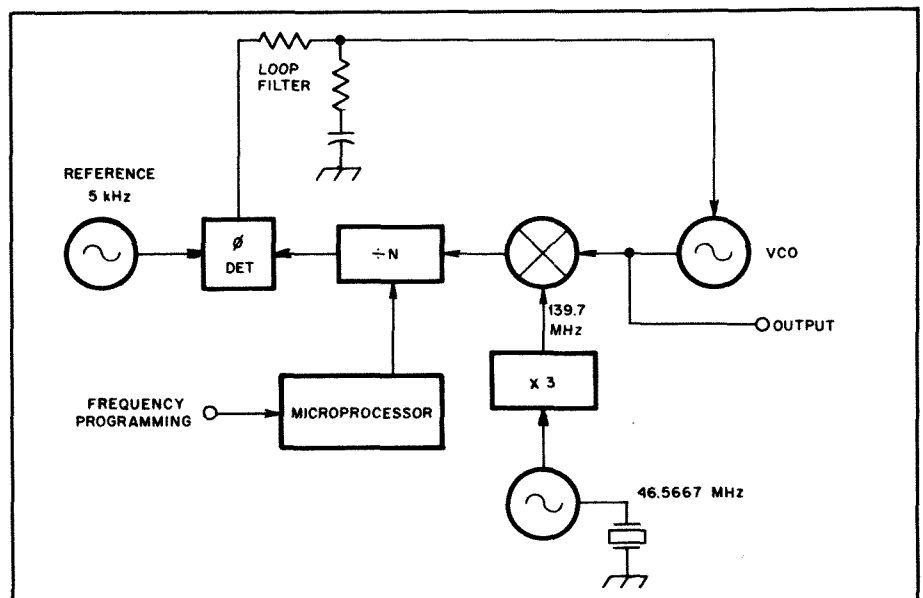

Fig 35—Block diagram of a microprocessor-controlled VHF synthesizer.

trolled by a microprocessor. A block diagram of this synthesizer is shown in Fig 35. The VCO must still shift for transmit and receive; it shares this problem with

the previous example. However, only two crystals are required—a significant advantage over the previous case.

One example of a synthesizer design that

does not require a VCO shift between transmit and receive is shown in Fig 36. In this design, the VCO serves as the receiver local oscillator at all times. On transmit, the VCO is mixed with a crystal-controlled, frequency-modulated oscillator operating at the receiver IF. Repeater offsets are handled by the programmable divider. For repeater operation, the VCO has to shift between transmit and receive, but only 600 kHz or 1 MHz, depending on the offset. That is an improvement over the previous examples, where the VCO was required to shift an amount equal to the receiver IF plus any repeater offset.

Like any heterodyning transmitter there is a possibility of transmitting spurious signals. To minimize this chance, the receiver IF should be as high as practical. In the example shown, the receiver IF is 16.9 MHz. The local oscillator range is 127.1 to 131.095 MHz. LO output is mixed with a 16.9-MHz, frequency-modulated crystal oscillator to provide the transmitted frequency. Care must be taken to prevent local oscillator radiation. The 16.9-MHz-signal is filtered easily. To effectively eliminate the local oscillator from the transmit signal requires a sharp tuned circuit. This circuit can be adjusted automatically with a varactor diode, tuned from the VCO control voltage. This technique usually reduces the spurious signal level to an acceptable limit.

Frequency synthesis at UHF uses similar techniques to those used at VHF, with some minor changes. The frequencies involved in this range limit the use of the dual-modulus synthesizer and make mixing schemes difficult. One acceptable method of UHF synthesis is to use a fixed-modulus

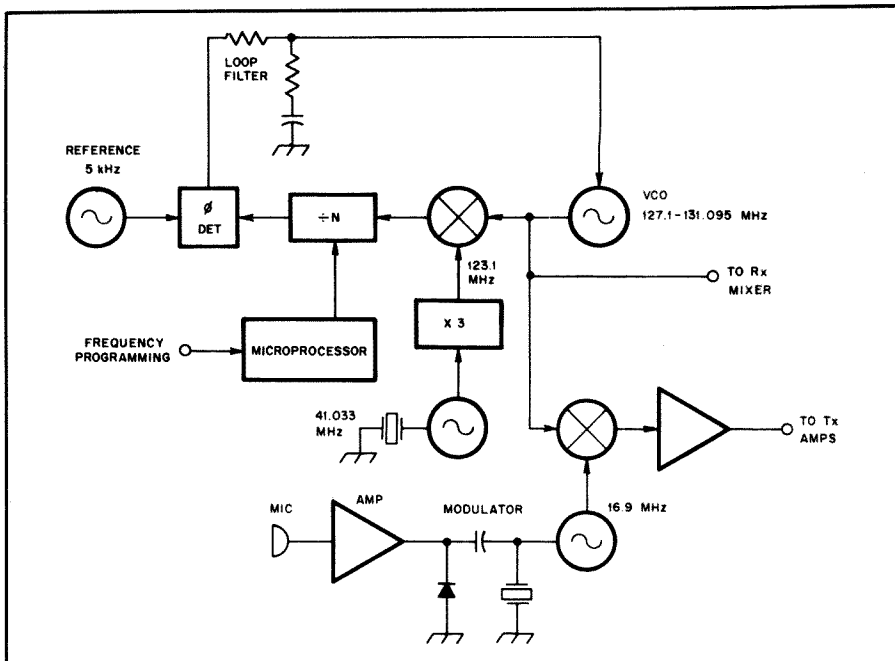

Fig 36—Block diagram of a synthesizer requiring only minimal VCO frequency shifting.

prescaler. Because most modes of operation at UHF are broadband, the presence of the reference frequency in the PLL is not a significant problem. Simple frequency dividers such as divide by 2, 4 or 8 are available for operating frequencies as high as 2 GHz and are expected to become available for even higher frequencies.

## Oscillator Phase Noise

The following material on phase noise was written by John Grebenkemper, KI6WX, and first appeared as a two-part article in March and April 1988 *QST*.

Oscillators have formed the basis of most radio communications systems since spark-gap transmitters were retired. Originally, these oscillators used piezoelectric crystals or high-Q LC tuned circuits as resonant elements. More recently, *phase-locked loops* (PLLs) have been used in radios with synthesized local oscillators. There is no theoretical reason that prevents a phase-locked oscillator from having better phase-noise characteristics than a free-running oscillator using an LC tuned circuit.

An ideal oscillator would generate a sine wave at a given frequency with no deviation in amplitude or phase over time. If we looked at this signal with an ideal spectrum analyzer, we would see all of the energy

concentrated at the fundamental frequency and none at any other frequency. If ideal oscillators existed, problems with phase noise wouldn't exist.

Oscillator signals vary in both amplitude and phase as a function of time. These variations are referred to as *amplitude noise* and *phase noise*. Amplitude noise is an undesired variation in the *amplitude* of an oscillator signal. If we use an oscilloscope to look at oscillator output, we can see that the amplitude peaks of the sine wave vary with time (Fig 37).

Phase noise is an undesired variation in the phase of the signal. In this case, an oscilloscope shows that the time between zero crossings of the signal varies over time when compared to the zero crossings of an ideal sine wave. An exaggerated example of phase noise is shown in Fig 38.

Several factors combine to make ampli-

tude noise much less important than phase noise. The first is that most oscillators tend to produce less amplitude noise than phase noise. This occurs because the active devices in most oscillators are operated in a gain-saturated condition. Gain saturation occurs when increasing the input to a device or stage results in no further increase in output. If a device or stage is sufficiently gain saturated, small changes in the amplitude of the input signal (amplitude noise, in other words) produce no change in the output level.

Amplitude noise is secondary in importance to phase noise for another reason. Most modern ham rigs use mixers in their signal-generation schemes. Because mixers are usually operated with their local-oscillator input ports gain saturated, any amplitude noise on the input signal generally does not appear on the mixer output.

Fig 37—Oscillator amplitude noise effects as viewed on an oscilloscope. The broken line shows the output of an ideal oscillator; the solid line shows the output waveform of an oscillator with a large amount of amplitude noise.

Fig 38—Oscillator phase-noise effects as viewed on an oscilloscope. The broken line shows the output of an ideal oscillator; the solid line shows the output waveform of an oscillator with a large amount of phase noise.

Fig 39—Phase-noise characteristics of two synthesized oscillators. The lower curve represents the output of a well-designed synthesized oscillator. The upper curve represents that of a poorly designed synthesized oscillator. Note the broad peak at 1 kHz, and the spikes visible near 60 and 120 Hz, and 11 and 22 kHz. (See text.)

## SPECIFYING PHASE NOISE LEVELS

There are many ways to display oscillator phase noise. The most common presentation is called single-sideband (SSB) phase noise. This is simply a display of the phase-noise characteristics on one side of the carrier. The SSB phase-noise presentation

has probably achieved its widespread use because SSB phase noise is easy to measure and interpret for the average person who is familiar with RF measurement techniques. The display of SSB phase noise is exactly what you would see if the oscillator was observed using an ideal spectrum analyzer with a 1-Hz sampling bandwidth.

The vertical axis is the SSB phase noise measured in units of “dBc/Hz.” The “dBc” means that we are measuring the power in the phase noise relative to the power in the carrier. The “Hz” implies that we are making this measurement in a 1-Hz bandwidth. (Phase noise is usually not actually *measured* in a 1-Hz bandwidth, for reasons of instrumentation limitations.)

The horizontal axis represents the difference between the measurement and oscillator frequencies, and is usually referred to as the *offset frequency*. Offset frequency is measured in Hz, and it is usually plotted on a logarithmic scale. An offset of 1 kHz means that we are measuring the phase noise 1 kHz from the carrier; an offset of 10 kHz is 10 kHz from the carrier, and so on. A 10-kHz offset from a 10-MHz carrier means that we are making measurements at 9.99 MHz or 10.01 MHz.

Two typical phase-noise measurements are shown in Fig 39. At an offset frequency of 0 Hz, the SSB phase noise is always 0 dBc/Hz, because we are measuring the carrier power, which is the reference for these measurements. At any other offset, the SSB phase noise is always a negative dB value.

Phase noise in a communications system can be divided into two different regions. The *in-band* or *close-in* phase noise is the component that is *within the modulation bandwidth* of the signal. The *out-of-band* or *far-out* phase noise is the component that is *beyond the modulation bandwidth* of the signal. The modulation bandwidth of an amateur SSB signal is 3 kHz. Therefore, we can define the close-in phase noise of an SSB signal as the noise at offsets of less than 3 kHz, and the far-out phase noise as the phase noise at offsets greater than that. The difference between close-in and far-out phase noise is similarly defined for modes with different modulation bandwidths.

The example used in Fig 39 shows the phase noise for two different synthesized oscillators. The phase-noise plot labeled “good” is the phase noise from an excellent synthesized local oscillator. These phase-noise characteristics are considered the best presently obtainable for oscillators used in HF receivers. The phase noise from this oscillator rapidly decreases with increasing offset frequency, reaching -160 dBc/Hz at an offset frequency of 100 kHz. The slight flattening of the phase-noise plot near 1 kHz results from the natural frequency of the PLL (the natural frequency produces optimum loop response). (It is normal for a synthesized oscillator to show flattening or a few dB of peaking of the phase noise at the natural frequency of the PLL.) This oscillator would present only minor phase-noise problems in amateur applications.

The phase-noise plot labeled “poor” is typical of what one would expect from an inferior synthesized oscillator. The characteristics of such an oscillator include strong

spurious signals, an underdamped PLL (lack of sufficient negative feedback), and a high phase-noise floor. Large spurious signals are shown at harmonics of 60 Hz and 11 kHz. These signals result from frequency modulation of the oscillator in the PLL, and are generally caused by inadequate shielding or poor loop design. The broad peak at 1 kHz results from an underdamped PLL. Any peaking greater than this is indicative of a poorly designed phase-locked oscillator.

The phase noise of the poorer oscillator in Fig 39 is only  $-130$  dBc/Hz at a 100-kHz offset. This is generally caused by deficient design of the phase-locked oscillator. Any of the above forms of degradation in the phase noise of an oscillator compromise the performance of a transmitter (and/or receiver).

## EFFECTS OF OSCILLATOR PHASE NOISE

In order to understand the effects of phase noise, we have to keep some basic principles in mind. The term *communications system* used here refers to the receiver, the transmitter to which the receiver is tuned, and other nearby transmitters. The term *system* is used to convey that phase-noise effects can result from *both the receiver and transmitters*, not just the affected receiver.

**Principle 1:** Whenever a carrier is passed through a mixer, the phase noise of the oscillator driving that mixer is *added* to the carrier. This means that the oscillator SSB phase-noise power at a given offset frequency is added to the phase noise already present on the carrier at the same offset frequency. For instance, suppose we pass an ideal carrier (one with no phase noise) through two mixers, each driven by an oscillator with an SSB phase noise of  $-130$  dBc/Hz at a 10-kHz offset. After passing the carrier through the first mixer, the SSB phase noise on the carrier is  $-130$  dBc/Hz. After passing the carrier through the second mixer, the phase noise on the carrier is  $-127$  dBc/Hz. This is the *sum* of the phase-noise *power* of the carrier and local oscillators at the 10-kHz offset frequency. (Summing two equal powers is a doubling of either power, or a 3-dB increase.  $-127$  dBc is twice as much power as  $-130$  dBc.) This example illustrates that *the oscillator with the worst phase-noise characteristics limits the performance of the system*. This principle holds for both transmitters and receivers.

**Principle 2:** *Phase noise on a transmitted signal causes effects identical to phase noise generated in a receiver.* (Of course, transmitter-generated phase noise can affect many users of the radio spectrum, while receiver-generated phase noise only affects the person using that receiver!)

**Principle 3:** Passing an oscillator signal through a filter *reduces* the phase noise in accordance with the filter bandwidth and attenuation characteristics. For instance,

passing a carrier through a filter (centered on the carrier frequency) with a bandwidth of 20 kHz reduces the phase noise for offset frequencies greater than 10 kHz. As a result of this, transmitters and receivers have an *apparent phase noise* that is usually less than the sum of their local oscillator phase-noise levels. The *apparent* phase noise is what limits the *system* performance.

This effect must be applied with a good understanding of exactly what the filtering does. For instance, in receivers, filtering *before* a mixer determines the apparent phase noise; in transmitters, filtering *after* a mixer determines apparent phase noise. The improvement in the apparent phase-noise floor achievable with filtering depends on the power level of the signal being filtered. A normal filter at room temperature generates thermal-noise power of about  $-170$  dBm/Hz. A 10-dBm signal passed through this filter can achieve a noise floor no lower than  $-160$  dBc/Hz.

## CLOSE-IN VERSUS FAR-OUT PHASE NOISE

The close-in and far-out phase-noise components act on a communications system in different ways. Close-in phase noise limits the performance of the system even when there is plenty of signal present. With an AM or FM signal, the close-in phase noise limits the maximum signal-to-noise ratio (SNR) that can be achieved by the system. With a frequency-shift-keyed or a phase-shift-keyed signal, the close-in phase noise limits the maximum bit error rate that the system can achieve. Both of these effects can be quantified once the communications system is defined. With an SSB voice signal, the effects are much harder to predict, but excessive phase noise does degrade SSB signal intelligibility to some extent.

The effect of close-in phase noise on FM signals is relatively easy to calculate, and makes a good case study of the effects of phase noise, because of the wide use of FM by amateurs in the VHF and UHF bands. Oscillator phase-noise limits derived from the FM case should be adequate for most other modulation modes, with the possible exception of phase-shift keyed modulation.

Phase noise on an oscillator signal has exactly the same effect as frequency modulating the oscillator with noise. In fact, given the SSB phase noise of an oscillator, it is possible to calculate the equivalent frequency deviation. This deviation is called the *incidental frequency modulation* (IFM) of the oscillator.

The phase noise in an FM communications system causes a constant noise level to appear at the receiver output, regardless of the strength of the received signal. This noise imposes a maximum SNR that the communications system can achieve.

It takes an oscillator with a very high level of close-in phase noise to degrade amateur communications systems. Most amateur communications are accomplished

with marginal signal to noise ratios, and the close-in phase noise would have to be very strong to cause problems in such situations. Therefore, for most amateur applications, close-in phase noise is relatively unimportant.

Far-out phase noise, however, can have a significant impact on amateur communications. Its main effect is to degrade the dynamic range of a communications system. This degradation can result from phase noise in either the receiver or the transmitter. If the transmitter has excessive phase noise, transmitted signals are partly composed of broadband FM noise. The phase-noise emissions of some current amateur equipment are capable of significantly increasing the noise level on an entire amateur band! The effect of this is generally experienced only by amateurs living within a few miles of the offending transmitter, because the power level of the phase noise is quite low. A kilowatt transmitter with a high level of phase noise produces only a few microwatts in a typical amateur receiving bandwidth. As low as this may seem, however, it can be quite a problem for nearby receivers when you consider that a typical HF receiver is capable of detecting signals of less than  $10^{-15}$  watts!

Far-out phase noise in a receiver oscillator is less destructive, because it affects only the receiver in which it is generated. The net effect, however, is the same: Any signal that reaches a mixer in the receiver is modulated by the phase noise in the local oscillator driving that mixer. As such, the signal appears to have at least as much phase noise as the local oscillator. Thus, sufficiently strong signals *off* the receiving frequency can degrade receiver sensitivity by raising the noise floor *at* the receiving frequency. Receiver dynamic range is reduced as the noise floor rises.

As an example, suppose that a transmitter has a power output of 1 kW and an SSB phase noise of  $-100$  dBc/Hz at a given offset frequency. At that offset frequency, the transmitter radiates noise at a level of  $-40$  dBm/Hz. In a 2-kHz bandwidth, this is equivalent to a noise level of  $-7$  dBm, or 200  $\mu$ W. This is sufficient power to cause significant interference to local receivers. *The effect on a receiver is the same as if the transmitter had low phase noise and the receiver had an SSB phase noise of  $-100$  dBc/Hz.* Fortunately, the oscillators in most amateur equipment don't have this much SSB phase noise at offset frequencies greater than a few kilohertz.

The effect of phase noise on an amateur communications system can be calculated with reasonable accuracy if a few simple assumptions are made. From the calculated effects, we can calculate the oscillator performance necessary to meet our requirements. The assumptions are:

- 1) The transmitter is located 1 mile from the receiver.

2) The EIRP (effective isotropic radiated power) of the transmitter is 100 W (+50 dBm).

3) The loss from the transmit antenna to the receive antenna is the same as in free space. (This isn't strictly true for signals propagated above ground, but it gives an approximation of the expected signal attenuation. The actual attenuation is almost impossible to calculate because of the effects of the local terrain.)

4) The receive antenna gain is 0 dBi in all directions.

5) Our goal is a phase-noise level that does not significantly degrade the performance of the communications system. That is, the received noise resulting from oscillator phase noise should be equal to or less than the background noise normally picked up by an antenna on a given amateur band. (Background noise is composed of radio emissions from our galaxy, as well as man-made noise and atmospheric noise, and varies with frequency.)

Table 1 shows the results of these calculations. The table shows values for both 14 MHz (representative of the HF bands) and 144 MHz (representative of the VHF bands). As can be seen from these calculations, the phase noise must be less than -140 dBc/Hz if there is to be no noticeable interference. A higher EIRP or less transmitter-to-receiver antenna separation would require even better phase-noise performance to guarantee no significant interference. The graph of Fig 40 shows phase-noise interference generated at 14 MHz as a function of transmitter-to-receiver antenna separation, and the apparent SSB phase noise of the system. The interference level is plotted in S units, assuming S9 is equal to 50  $\mu$ V and each S unit is 6 dB. As you can see from the graph, an SSB phase noise of -120 dBc/Hz at a distance of 500 feet produces nearly an S9 signal. This graph may be applied to local situations to estimate the interference potential that could result from oscillator phase noise.

## PHASE NOISE LEVELS IN AMATEUR EQUIPMENT

Equipment cost limits the extent to which we can minimize phase noise in communications systems; with this in mind, we can set rough phase-noise performance standards for equipment in various price ranges.

Curves showing recommendations for such standards appear in Fig 41. These curves represent tools for comparison of phase-noise performance in amateur equipment.

Four curves are shown: "excellent," "good," "fair" and "poor." When the phase-noise characteristics of a radio are known, they can be compared to the curves in Fig 41. The worst curve that a radio's phase-noise characteristics pass through should be considered the performance of that radio. The "excellent" curve approx-

**Table 1**  
**Typical Maximum Tolerable Phase-Noise Levels**

	14 MHz	144 MHz
EIRP	+50 dBm	+50 dBm
Loss from transmitter to receiver (distance = 1 mile)	60 dB	80 dB
Signal power at receiving antenna (0-dBi gain receiving antenna)	-10 dBm	-30 dBm
Noise power at receiving antenna (background noise)	-150 dBm/Hz	-172 dBm/Hz
Equivalent SSB phase noise	-140 dBc/Hz	-142 dBc/Hz

This table shows maximum phase-noise levels tolerable in a communications system before dynamic range is significantly degraded. In both cases, EIRP is 100 W; separation between transmitting and receiving antennas is 1 mile; the receiving antenna is omnidirectional and has 0 dBi gain; and the receiver is sensitive enough to detect the noise.

At 14 MHz, path loss and received noise power allow the receiver to detect any phase noise stronger than -140 dBc/Hz. At 144 MHz, background noise is lower and path loss is higher, resulting in a tolerable equivalent phase-noise level of -142 dBc/Hz at this frequency. See text for additional information.

**Fig 40—Phase-noise interference at 14 MHz as a function of the distance between transmitting and receiving antennas. The curves are based on a transmitter EIRP of 100 W and a receiving bandwidth of 2 kHz. The path loss from the transmit antenna to the receive antenna is assumed to follow the free-space attenuation curve. S9 is equivalent to 50  $\mu$ V.**

imates the best performance that can be expected from modern HF and VHF synthesized oscillators. For amateur equipment, this curve is approached by free-running LC and crystal oscillators, and by the very best transceivers.

The "good" curve represents what is achieved by most well-designed amateur equipment. It doesn't cost a great deal more to design a radio that meets this curve (as opposed to the "poor" or "fair" curves). A radio with phase-noise performance that only meets the "fair" curve hasn't been designed with much regard for minimizing phase noise. The "poor" curve represents a design that is so poor that a transmitter with this performance shouldn't be used on the amateur bands because of the great amount of interference it can generate.

The close-in phase-noise characteristics shown in the curves of Fig 41 are relatively

easy for most oscillators to achieve. The close-in regions of the curves were derived mainly from the effects of IFM on the limiting FM SNR. Table 2 lists the close-in phase-noise IFM integrated from 10 Hz to 10 kHz for each of these curves. (Even a radio generating the IFM level corresponding to phase noise matching the "poor" curve provides adequate voice communications capability.)

## MEASURING PHASE NOISE

Equipment capable of measuring low levels of far-out phase noise is quite expensive. It is not unusual for commercial enterprises to invest \$100,000 in good phase-noise measurement equipment. Inexpensive techniques are, however, available for measuring the apparent phase noise of communications receivers and transmitters. The equipment necessary to measure receiver phase noise can be built

Fig 41—Phase-noise performance levels for amateur equipment. The curves from top to bottom represent poor, fair, good and excellent phase-noise performance. (See text.)

Fig 42—Block diagram of test setup for measuring the SSB phase noise of an SSB or CW receiver.

by enterprising amateurs for well under \$100.

### Measuring Receiver Phase Noise

A block diagram of a receiver phase-noise measurement setup is shown in Fig 42. The test setup consists of an oscillator, a step attenuator and an ac voltmeter. The output of the oscillator is fed through the attenuator to the receiver's RF input. The ac voltmeter is connected to the audio output of the receiver. The receiver is operated in SSB or CW mode with the AGC disabled.

The oscillator and step attenuator must be carefully constructed (well shielded, minimum necessary lead lengths and so on) for proper operation of this test setup. A simple oscillator circuit suitable for use in this application appears on page 126 of the ARRL publication *Solid State Design for the Radio Amateur*. The oscillator provides the reference signal for measuring phase noise. The phase noise of the oscillator must be less than that of the receiver if we are to measure receiver phase noise accurately. The oscillator should have a power output of at least +10 dBm (10 mW) into 50  $\Omega$ . Less power than this may limit the accuracy of the measurement setup at low phase-noise levels. The oscillator should be constructed in a metal box and powered by an internal 9-V battery to minimize unwanted signal leakage.

The step attenuator must have a maximum attenuation of at least 140 dB. Prefer-

ably, it should be adjustable in 1-dB steps. It is difficult to design a single attenuator circuit that provides this much attenuation, so a step attenuator with a maximum of 60 or 70 dB of attenuation should be used in series with fixed attenuators to obtain the maximum value. A design for a suitable step attenuator is given in Chapter 25. Each of the fixed attenuators can be constructed in a shielded enclosure using standard Pi or T resistor configurations to achieve the desired attenuation. Use BNC connectors on the oscillator and step attenuator; they have better shielding properties than UHF connectors. Commercial step attenuators and in-line coaxial attenuators are sometimes available on the surplus market. If you choose to build attenuators, use 5% (or better) precision resistors. The accuracy of the phase-noise measurements depend to a great extent on the accuracy of the attenuators.

The ac voltmeter is used to measure the audio output level from the receiver. The voltmeter should measure true RMS voltage, but commonly available peak-reading ac voltmeters are adequate for this application.

Phase-noise measurements are done on the band for which the oscillator is built. Measurements should be made in each amateur band, since phase-noise levels of many receivers vary from one amateur band to another. Briefly, the measurement procedure is as follows: A reference audio output level is established by tuning the

**Table 2**  
**Incidental Frequency Modulation**

Curve	IFM
Excellent	0.4 Hz
Good	2.5 Hz
Fair	20 Hz
Poor	160 Hz

Incidental frequency modulation (IFM) resulting from the phase-noise levels shown in Fig 41. The IFM was calculated for the frequency range from 10 Hz to 10 kHz.

receiver to the oscillator frequency and measuring the audio output voltage. The receiver is then tuned above (or below) the oscillator frequency in increments of the desired offset frequency. The attenuation is then decreased until the noise voltage at the audio output is the same as the reference level. The difference in the two attenuator settings is then corrected for the receiver bandwidth to give the SSB phase noise at that offset frequency. The process is then repeated for several different offset frequencies. The step-by-step measurement procedure follows.

### Step-By-Step Measurement Procedure

1) Connect the test equipment as shown in Fig 42. Set the step attenuator to its maximum attenuation. Switch the oscillator out of the line. Set the receiver for SSB or CW reception with the AGC disabled. Preamplifiers or input attenuators in the receiver should be disabled, if possible. Use the narrowest IF bandwidth available in the receiver. Set the RF and AF gain controls to maximum, unless this causes the audio amplifier to overload from receiver noise. In case of audio-amplifier overload, reduce the audio gain until there is a minimum of 10 dB of headroom in the audio amplifier. This can be done by decreasing the AF gain (while monitoring audio output voltage) by 10 dB after all signs of gain compression disappear. In other words, decrease the AF gain to 10 dB below the point at which the audio output voltage begins to vary linearly with adjustment of the AF gain control.

2) Determine the 6-dB bandwidth of the receiver. An easy way to do this is to enable the oscillator, tune the oscillator signal through the receiver passband and note the frequencies at which the audio voltage is 6 dB below the peak response. The difference between the upper and lower frequencies is the receiver's bandwidth. Alternatively, the published 6-dB bandwidth for the receiver can be used. The bandwidth measurement doesn't have to be very accurate—a 25% error in the bandwidth factor affects the phase-noise measurement by only 1 dB. Record the receiver bandwidth ( $\Delta f$ ).

3) Switch the oscillator into the line. Center the oscillator signal in the receiver passband. Switch the oscillator out of the line and measure and record the audio output voltage. Switch the oscillator into the line again, and adjust the step attenuator until the audio voltage increases by 41% (3 dB) from the no-signal value. The signal

is now at the receiver's MDS (minimum discernible signal) level. This setting is a compromise: A higher setting allows more precise measurement of the audio output voltage; a lower setting decreases the possibility of overloading the receiver front end. Record the frequency to which the receiver is tuned ( $f_0$ ), the setting of the step attenuator ( $A_0$ ), and the audio output voltage ( $V_0$ ).

4) Measure the phase noise by first tuning the receiver to the desired offset frequency, given by  $f_0 + f$ , where  $f$  is the offset frequency. Then, adjust the attenuator until the audio output voltage is as close as possible to ( $V_0$ ). Record the total attenuation ( $A_1$ ) and the audio voltage ( $V_1$ ). The SSB phase noise at this offset frequency is found by

$$L(f) = A_1 - A_0 - 10 \log (\Delta f)$$

where

$$L(f) = \text{SSB phase noise in dBc/Hz}$$

5) Determine if the receiver is overloaded at this offset frequency as follows: Decrease the attenuation by 3 dB. Note the audio voltage at the new attenuator setting ( $V_2$ ). The audio output voltage of the receiver should increase by approximately 22% (1.7 dB) from  $V_1$ . If it increases by less than 18% (1.4 dB), it is likely that some stage in the receiver is overloaded, and the SSB phase-noise measurement is inaccurate. If the overload is in the audio stages, it can be eliminated by decreasing the audio gain and repeating the measurements. If the overloading is occurring in the RF or IF stages, the receiver's blocking dynamic range has been exceeded. The overload may be eliminated by reducing the receiver's RF gain and repeating the measurements. The existence of this problem indicates that, at this offset frequency, the receiver's performance is limited by blocking dynamic range, not phase noise.

6) Repeat steps 4 and 5 for several offset frequencies. Ideally, measurements should be made at offset frequencies separated by no more than half of the receiver's bandwidth, in order to make sure that no discrete phase-noise components are overlooked. This is tedious at the greater offset frequencies. Generally, a coarser sampling is adequate to plot the phase-noise curve, as long as you check the intermediate offset frequencies to make sure that no discrete signals are present. The measurements can start at offset frequencies as close as a few times the receiver's bandwidth, if the receiver has good IF filters. You can determine if the offset is too small by disconnecting the audio voltmeter from the receiver and listening to the audio. If you can hear the carrier signal at all, the offset is too small. All that should be present is noise if the measurement is to be accurate. Increase the offset until no trace of carrier remains in the audio to be sure of the measurement.

The technique outlined in the steps above is quite accurate. SSB phase-noise levels of less than  $-160$  dBc/Hz can be measured

**Table 3**

### SSB Phase Noise of ICOM IC-745 Receiver Section

Oscillator output power =  $-3$  dBm (0.5 mW)

Receiver bandwidth ( $\Delta f$ ) = 1.8 kHz

Audio noise voltage = 0.070 V

Audio reference voltage ( $V_0$ ) = 0.105 V

Reference attenuation ( $A_0$ ) = 121 dB

Offset Frequency (kHz)	Attenuation ( $A_1$ ) (dB)	Audio $V_1$ (volts)	Audio $V_2$ (volts)	Ratio $V_2/V_1$	SSB Phase Noise (dBc/Hz)
4	35	0.102	0.122	1.20	-119
5	32	0.104	0.120	1.15	-122*
6	30	0.104	0.118	1.13	-124*

200	0	0.104			-154
250	0	0.100			-154
300	0	0.098			< -154
400	0	0.096			< -154
500	0	0.096			< -154
600	0	0.097			< -154
800	0	0.096			< -154
1000	0	0.096			< -154

Asterisks indicate measurements possibly affected by receiver overload (see text).

on a receiver that has good sensitivity and a high gain-compression point (good dynamic range), as determined in step 5. It is difficult to construct an oscillator that has a noise floor much below this level, and, as mentioned earlier, the oscillator phase-noise level limits the accuracy of the measurement setup.

This measurement technique has advantages and disadvantages. One of its major advantages is that it measures the *apparent* phase noise of the receiver. Apparent phase noise includes the effects of filters; it is the phase noise that actually limits a receiver's dynamic range.

One disadvantage of this measurement technique is that it doesn't allow *direct* measurement of the phase noise of an oscillator. Therefore, it can't be used to directly measure the phase noise of a transmitter. This limitation can be overcome by using a receiver with known phase-noise characteristics to measure the phase noise of a transmitter. The transmitter is substituted for the oscillator in the test setup, and its output is attenuated to the power level of the oscillator. As long as the transmitter phase noise is greater than that of the receiver, measurements of the transmitter's phase noise will be accurate.

Another disadvantage is that, at some offset frequencies, the receiver's dynamic range may make phase-noise measurement impossible. Precision in this measurement technique requires that the oscillator out-

Fig 43—Measured SSB phase noise of an ICOM IC-745 transceiver (serial number 01528).

put be variable from a very low level to a very high level, in small, precise steps.

Table 3 and Fig 43 show phase-noise characteristics measured in the receiver section of an ICOM IC-745 transceiver using this method. Table 3 includes the attenuation and voltage values to show their relationships to phase-noise levels in the IC-745 over this range of offset frequencies. The data obtained from the ratio of  $V_2$  to  $V_1$  indicates that the receiver was probably overloaded at offset frequencies from 5 kHz to 15 kHz. This measurement was limited to an SSB phase-noise floor of  $-154$  dBc/Hz because of the low power-output level of the oscillator. Fig 43

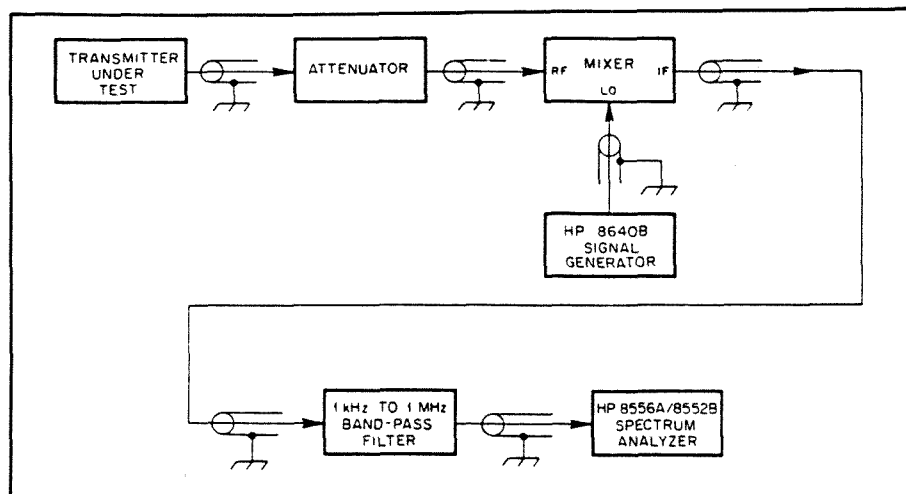

Fig 44—ARRL transmitter phase-noise measurement setup.

is based on the far-out phase noise data obtained from Table 3, as well as the close-in phase noise measured using laboratory test equipment and the same IC-745. The data obtained using the method described earlier and that obtained from the laboratory test equipment closely track each other. The phase-noise performance of this transceiver generally exceeds that indicated by the "good" curve in Fig 41.

#### TRANSMITTER PHASE-NOISE MEASUREMENT IN THE ARRL LAB

The system used to measure transmitter phase noise in the ARRL Lab essentially consists of a direct-conversion receiver with very good phase-noise characteristics. As shown in Fig 44, an attenuator is used after the transmitter, a Mini-Circuits ZAY-1 mixer, a Hewlett-Packard 8640B signal generator, a bandpass filter and an audio-frequency spectrum analyzer (HP 8556A/8552B) to make the measurements. The transmitter signal is mixed with the output of the signal generator, and signals produced in the mixing process that are not required for the measurement process are filtered out. The spectrum analyzer then displays the transmitted phase-noise spectrum. The 100 mW output of the HP 8640B is barely enough to drive the mixer—the setup would work better with 200 or even 400 mW of drive. To test the phase noise of an HP 8640B, we use a second 8640B as a reference source. It is quite important to be sure that the phase noise of the reference source is lower than that of the signal under test, because what is actually being measured is the combined phase-noise output of the signal generator and the transmitter. It would be quite embarrassing to publish phase-noise plots of the reference generator instead of the transmitter under test! The HP 8640B has much cleaner spectral output than most transmitters.

Fig 45 shows a phase noise photograph for ICOM 745 serial number 03101. This photograph was taken directly from the spectrum-analyzer display, using the test

setup shown in Fig 44. The photo does not necessarily reflect the phase-noise characteristics of all ICOM 745 transceivers.

The carrier is not shown in the photograph because it is nulled by heterodyning and bandpass filtering. The log reference level (the top horizontal line on the scale in the photos) represents  $-60$  dBc/Hz. It is common in industry to use a 0-dBc log reference, but such a reference level would not allow measurement of phase-noise levels below  $-80$  dBc/Hz. The actual measurement bandwidth used on the spectrum analyzer is 100 Hz, but the reference is scaled for a 1-Hz bandwidth. This allows phase-noise levels to be read directly from the display in dBc/Hz. Because each vertical division represents 10 dB, the photos show the noise level between  $-60$  dBc and  $-140$  dBc. The horizontal scale is 2 kHz per division.

#### What do the Phase-Noise Pictures Mean?

Although they are useful for comparing different radios, phase-noise photographs can also be used to calculate the amount of interference you may receive from a nearby transmitter with known phase-noise characteristics. An approximation is given by

Interfering signal level =  $NL + 10 \times \log BW$   
where

Interfering signal level is in dBc

NL is the noise level on the receiving frequency

BW is receiver IF bandwidth in Hz

For instance, if the noise level is  $-90$  dBc and you are using a 2.5-kHz SSB filter, the interfering signal will be  $-56$  dBc. In other words, if the transmitted signal is 20 dB over S9, and each S unit is 6 dB, the interfering signal will be as strong as an S3 signal.

The measurements made in the ARRL Lab apply only to transmitted signals. It is reasonable to assume that the phase-noise characteristics of most transceivers are similar on transmit and receive, because the

Fig 45—ICOM IC-745 (serial number 03101) phase-noise characteristics. Measurement frequency: 3.5 MHz, power output: 100 W.

same oscillators are generally used in the local-oscillator (LO) chain.

In some cases, the receiver may have better phase-noise characteristics than the transmitter. Why the possible difference? The most obvious reason is that circuits often perform less than optimally in strong RF fields, as anyone who has experienced RFI problems can tell you. A less-obvious reason results from the way that many high dynamic-range receivers work. To get good dynamic range, a sharp crystal filter is often placed immediately after the first mixer in the receive line. This filter removes all but a small slice of spectrum for further signal processing. If the desired filtered signal is a product of mixing an incoming signal with a noisy oscillator, signals far away from the desired one can end up in this slice. Once this slice of spectrum is obtained, however, unwanted signals cannot be reintroduced, no matter how noisy the oscillators used in further signal processing. As a result, some oscillators in receivers don't affect phase noise.

The difference between this situation and that in transmitters is that crystal filters are seldom used for reduction of phase noise in transmitting because of the high cost involved. Equipment designers have enough trouble getting smooth, click-free break-in operation in transceivers without having to worry about switching crystal filters in and out of circuits at 40-WPM keying speeds!

#### CONCLUSION

Close-in phase noise generally has little effect on the performance of amateur communications systems. However, far-out phase noise *can* significantly reduce the dynamic range of a receiver. Far-out phase-noise performance has effects just as critical as blocking dynamic range and two-tone dynamic range performance of receivers. Ideally, these measurements should be made for a range of offset frequencies. Far-out phase noise in receivers can be measured with relatively inexpensive test equipment, as long as care is taken to perform the measurements properly.

# Radio Transmitting Principles

Even though some modern transmitters and transceivers contain only solid-state devices, it is still practical to use a hybrid circuit that contains a mixture of tubes and active semiconductor stages. Typically, the unit has transistors, diodes and ICs up to the driver stage of the transmitter. At that point one will find a tube driver used to supply RF power to a vacuum-tube amplifier. The amplifier might consist of a pair of 6146Bs.

The principal advantage of tube amplifiers is that they are somewhat less subject to damage from excessive drive levels and mismatched loads. However, a properly designed solid-state driver and PA section should be immune to output mismatch damage, provided an SWR-protection circuit has been included in the transmitter. A solid-state amplifier is slightly more difficult to design and have work correctly than is a tube amplifier of equivalent power. This is because purity of emissions is harder to achieve when transistor power stages are employed. Transistors generate considerably more harmonic energy than tubes do, and are prone to self-oscillation at LF, VLF and audio frequencies unless some careful design work is done. This is not generally true of tube amplifiers.

If one is to ignore these problems and concentrate mainly on cost and convenience, transistors may have the edge over tubes. A 13.6-volt design can be operated directly from an automotive or solar-electric supply, whereas a tube amplifier requires a high-voltage power supply for mobile, portable and fixed-station use. When an ac power source is required, the cost of a high-voltage, medium-current supply for tubes versus a low-voltage, high-current power source for transistors is similar, provided new components are used in both. At power-output levels in excess of approximately 150 watts, the transistor-amplifier power supply becomes rather expensive because of complex regulator-

circuit requirements. This is why most amateurs use vacuum tubes in high-power HF and VHF amplifiers. The number of power transistors required (plus combiners) to generate a 1-kW signal may run considerably higher in cost than a tube or tubes for an amplifier of equivalent power. The price of large heat sinks versus a cooling fan may place the solid-state amplifier in a prohibitive price class also.

The decision to buy or build a transmitter is founded on some basic considerations: cost compared to features; professional appearance contrasted to that of homemade equipment; the knowledge and satisfaction gained from building equipment, as weighed against buying commercially made gear and simply becoming an operator. The judgment must fit the amateur's objectives and affluence. Home-built transmitters are usually easier to service than commercial ones because the builder knows the circuit layout and how each stage functions. Furthermore, the cost of maintenance is markedly lower for homemade equipment than for most factory-built gear. But the greatest significance to home-built circuits is the knowledge gained from constructing a project and the pride that goes with using it on the air!

Not all parts of a transmitter are covered in depth in this chapter. A discussion of frequency-generating circuits is found in Chapter 10. For information on RF power amplifiers, see Chapter 15.

### Above 50 MHz

The frequencies above 50 MHz were once a world apart from the rest of Amateur Radio — in equipment required, in modes of operation and in results obtained. Today these worlds blend increasingly.

The almost universal use of SSB for voice work in the HF range has had a major impact on equipment design for the VHF and even UHF bands. Many amateurs have

a considerable investment in HF sideband gear. This equipment provides accurate frequency calibration and good mechanical and electrical stability. It is effective in CW as well as SSB communication. These qualities are attractive to VHF operators, so it is natural for them to look for ways to use HF gear on frequencies above 50 MHz.

Use of VHF accessory devices, both ready made and homebuilt, is increasing. This started years ago with the VHF receiving converter. Similar conversion equipment for transmitting has been widely used since SSB has been on the HF bands. Today the HF trend is to one-package stations, transceivers. The obvious move for many VHF operators is a companion box to perform both transmitting and receiving conversion functions. Known as transverters, these are offered by several manufacturers. They are also relatively simple to build, and are thus attractive projects for the home-builder of VHF gear.

CW, SSB and FM are the predominant modes on the VHF bands. Each method of communication has certain transmitter requirements. In general equipment used for FM is of the oscillator-multiplier type. The multiplier stages are needed to realize the desired deviation.

Because SSB cannot be passed satisfactorily through a frequency-multiplication stage, generation of VHF SSB signals requires the use of one or more mixer stages. VHF CW may be generated either by mixing or by frequency multiplying. Recently, manufacturers of amateur FM transceivers have been using a combination of both approaches. In the multimode VHF transceiver, which offers the operator a choice of CW, SSB, FM and often AM, we find both approaches to signal generation.

### Transmitter Basics

The most basic type of transmitter is one that contains a single stage, is crystal con-

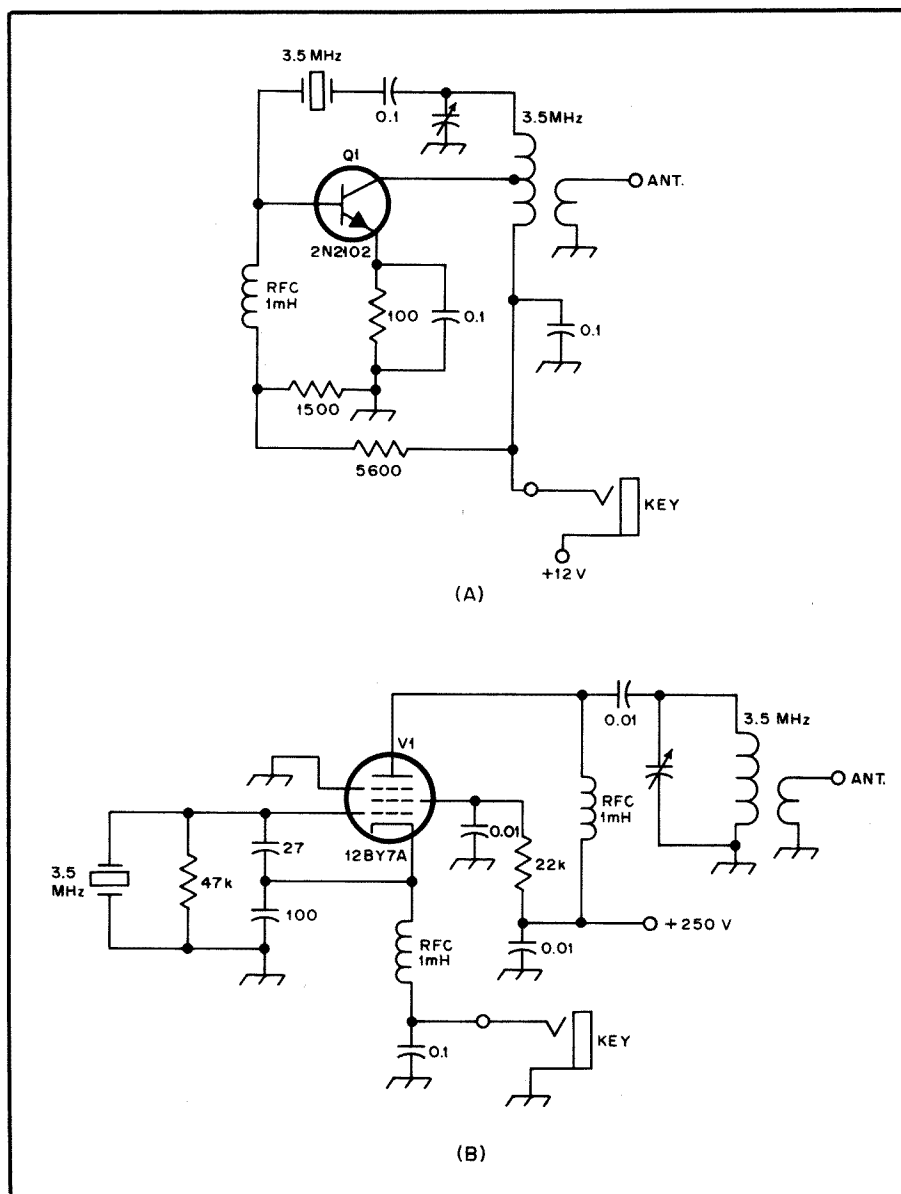

Fig. 1 — A transistor oscillator is shown at A. The example at B illustrates a type of crystal oscillator.

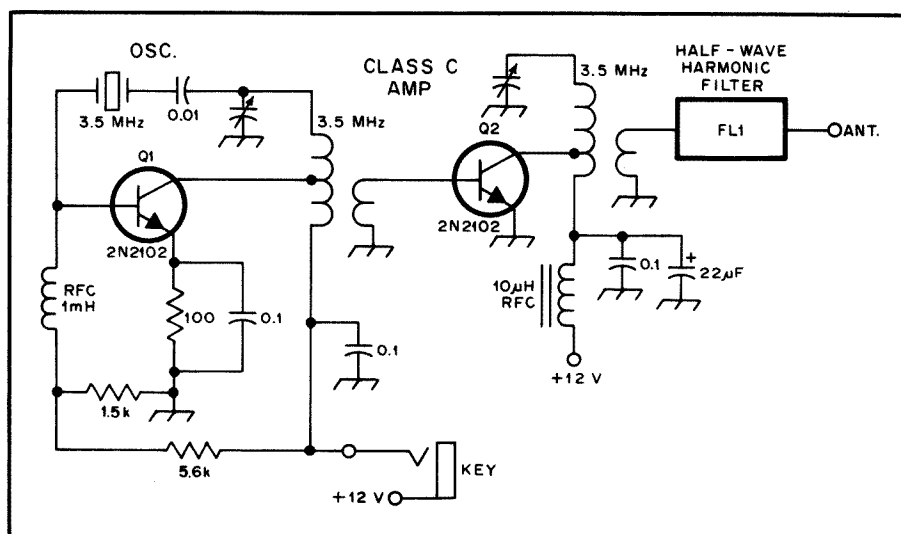

Fig. 2 — Circuit example of a simple, solid-state CW transmitter.

trolled, and is designed for CW operation. A circuit example is given in Fig. 1. This kind of transmitter is not especially suitable for use on the air because it is inefficient and is prone to generating a chirpy CW signal unless loaded lightly. But the same circuit is entirely acceptable when followed by an isolating stage (buffer-amplifier) as shown in Fig. 2. The second stage not only builds up the power level, but also gives the oscillator a relatively constant load to look into. The constant load helps to prevent oscillator pulling and attendant chirping of the CW note.

Fig. 3 illustrates the basic types of transmitters for CW and RTTY work. The drawing at A represents the general circuit given in Fig. 2. Illustration B is an expansion of that circuit and includes a frequency multiplier. A heterodyne type of generator, which is currently popular for multiband transmitters and transceivers, is shown as the exciter section of a transmitter in drawing C. A frequency synthesizer is shown as the RF generator at D.

For operation on AM, any of the lineups given in Fig. 3 is suitable, provided a modulator is added. It is used to modulate the operating voltage to the PA stage, or in some designs the operating voltage to the PA and the stage immediately before it.

The block diagram of Fig. 4 outlines the functional stages of an SSB transmitter. Z1 can be a simple VFO, a heterodyne generator (Fig. 3C) or a frequency synthesizer. The essential difference between this type of transmitter and one that would be used for CW/RTTY is that the RF amplifiers must operate in Class A, AB or B (linear), rather than in Class C, which is suitable for CW work. However, linear amplifiers are entirely satisfactory for any transmission mode at a sacrifice in efficiency. Once the SSB signal is generated it cannot be passed through a frequency multiplier. All post-filter stages must operate straight through. Class C amplifiers are generally used in FM transmitters as well as in CW and RTTY transmitters.

Fig. 5 illustrates two approaches to VHF FM transmitters. Shown at A is a transmitter that uses phase modulation, also known as indirect FM. Multiplier stages bring the signal to the operating frequency and increase the deviation to the desired range. A frequency-synthesized direct FM transmitter is shown at B. Fewer multiplier stages are required for this method because greater deviation can be realized at the modulator. Audio is amplitude limited and the frequency response is shaped before modulation in both transmitters.

### Crystal Switching

Although several crystals for a single oscillator can be selected by mechanical means, a switch must be contained in the RF path. This can impose severe restrictions on the equipment layout. Furthermore, mechanical switches normally require that they be operated from the front

panel of the transmitter or receiver. That type of format complicates the remote operation of such a unit. Also, the switch leads can introduce unwanted reactances in the crystal circuit. A better technique is illustrated in Fig. 6, where D1 and D2 — high-speed silicon switching diodes — are used to select one of two or more crystals from some remote point. As operating voltage is applied to one of the diodes by means of S1, it is forward biased into "hard" conduction, thereby completing the circuit between the crystal trimmer and ground. Some schemes actually call for reverse-biasing the unused diode or diodes when they are not activated. This ensures almost complete cutoff, which may not be easy to obtain in the circuit shown because of the existing RF voltage on the anodes of D1 and D2.

### VARIABLE-FREQUENCY OSCILLATORS

The theory and general application of variable-frequency oscillators is treated in Chapter 10. The circuit principles are the same regardless of the VFO application.

Some additional considerations pertain to the use of VFOs in transmitters as compared to a VFO in a receiver. Generally, heating of the interior of a transmitter cabinet is greater than in a receiver. This is because considerably more power is being dissipated in the transmitter. Therefore, greater care must be given to oscillator long-term stability. Temperature-compensating capacitors are often needed in the frequency-determining portion of the oscillator to level off the long-term stability factor. Some oscillators are designed for use with a temperature-control oven for the purpose of maintaining a relatively constant ambient temperature in the oscillator compartment — even while the equipment is otherwise turned off. Another design

Fig. 3 — Block diagrams of various transmitters that use specific frequency-generation methods.

matter related to a transmitter-contained VFO is RF shielding of the oscillator and the attendant low-level buffer-isolation stages that follow it. Fairly high levels of stray RF can be present in a transmitter and some of that energy may migrate to the oscillator section by means of stray radiation or conduction along wiring leads or circuit-board elements. Thus, it is important to provide as much physical and electrical isolation as possible. The VFO should be housed in a rigid metal box. All dc leads entering the enclosure require RF-decoupling networks that are effective at all frequencies involved in the transmitter design. The VFO box needs to be fastened securely to the metal chassis on which it rests to ensure good electrical contact. Excessive stray RF entering the VFO circuitry can cause severe instability and erratic oscillator operation.

#### VFO Dials

One of the tasks facing an amateur builder is the difficulty of finding a suitable dial and drive assembly for a VFO. A dial should provide a sufficiently slow rate of tuning — 10 to 25 kHz per knob revolution is considered optimum — without backlash. Planetary drives are popular because of their low cost; however, they often develop objectional backlash after a short period of use. Several types of two-speed drives are available. They are well suited to home-made amateur equipment. The Eddystone 898 precision dial has long been a favorite with amateurs, although the need to elevate the VFO far above the chassis introduces some mechanical stability problems. If a permeability-tuned oscillator (PTO) is used, one of the many types of turn counters made for vacuum variable capacitors or rotary inductors may be employed.

#### Linear Readout

If a linear-dial frequency readout is

desired, the variable capacitor must be only a small portion of the total capacitance in the oscillator tank. Capacitors tend to be very nonlinear near the ends of rotation. A gear drive providing a 1.5:1 reduction should be employed so that only the center of the capacitor range is used. Then, as a final adjustment, the plates of the capacitor must be filed until linear readout is achieved. In a PTO, the pitch of the oscillator coil winding may be varied so that a linear frequency change results from the travel of the tuning slug. A different approach is to use a variable-capacitance diode (Varicap) as the VFO tuning element. A meter that reads the voltage applied to the Varicap is calibrated to indicate the VFO frequency.

#### Electronic Dials

An electronic dial consists of a simplified frequency counter that reads either the VFO or operating frequency of a transmitter or receiver. The advantage of an electronic dial is the excellent accuracy (to 1 hertz, if desired) and the fact that VFO tuning does not have to be linear. The readout section of the dial may use neon-glow tubes called Nixies® or a seven-segment display using incandescent lamps, filament wires in a vacuum tube, LCDs (liquid crystal display) or LEDs (light-emitting diodes). The use of MSI and LSI circuits, some containing as many as 200 transistors on a single chip, reduces the size required for an electronic dial to a few square inches of circuit-board space.

A typical counter circuit is given in Fig. 7. The accuracy of the counter is determined by a crystal standard, often referred to as a clock. The output from a 100-kHz calibration oscillator, the type often used in receivers and transceivers, may be employed if an accuracy of 100 Hz is sufficient. For readout down to 1 Hz, a 1- to 10-MHz AT-cut crystal should be chosen, because this type of high-accuracy crystal

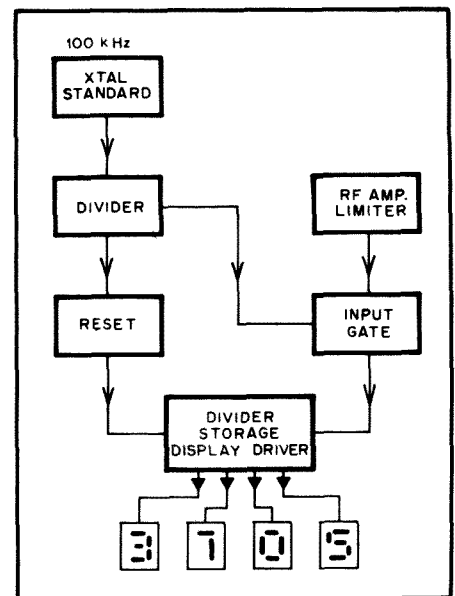

Fig. 7 — Frequency counter block diagram.

exhibits the best temperature stability. The clock output energy is divided in decade-counter ICs to provide the pulse that opens the input gate of the counter for a preset time.

The number of RF cycles that pass through the gate while it is open are counted and stored. Storage is used so the readout does not blink. At the end of each counting cycle, the stored information activates the display LEDs, which present the numbers counted until another count cycle is complete. A complete electronic dial arranged to be combined with an existing transmitter or receiver was described in October 1970 *QST*. Also, Macleish et al. reported an adapter that allows a commercially made frequency counter to be mated with ham gear so the counter performs as an electronic dial (May 1971 *QST*).

#### Frequency Multiplication

If it is necessary to use frequency multipliers at some point after the VFO or other frequency generator in a transmitter, the circuits of Fig. 8 can be applied. Of course, vacuum-tube multipliers are entirely suitable if the design is not one that uses semiconductors. The fundamental principles for frequency multiplication are applicable to tubes and transistors alike. The requirement is to operate the devices in Class C. Although a transistor circuit may be operated with forward bias applied to a frequency multiplier, the stage must be driven hard enough to override the bias and operate Class C. Forward bias is sometimes used in a multiplier stage (solid state) to lower the excitation requirements. Negative voltage (reverse bias) is often used on the grid of a vacuum-tube multiplier, but forward bias is not.

The circuit of Fig. 8A is probably the least suitable for frequency multiplication. Typically, the efficiency of a doubler of this

type is 50 percent, a tripler is 33 percent and a quadrupler is 25 percent. Additionally, harmonics other than the one to which the output tank is tuned will appear in the output unless effective band-pass filtering is applied. The collector tap on L1 of Fig. 8A is placed at a point that offers a reasonable compromise between power output and spectral purity. The lower the tap with respect to  $V_{CC}$ , the lighter the collector loading on L1 and the greater the filtering action of the tuned circuit. The trade-off is, however, a reduction in output power as the mismatch of the collector to the load increases.

A push-push doubler is shown at Fig. 8B. Because of the conduction angle of this type of circuit the efficiency is similar to that of a straight amplifier operating in Class C. Also, the driving frequency ( $f$ ) will be well attenuated at the doubler output if electrical balance and component symmetry are ensured. A 12AU7A tube will work nicely in this type of circuit well into the VHF region. T1 in this example is a trifilar-wound, broad-band toroidal transformer. It drives the gates of Q1 and Q2 in push-pull (opposite phase). The drains are in parallel and are tuned to  $2f$ . R1 is used to establish electrical balance between Q1 and Q2. R1 is set while the doubler is being fully driven. Diode doublers can be used in a similar circuit; see Chapter 4.

A push-pull tripler is illustrated in Fig. 8C. The matter of electrical balance and symmetry is important to proper operation. The circuit discriminates against even harmonics, aiding spectral purity. The efficiency is somewhat better than a tripler using the circuit of Fig. 8A. If vacuum tubes are used in the circuits of Fig. 8, the input ports should employ high-impedance tuned circuits for best performance.

#### The Oscillator-Multiplier VHF Transmitter

This type of transmitter, which may be used for FM or CW, generally starts with a crystal oscillator operating in the HF range, followed by one or more frequency-multiplier stages and at least one amplifier stage. While relatively simple to construct, such transmitters can cause much grief unless the builder takes precautions to prevent undesired multiples of the oscillator and the multiplier stages from being radiated. For frequencies below 450 MHz the transmitting mixer is not difficult to construct and is recommended for most applications. Spurious-signal radiation is much easier to prevent with the mixer, although it does not lend itself to compact FM equipment design. For operation on the amateur UHF bands, the oscillator-multiplier approach offers definite advantages. Fig. 9 shows how the harmonics of a 144-MHz signal may be multiplied to permit operation on amateur UHF and microwave bands. Stability at 144 MHz is easy to realize with current technology, making stable microwave signals simple to generate. Varactor diodes are used as

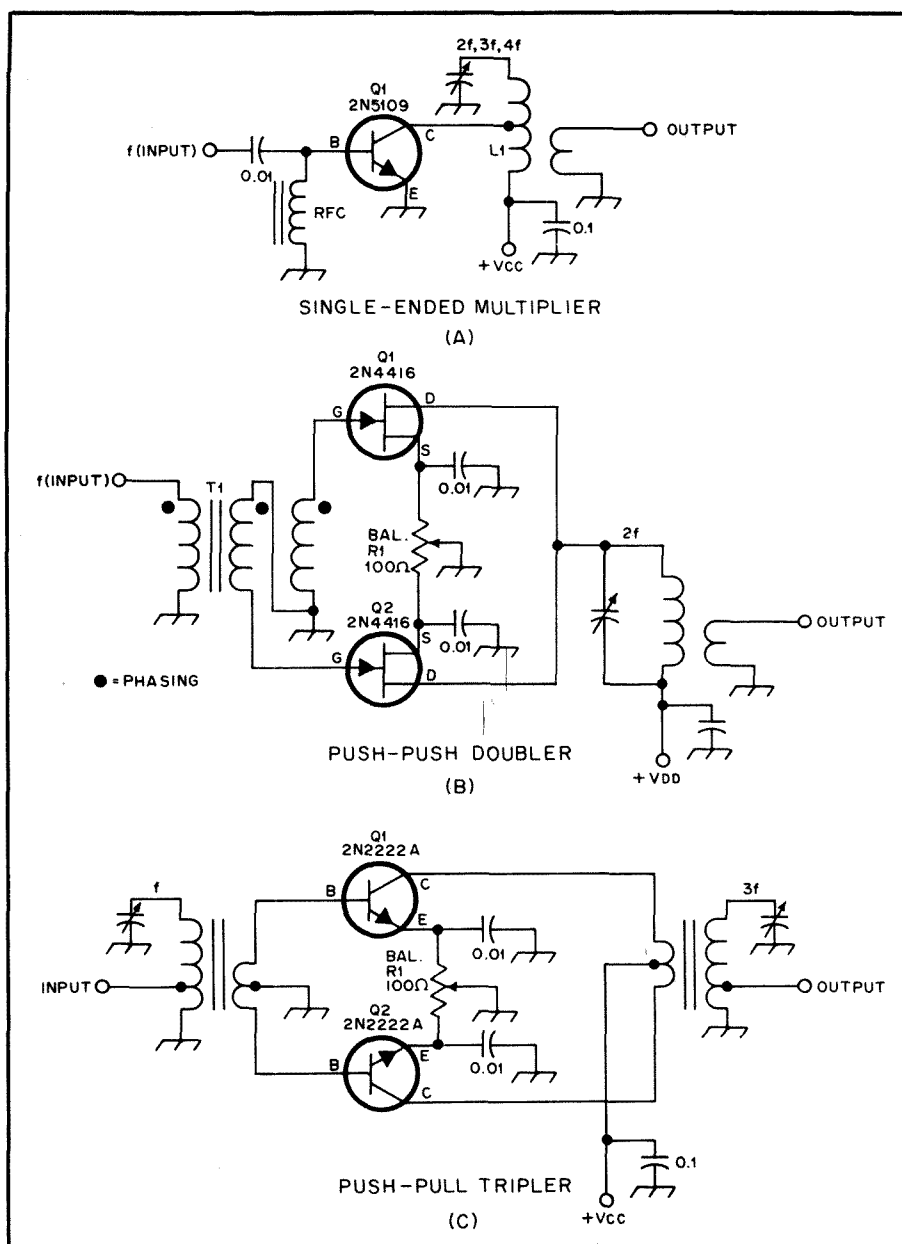

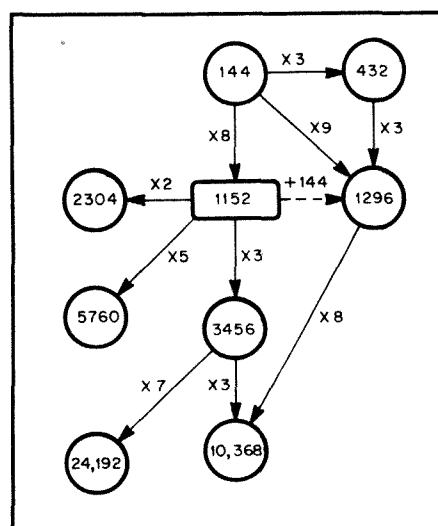

Fig. 8 — Single-ended multiplier (A), push-push doubler (B) and push-pull tripler (C).

frequency-multiplying devices. They are installed in resonant cavities. Operation will probably be crystal controlled, as even the best transceiver/transverter combination used to generate the 144-MHz signal may create problems when the output is multiplied in frequency 40 times! A frequency synthesizer with a stable reference oscillator may be used to generate the 144-MHz signal, but its output should be well filtered to eliminate noise.

Fig. 9 — Multiplier scheme for generating RF on weak-signal communication frequencies at UHF and above. All frequencies are in megahertz. An 1152-MHz LO can be used to drive microwave multiplier circuits or serve as an LO for a 1296-MHz transverter with a 144-MHz IF.

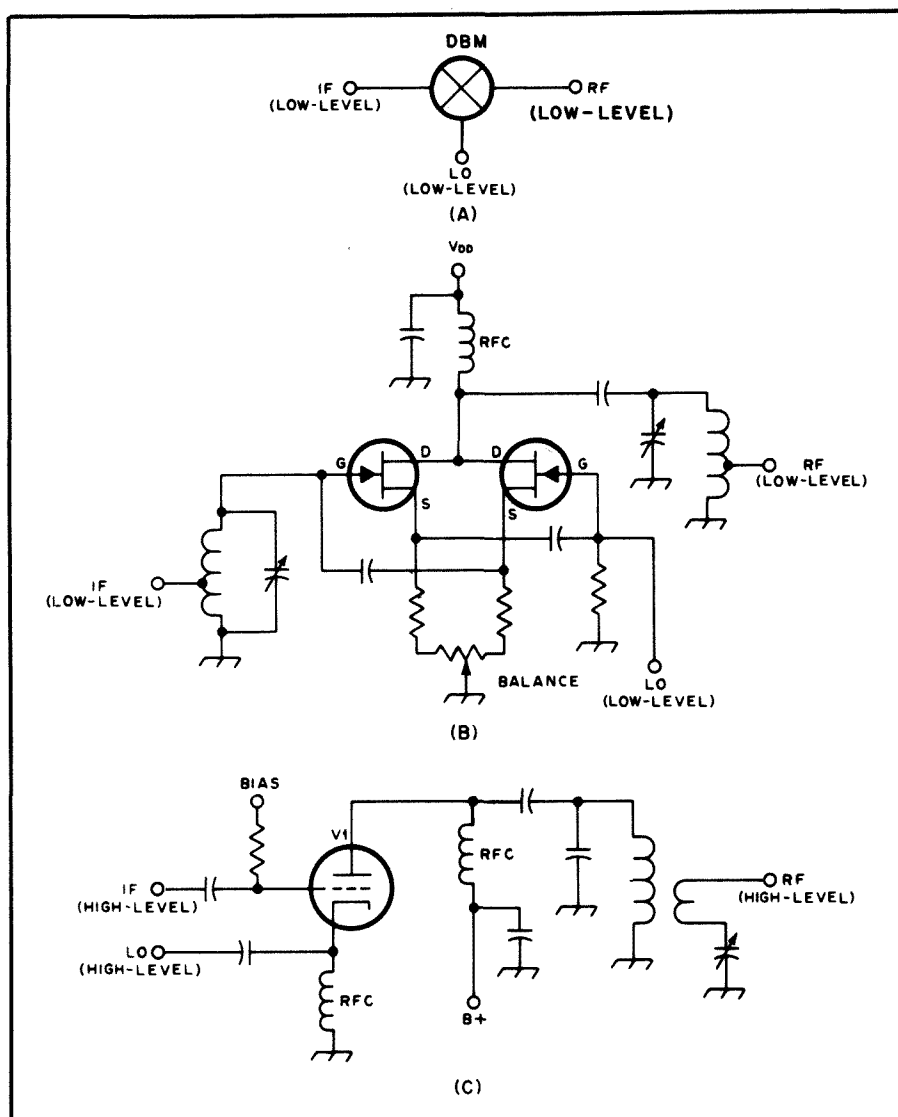

Fig. 10 — A trio of commonly used VHF transmitting mixers. At A, perhaps the simplest, a commercially available diode doubly balanced mixer. RF output is CW, requiring the use of several stages of amplification to reach a useful level. At B, a singly balanced mixer using FETs. Adjustment of this circuit is critical to prevent the local-oscillator signal from leaking through. A mixer of this type can supply slightly more output than a diode mixer (3 dBm, as opposed to 1 dBm for the mixer shown at A). At C, a high-level mixer using a vacuum-tube triode is shown. In this case, V1 might be a type 2C39 or 7289 tube. With the correct circuit constants this mixer could provide an SSB output of 15 watts on 1296 MHz. Power input would be about 100 watts! In addition, 10 watts of LO and 5 watts of IF drive would be needed. Despite these requirements, such a circuit provides a relatively low-cost means of generating high-level microwave SSB. Spurious outputs at the LO and image frequencies will be quite strong. To attenuate them, a strip-line or cavity filter should be used at the mixer output.

Although spurious outputs of the various multiplier stages may not cause harmful interference, that is no excuse for not removing them. In most cases, the Q of successive cavities will suffice. A band-pass filter may be used to filter the final multiplier stage.

### Transmitting Mixers

With the possible exception of the power levels involved, there is no reason to consider transmitting mixers differently than their receiving counterparts. One thing to keep in mind is that many deficiencies in the transmitter mixer will show up on the air. Receiver mixer troubles are *your* problem. Transmitter mixer troubles

become everyone's problem!

A trio of popular types of transmitting mixers is shown in Fig. 10. The doubly balanced diode mixer at A may be built using discrete components or the phase relationship between ports may be established using etched-circuit strip lines. Miniature DBMs are available at low cost from several manufacturers. They offer an almost foolproof method of generating VHF SSB. Another popular mixer uses a pair of FETs in a singly balanced configuration. If care is taken in construction and adjustment, local-oscillator rejection will be adequate with this circuit. To be safe, a series-tuned trap, designed to attenuate the LO leakage even further,

should follow this stage. A typical FET balanced mixer is shown in Fig. 10B.

Finally, we see a typical vacuum-tube mixer (Fig. 10C). Because it can handle more power, the tube mixer has endured at VHF. Its higher output, when compared to most solid-state mixers, reduces the number of subsequent amplifier stages needed to reach a specific power level. This is the only advantage of using them as mixers, at least on the lower VHF bands.

### High-Level Transmitting Mixers

When you are designing a transmitting converter for VHF, the trade-offs between the advantages of mixing at a low power level, such as in a diode-ring mixer, and using several stages of linear amplification must be weighed against the cost of amplifying devices. On 432 MHz and above, it may be desirable to mix the IF and local-oscillator signals at a fairly high level. This method makes it unnecessary to use costly linear devices to reach the same power level. High-level mixing results in a slightly distorted signal, so it should be used only when essential.

Fig. 11 gives the schematic diagram of a typical 432-MHz high-level mixer. V1 is the final amplifier tube of a retired commercial 450-MHz FM transmitter. The oscillator and multiplier stages now produce local-oscillator injection voltage, which is applied to the grid as before. The major change is in the cathode circuit. Instead of being directly at ground, a parallel LC circuit is inserted and tuned to the IF. In this case 10-meters was chosen. With the exception of 144 MHz, any amateur band could serve as the IF. A 144-MHz IF is unsuitable because the third harmonic would appear at the output, where it would combine with the desired signal. For that reason, some additional output filtering is needed with this circuit. The original crystal in the transmitter is replaced with one yielding an output at the desired local-oscillator frequency, then the intermediate stages are retuned.

One disadvantage of the high-level mixer is the relatively large amount of local-oscillator injection required. In many cases it is simpler to mix at a lower level and use linear amplifiers than to construct the local-oscillator chain. On the higher bands, it may be feasible to generate local-oscillator energy at a lower frequency and use a passive varactor mixer to reach the injection frequency. In this case the previous statements about diode-multiplier spurious outputs apply. If the local-oscillator injection is impure, the mixer output will be also. For further information on mixers see Chapters 4 and 12 of this publication and *Solid State Design for the Radio Amateur*, an ARRL publication.

### Output Filtering

Output purity from oscillators, multipliers and amplifiers is of paramount importance to the performance of

numerous circuits. In the interest of compliance with current FCC regulations, wherein all spurious emissions from a transmitter must be 40 dB or greater below the peak power of the desired signal at HF and 60 dB or greater between 30 and 225 MHz, filtering is important. The type of filter used — band-pass, notch, low-pass or high-pass — will depend on the application. Band-pass filters afford protection against spurious responses above and below the amateur band for which they have been designed. Low-pass filters attenuate energy above the desired output frequency, while high-pass filters reduce energy below the band of interest.

It is common practice to include a harmonic filter at the output of a VFO chain to ensure purity of the driving voltage to a mixer or amplifier stage. The filter bandwidth must be adequate for the tuning range of the VFO in order to prevent attenuation of the output energy within the desired band. For this reason, some designers prefer to use a low-pass type of filter instead of a band-pass one.

The information contained in Figs. 12 through 14 and in Tables 1 through 5 will allow the builder to select an appropriate Chebyshev filter design to fulfill a particular need. Information is included for both high-pass and low-pass filters with 1, 0.1, 0.01 and 0.001 dB band-pass ripple. These figures correspond to SWRs of 2.66, 1.36, 1.10 and 1.03, respectively. Additionally, information is provided for both T and pi types of filter configurations.

The filters are normalized to a frequency of 1 MHz and an input and output impedance of 50 ohms. To translate the designs to other frequencies, simply divide the component values by the new frequency in megahertz. (The 1-MHz value represents a "cutoff" frequency. That is, the attenuation increases rapidly above this frequency for the low-pass filter or below this frequency for the high-pass filter. This effect should not be confused with the variations in attenuation in the passband.) For instance, if it is desired to reduce harmonics from a VFO at frequencies above 5 MHz (the new cutoff frequency), the inductance values would be divided by 5 and the capacitance values multiplied by 5.

Other impedance levels can also be used by multiplying the inductor values by the ratio  $Z_o/50$  and the capacitor values by  $50/Z_o$ , where  $Z_o$  is the new impedance. This factor should be applied in addition to the ones for frequency translation.

In order to select a suitable filter design the builder must determine the amount of attenuation required at the harmonic frequencies (for the low-pass case) or subharmonic frequencies (for the high-pass application). Additionally, the builder must determine the maximum permissible amount of band-pass ripple and therefore the SWR of the filter. With this information the builder can refer to Table 1 to select an appropriate filter design. The at-

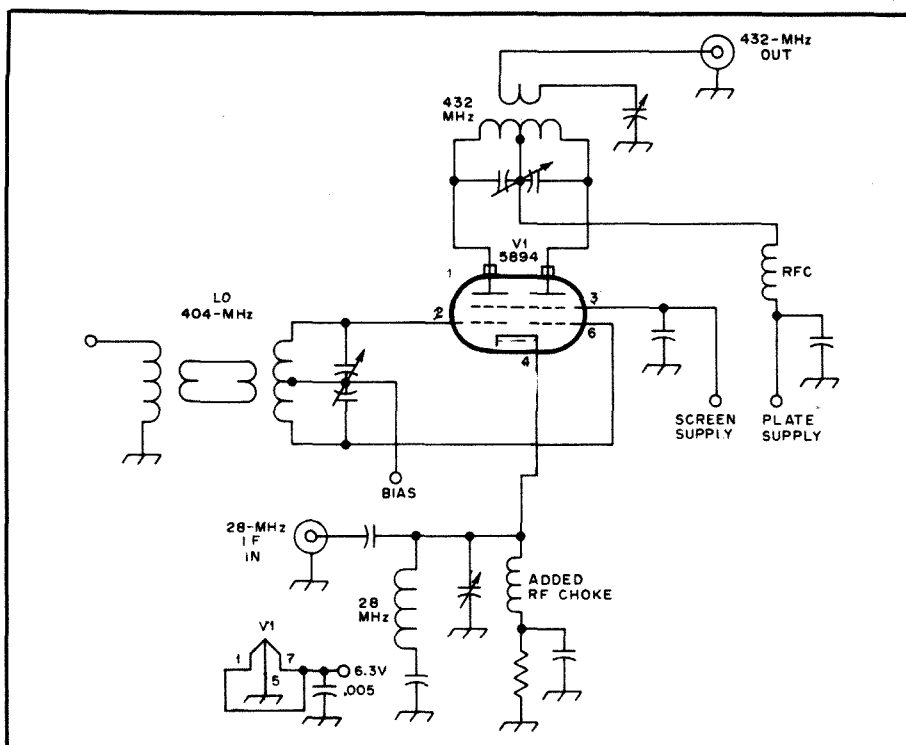

Fig. 11 — Partial schematic diagram of a 70-cm (432-MHz) mixer, built from a converted FM transmitter. The original oscillator-multiplier-driver stages of the unit now provide LO injection. A stripline filter should be used at the output of the mixer to prevent radiation of spurious products.

Fig. 12 — A representative drawing of the amplitude vs. frequency response that can be expected from a 5-element low-pass filter designed from the information contained in Tables 2 or 3. The exact amount of attenuation (theoretical) can be obtained from Table 1. This drawing shows how passband ripple and roll-off slope are interrelated.

tenuation values given here are theoretical and assume perfect components, no coupling between filter sections and no signal leakage around the filter. A "real life" filter should follow these values fairly close down to the 60- or 70-dB attenuation level. At this point the theoretical response will likely be degraded somewhat by the factors just mentioned. Once the filter design has been selected the builder

can refer to Tables 2 through 5 to obtain the normalized component values.

In many cases the calculated capacitor values will be sufficiently close to a standard value so that the standard-value item may be used. Alternatively, a combination of fixed-value silver-mica capacitors and mica compression trimmers can be used in parallel to obtain the chart values. Toroidal inductors, because of their self-shielding

properties, are ideal for use in these filters. Miniductor stock can also be used. However, it is much bulkier and will not offer the same degree of shielding between filter sections. Disc ceramic or paper

capacitors are not suitable for use in RF filters. Standard mica or silver-mica types are recommended.

Fig. 13 shows a filter that was designed with the information contained in Table 3.

Fig. 13 — A photograph of a 7-element low-pass filter designed with the information contained in Table 3. The filter is housed in a small aluminum Minibox.

It is a 7-element, low-pass type of pi configuration. The unit is housed in a small aluminum Minibox and makes use of BNC connectors for the input and output connections.

### Driver Stages

The choice between tubes and transistors in low-level amplifier and driver stages will depend on the nature of the composite transmitter. Some designs contain a mixture (hybrid) of tubes and semiconductors, while other circuits have no vacuum tubes at all. If tubes are used in a hybrid circuit, they are generally restricted to the driver and PA sections of the transmitter.

There is no reason why tubes should be used in preference to power transistors for output powers up to say, 150 watts, despite the prevailing myth that tubes are more rugged, operate more stably and produce less spurious output. It is true that transistors are less tolerant than tubes to SWR levels in excess of 2:1, but a correctly designed transistor amplifier can be operated safely if SWR-protection circuitry is included. Furthermore, spectral purity can be just as good from a solid-state amplifier as it is from a vacuum-tube amplifier. A harmonic filter normally follows a solid-state power stage, whereas this measure may not be required when tubes are used. Amplifier IMD (third- and fifth-order products) in solid-state power stages which operate linearly is fully as acceptable as that observed in most tube types of linear amplifiers. Typically, if a design is correct, the IMD will be on the order of -33 dB from the reference power value.

The major area of concern when designing a solid-state driver or PA section is to prevent low-frequency self-oscillations. Such parasitics tend to modulate the carrier and appear as spurious responses within the amplifier passband. The low-frequency parasitics occur as a result of the extremely high gain exhibited by HF and VHF transistors at the low-frequency end of the spectrum. The theoretical gain increase for a given transistor is 6 dB per octave as the operating frequency is lowered. The same is not true of vacuum tubes. Therefore, it is necessary to employ

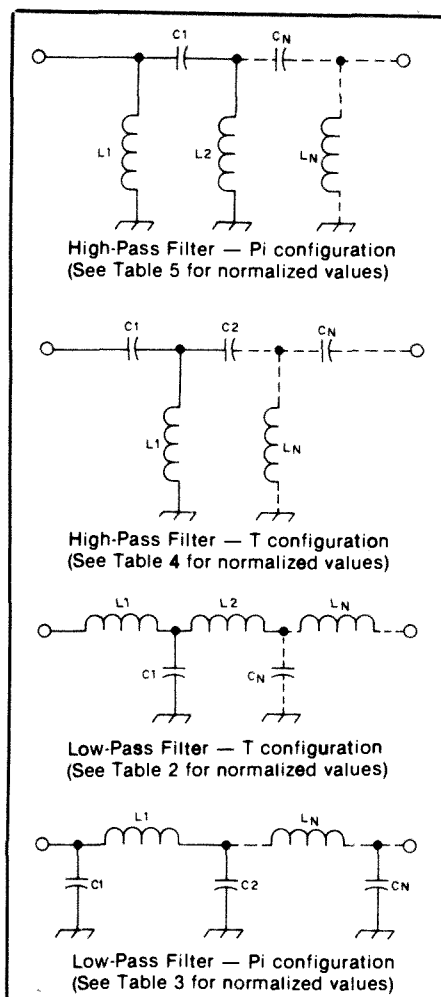

Fig. 14 — Shown here are the four filter types discussed in the text and Tables 1 through 5.

quality decoupling and bypassing in the circuit. It is similarly important to use low-Q, low-inductance RF chokes and matching networks to discourage low-frequency tuned-base, tuned-collector oscillations. The suppression concepts just discussed are illustrated in Fig. 15 at B and C. In the circuit at B there are two 950-mu ferrite beads added over the pigtail of RFC1 to swamp the Q of the choke. Three bypass capacitors (0.001, 0.01 and 0.1  $\mu$ F) are used with RFC2 of Fig. 15B to provide effective RF decoupling from VHF to MF. A 22- $\mu$ F capacitor is used near RFC2 to bypass the + $V_{cc}$  line at low frequency and audio. This method is recommended for each high-gain solid-state stage in a transmitter.

#### Driver Circuits

The circuits of Fig. 15A and 15B are typical of those that would be employed to excite a tube-type PA stage. The 6GK6 tube driver at A can be biased for Class C or Class AB operation, making it suitable for CW or SSB service. Of course, the AB mode would be suitable for CW and SSB, and would require considerably less excitation power than would the same stage

operating in Class C. Other tubes that perform well in this circuit are the 6CL6, 12BY7A and 5763. The output tank is designed for high impedance so it will interface properly with the high-impedance grid of the PA. It may be necessary to include a neutralization circuit with this type of amplifier, especially if care is not exercised in the layout. The high transconductance of the 6GK6 series encourages self-oscillation near the operating frequency. Z1 is a parasitic choke that should be included as a matter of course to prevent VHF parasitics.

A transistor amplifier suitable for driving a Class C tube PA is presented in Fig. 15B. Q1 operates Class C, so it is not satisfactory for amplifying SSB energy. However, forward bias (approximately 0.7 volt) can be added between the emitter and ground to move the operating curve into the Class AB (linear) region, thereby making the stage suitable for SSB signal amplification. A 1.5-ohm resistor can be added between the emitter and ground to help prevent thermal runaway and to introduce degeneration

(feedback) for enhancing stability. No bypass capacitor would be used from emitter to ground if this were done. T1 is a narrow-band toroidal RF transformer that has a turns ratio suitable for transforming the collector impedance to the grid impedance (determined by the value of the grid resistor of the PA) of the final amplifier. The secondary winding of T1 is tuned to resonance at the operating frequency. Approximately 1 watt of output can be taken from Q1 in the HF region when a 12-volt  $V_{cc}$  is used. This is ample power for driving a pair of 6146B tubes in Class AB1.

A broadband solid-state driver is shown in Fig. 15C. The trade-off for broadband operation (1.8 to 30 MHz in this example) is a reduction in maximum available gain. Therefore, the output from Q1 of Fig. 15C will be less than 1 watt. The stage operates Class A, making it linear. The emitter is unbypassed to provide emitter degeneration. Shunt feedback is used between the base and collector to enhance stability and contribute to the broadband characteristic the

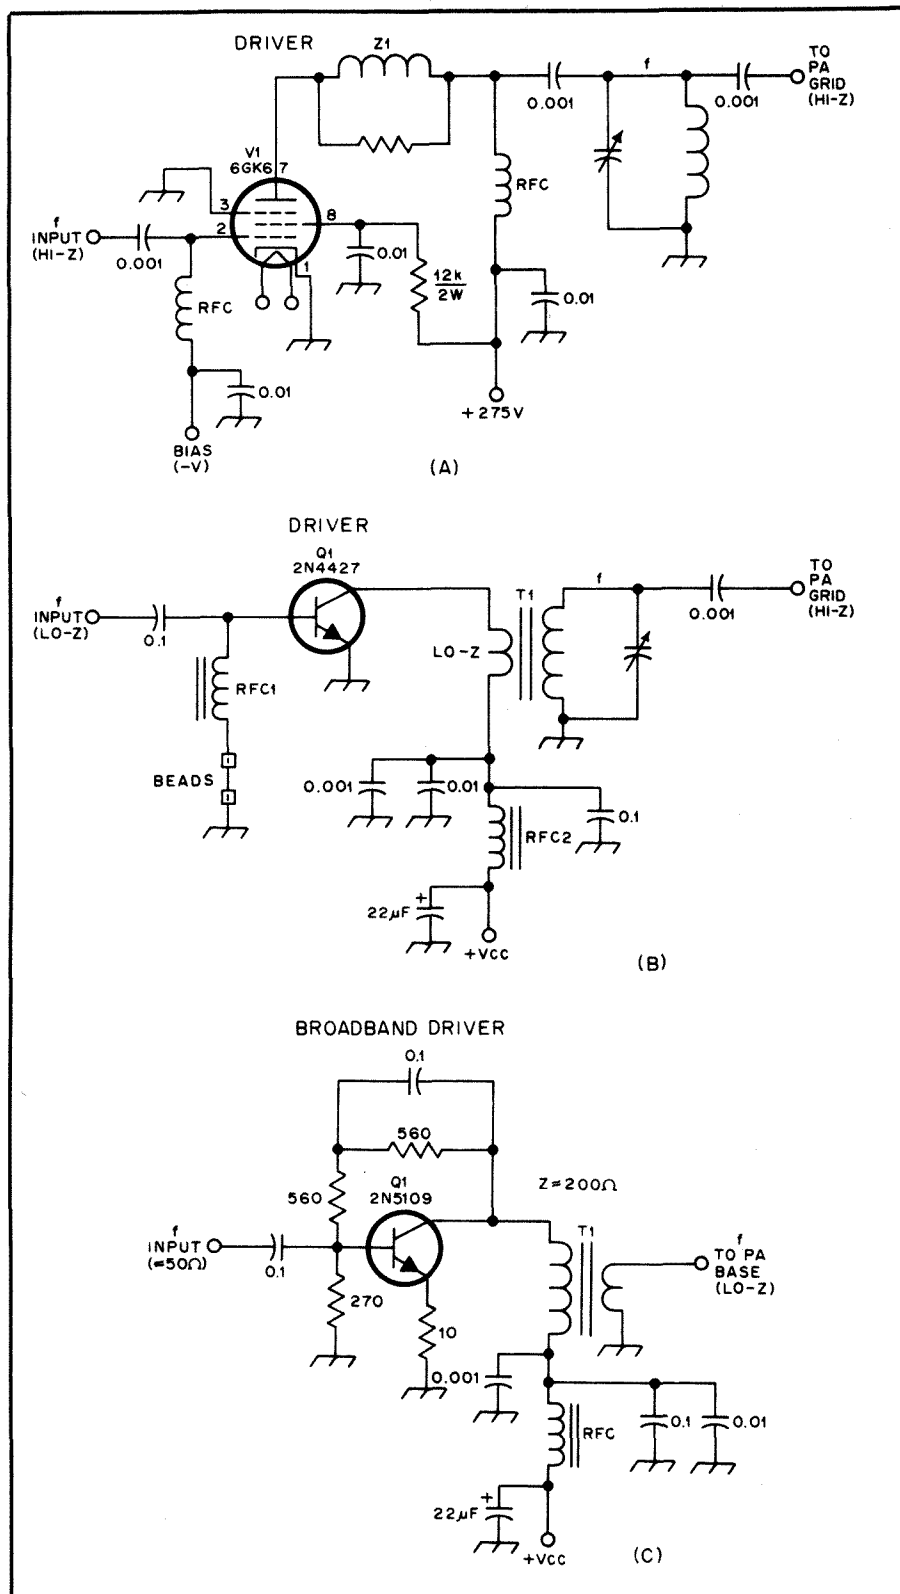

Fig. 15 — Circuit examples of transistor and tube driver stages for use in transmitters.

circuit. T1 is a conventional broadband transformer wound on a toroid core. The turns ratio is adjusted to match the approximate 200-ohm collector impedance to the base impedance of the transistor PA stage — typically less than 5 ohms. Heat sinks are required for the transistors of Fig. 15B and C. The primary of T1 should have

a reactance of roughly four times the collector impedance at the lowest proposed operating frequency. Therefore, for 1.8 MHz the primary winding would be 70 μH ( $X_L = 800$  ohms). This can be achieved easily by using an FT50-43 Amidon core. The primary advantage to a broadband driver is that it need not be band-switched

or peaked by means of a front-panel control. The transistor selected for broadband service should have very high  $f_T$  and beta ratings. Transistors designed for UHF service are excellent as HF amplifiers when broadbanding is contemplated. Neutralization is not necessary when using bipolar-transistor amplifiers.

A practical three-stage broadband amplifier strip is shown schematically in Fig. 16. With an input level of 10 mW, it is possible to obtain 1.4 watts of output from 3.5 to 29 MHz. A keying transistor (Q4) is included for turning the amplifier off by means of a VOX, or for keying it during CW operation.

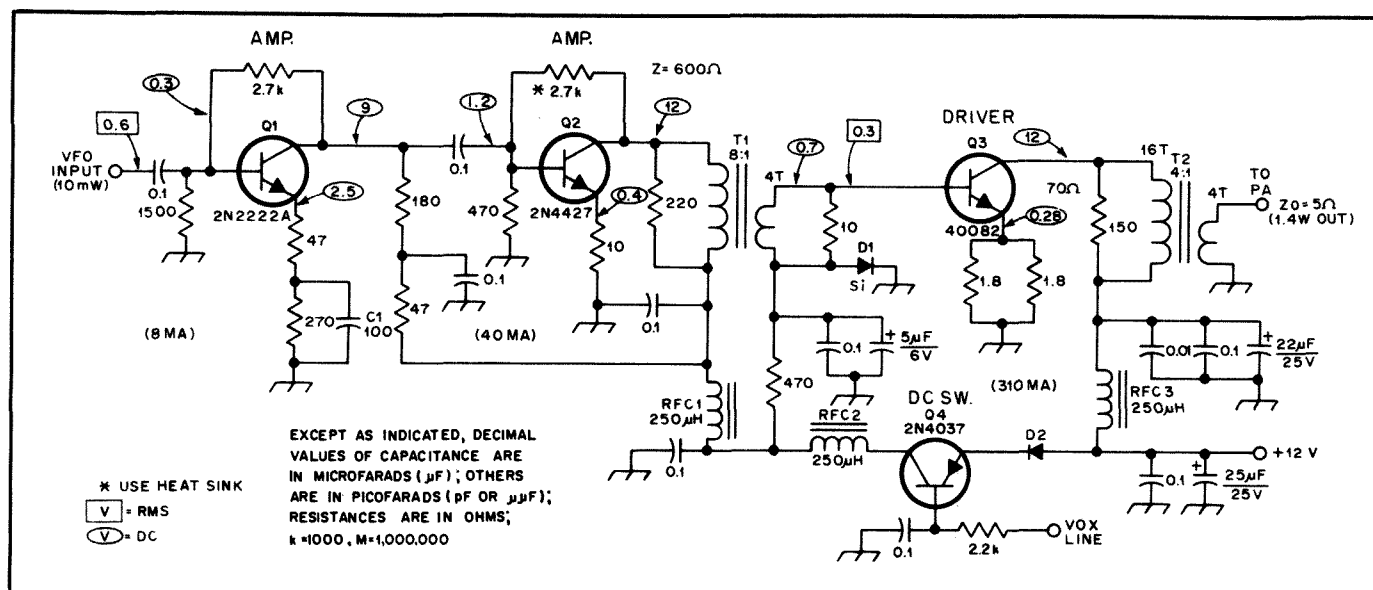

RMS and dc voltages are noted on the diagram of Fig. 16 to aid in troubleshooting. Overall gain for the strip at 7 MHz is 31 dB, with slight gain variations elsewhere in the passband. T1 consists of 30 turns of no. 28 enameled wire (primary) on an FT50-43 toroid core. The secondary has four turns of no. 28 wire. T2 uses 16 turns of no. 28 enameled wire (primary) looped through an Amidon BLN-43-302 ferrite balun core. The secondary contains four turns of no. 28 wire. RFC1, RFC2 and RFC3 are 250-μH units. They are made by winding 20 turns of no. 28 enameled wire on FT37-43 toroid cores. D1 and D2 are 1-A, 50-P1V rectifier diodes. This driver was designed to excite a Motorola MRF449A PA stage to a power-output range from 15 to 30 watts. C1 at the emitter of Q1 can be selected to provide the overall gain needed in this strip. The value given at C1 proved suitable for the ARRL version of this amplifier. The final value will depend on the gain of the individual transistors acquired for this circuit.

#### Coupling Between Transmitter Stages

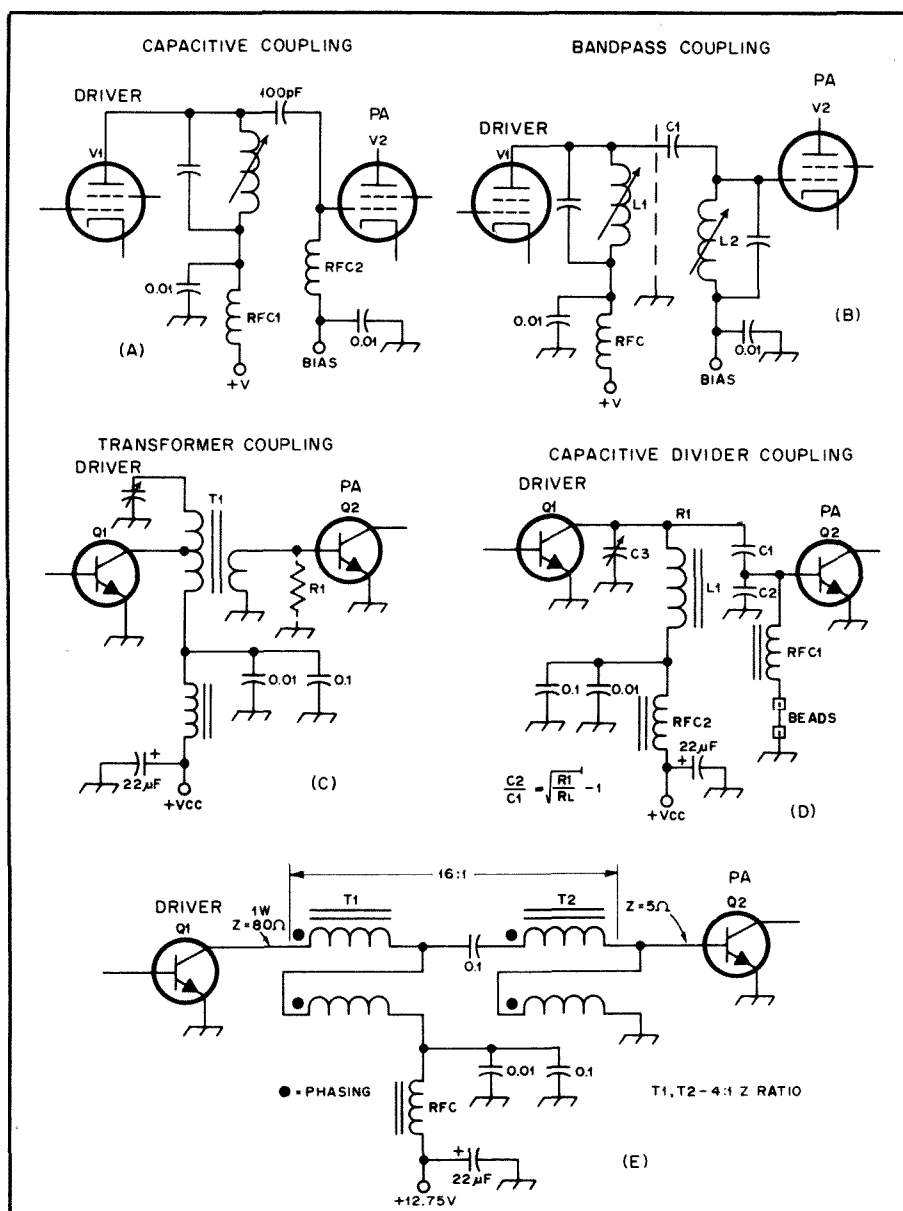

Correct impedance matching between a stage and its load provides maximum transfer of power. The load can be an antenna or a succeeding stage in a transmitter. Thus, the output impedance of a stage must be matched to the input of the following stage. Various forms of coupling networks are popular for use in tube or transistor circuits. The choice will depend on a number of considerations — available driving power versus tolerable mismatch, the selectivity required and impedance matching can be approximated by

$$Z = \frac{V_{cc}^2}{2P_o}$$

where  $Z$  is in ohms and  $P_o$  is the power output from the stage. However, determining the input impedance of the base of the following stage is difficult to do without expensive laboratory equipment. Generally, when the PA delivers more than 2 watts of output power, the base impedance of that stage will be less than 10 ohms — frequently just 1 or 2 ohms. For this reason, some kinds of LC matching networks do not lend themselves to the application. Furthermore, with the precise input impedance

of a transistor power amplifier not known, it becomes desirable to use what is sometimes referred to as a “sloppy” matching network. This is an LC network in which both the inductance and capacitance elements are variable to allow wide range of adjustment for matching. On the other hand, some designers purposely introduce a mismatch between stages to control the power distribution and aid stability. When this technique is used, it is necessary to have more driving power than would be needed under a matched condition. An intentional mismatch results in a trade-off between gain and the desired end effect of introducing a mismatch.

**Fig. 17 — Typical coupling methods for use between amplifier stages. See text.**

manufacturer's data sheet. The impedance values depend on the operating frequency and power level of the transistor — a very complex set of curves. Most data sheets list specific values of input and output capacitance, which do not vary with the operating frequency or power level.

The interstage coupling method shown in Fig. 17A is a common one when vacuum tubes are employed. The driver plate has a tuned circuit that is resonant at the operating frequency. A low-value coupling capacitor (100 pF in this example) routes the drive from the plate of V1 to the grid of V2 across a high-impedance element, RFC2. RFC1 is used as part of the decoupling network for the supply voltage to V1.

Band-pass coupling between tube stages is demonstrated at Fig. 17B. C1 has a very small capacitance value and is chosen to provide a single-hump response when the two resonators (L1 and L2) are peaked to the operating frequency. The principal advantage to this circuit over that of Fig. 17A is greater purity of the driving energy to V2 by virtue of increased selectivity. As an alternative to capacitive coupling (C1), link coupling can be used between the cold ends of L1 and L2. Similar band-pass networks are applicable to transistor stages. The collector and base of the driver and PA stages, respectively, would be tapped down on L1 and L2 to minimize loading. This helps preserve the loaded Q of the tuned circuits, aiding selectivity.

A common form of transformer coupling is shown in Fig. 17C. T1 is usually a toroidal inductor for use up to approximately 30 MHz. At higher frequencies it is often difficult to obtain a correct impedance ratio. Depending on the total number of transformer turns used, the secondary might call for less than one turn, which is impractical. However, for most of the spectrum up to 30 MHz this technique is entirely satisfactory. The primary tap on T1 is chosen to transform the collector impedance of Q1 to the base impedance of Q2 by means of the turns ratio between the tapped section and the secondary winding of the transformer. If there is a tendency toward self-oscillation, R1 may be added in shunt with the secondary to stabilize Q2. The value used will be in the 5- to 27-ohm range for most circuits. The rule of thumb is to use just enough resistance to tame the instability.

A method for coupling between stages by means of a capacitive divider is illustrated in Fig. 17D. The net value of C1 and C2 in series must be added to the capacitance of C3 when determining the inductance required for resonance with L1. The basic equation for calculating the capacitance ratio of C1 and C2 is included in the diagram. RFC1 serves as a dc return for the base of Q2. The Q of the RF choke is degraded intentionally by the addition of two 950-mu ferrite beads. This aids stability, as discussed earlier in this chapter.

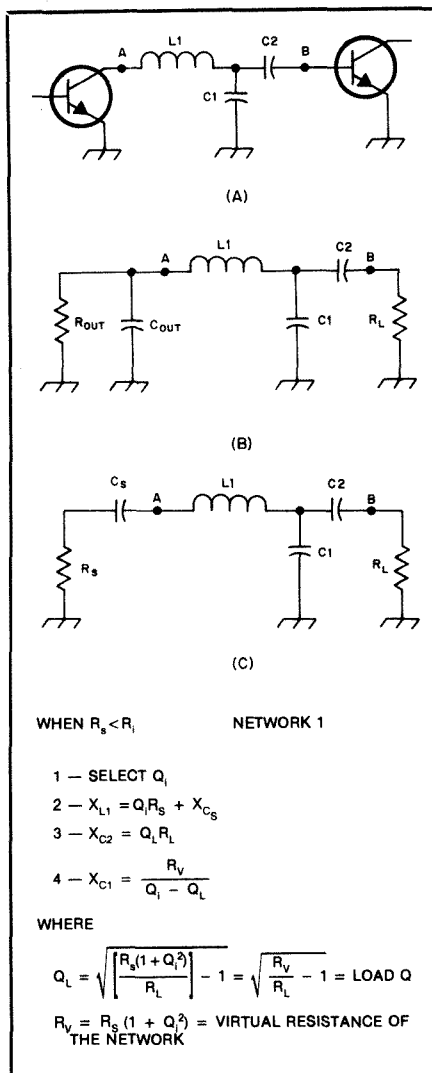

Fig. 18 — Circuit and mathematical solution for matching network no. 1. Actual circuit (A), parallel equivalent (B) and series equivalent (C).

An advantage to using this type of circuit is that VHF and UHF parasitics are discouraged and harmonic currents are attenuated when C2 is fairly high in capacitance. This is not true of the circuit in Fig. 17C.

When the impedance levels to be matched are of the proper value to permit employing specific-ratio broadband transformers, the circuit of Fig. 17E is useful. In this example, two 4:1 transformers are used in cascade to provide a 16:1 transformation ratio. This satisfies the match between the 80-ohm collector of Q1 and the 5-ohm base of Q2. The shortcoming of this technique is the lack of selectivity between stages, but the advantage is in the broadband characteristic of the coupling system. The phasing dots on the diagram near T1 and T2 indicate the correct electrical relationship of the transformer windings.

#### Network Equations

The three networks shown in Figs. 18,

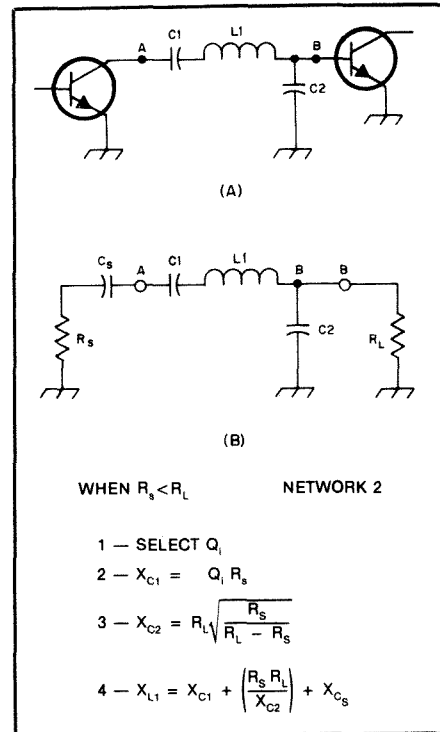

Fig. 19 — Circuit and equations for network no. 2. Actual circuit (A) and series equivalent (B).

Fig. 20 — Network-solution equations and circuit for network no. 3. Actual circuit (A) and series equivalent (B).

19 and 20 will provide practical solutions to many of the impedance-matching problems encountered by amateurs. In each of the figures it is assumed that the output

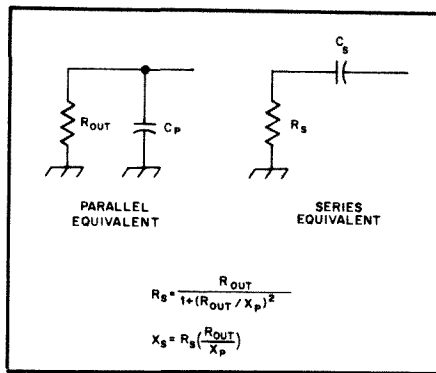

Fig. 21 — Parallel and series equivalent circuits and the formulas used for conversion.

impedance being matched is lower than the input impedance of the following stage. If this is not the case, the network (the circuit elements between the points marked A and B) can be turned around to provide the correct transformation.

Normally, the output impedance of a transistor is given as a resistance in parallel with a capacitance,  $C_{out}$ . To use the design equations for these three networks, the output impedance must first be converted from the parallel form ( $R_{out}$  and  $C_{out}$ ) to the equivalent series form ( $R_s$  and  $C_s$ ). These equivalent circuits and the equations for conversion are given in Fig. 21. Often the output capacitance is small enough that it may be neglected; the resulting error is compensated for by using variable components in the network.

The low-pass T network (Fig. 20) has the advantage of matching a wide range of impedances with practical component values. Some designers feel that of the various networks used in solid-state work, the T network is best in terms of collector efficiency. The harmonic suppression afforded by the T network varies with the transformation ratio and the total Q of the network. For stages feeding an antenna, additional harmonic suppression will normally be needed. This is also true for networks 1 and 2. These three networks are covered in detail in *Motorola Application Note AN-267*. Another excellent paper on the subject was written by Becciolini, *Motorola Application Note AN-271*.

The equations for networks 1, 2 and 3 were taken from AN-267. That paper contains computer solutions to these networks and others, with tabular information for various values of Q and source impedances. A fixed load value of 50 ohms is the base for the tabular data.

A design example for network 3 is given in Fig. 22. The solutions for the other two networks follow the same general trend, so examples for networks 1 and 2 will not be given. In Fig. 22 the component " $C_{out}$ " is taken from the manufacturer's data sheet. If it is not available, it can be ignored at the expense of a slight mathematical error in the network determination. By making

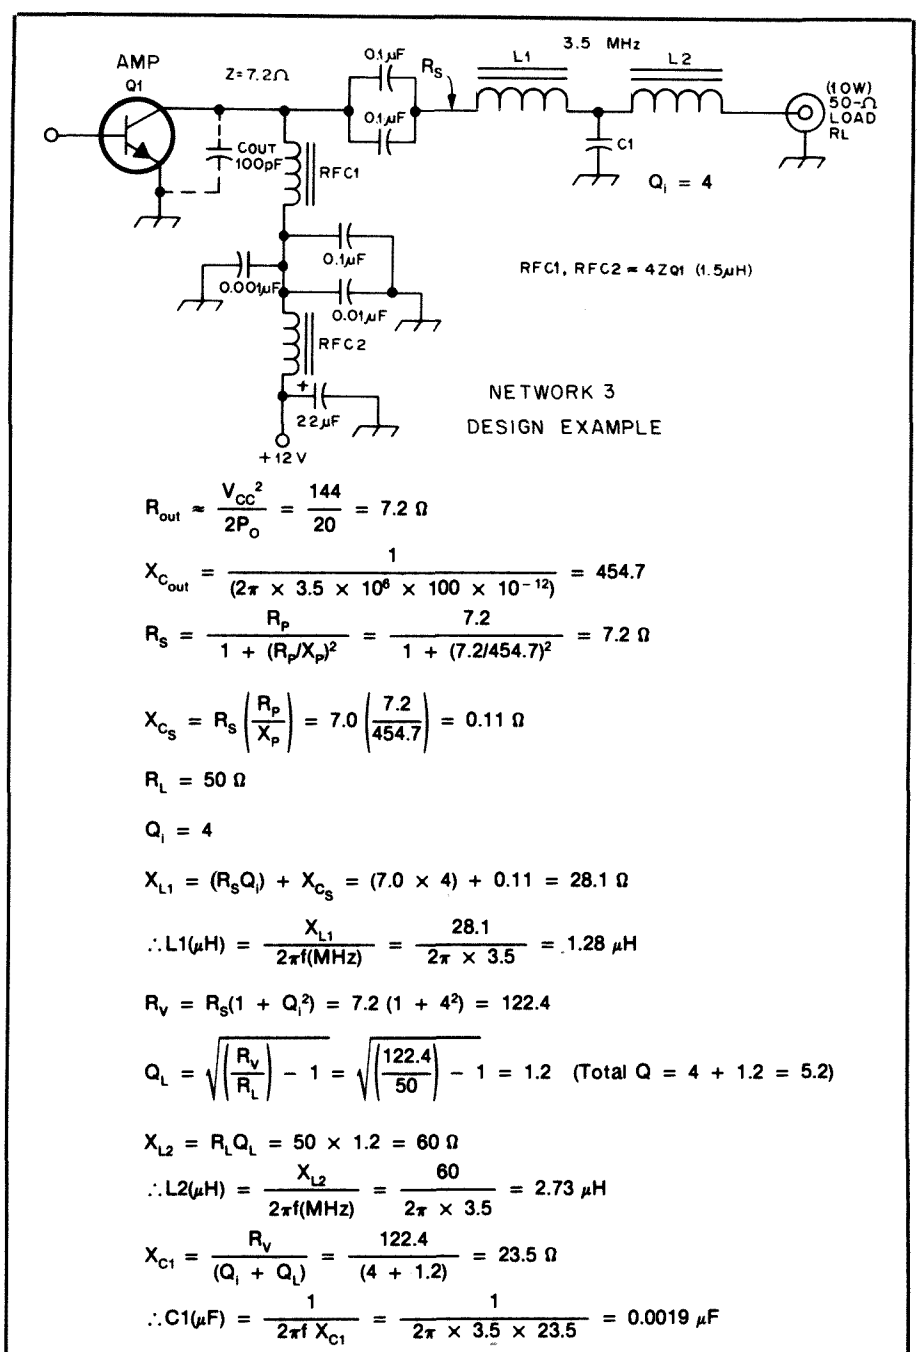

Fig. 22 — A practical example of network no. 3 and the solution to the network design.

$C1$  variable the network can be made to approximate the correct transformation ratio. At the lower frequencies  $C1$  will be fairly large in value. This may require a fixed-value silver-mica capacitor in parallel with a mica compression trimmer to obtain the exact value of capacitance needed. The equations will seldom yield standard values of capacitance.

$L1$  and  $L2$  of Fig. 22 can be wound on powdered-iron toroid cores of suitable cross-sectional area for the power involved. This is explained in an earlier chapter of this book.  $L1$  and  $L2$  should be separated by mounting them apart and at right angles. Alternatively, a shield can be used

between the inductors. This will prevent unwanted capacitive and inductive coupling effects between the input and output terminals of the network. Despite the self-shielding nature of toroidal inductors, some coupling is possible when they are in close proximity.

### Broadband Transformers

Toroidal broadband transformers are very useful in a great many amateur applications. Some of the more popular transformer configurations are presented here for those who wish to use them in matching networks associated with solid-state devices and tubes. It is important to

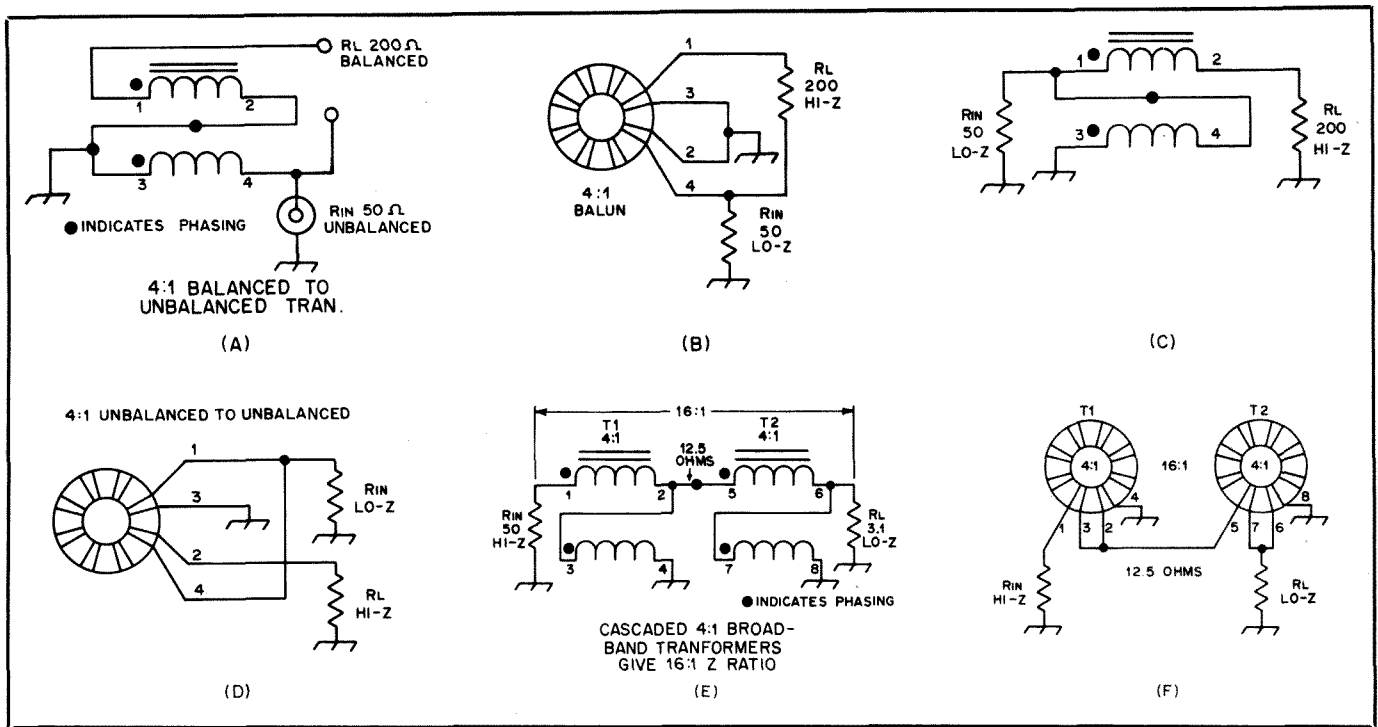

Fig. 23 — Circuit illustrations of 4:1 broadband transformers.

realize that broadband transformers are best suited to low-impedance applications, say, up to a few hundred ohms. They should be thought of as devices that can transform one impedance to another, in terms of their transformation ratio. They should not be regarded as devices that are built for some specified pair of impedances, such as 200 ohms to 50 ohms in the case of a 4:1 transformer. The term “balun” pertains only to a broadband transformer that converts a balanced condition to one that is unbalanced, or vice versa.

The broadband transformers illustrated in Figs. 23, 24 and 25 are suitable for use in solid-state circuits, as matching devices between circuit modules and in antenna-matching networks. For low power levels the choice of core material is often ferrite. Powdered-iron is more often the designer's preference when working with high power levels. The primary reason to avoid ferrite at high power is the potential for damage to the core material during saturation and overheating. This can alter the permeability factor of the core material permanently. Powdered-iron is more tolerant in this regard.

Fig. 23 shows two types of 4:1 transformers, plus a method for connecting two of them in series to effect a 16:1 transformation. The circuit at E is often used between a 50-ohm source and the base of an RF power transistor.

Two styles of 9:1 transformer are shown in Fig. 24 at A and C. They are also found at the input to transistor amplifiers and between the collector and the load. The variable-ratio transformer of Fig. 24C is ex-

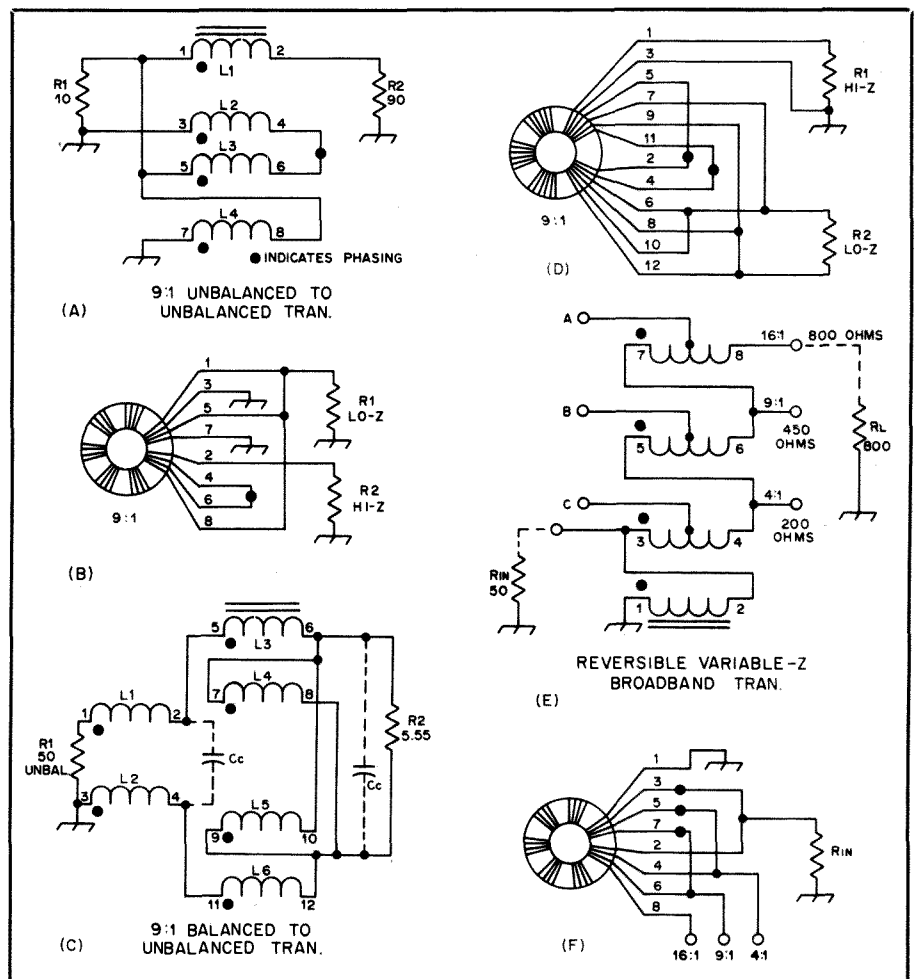

Fig. 24 — Circuit examples of 9:1 broadband transformers (A and C) and a variable-impedance transformer (E).

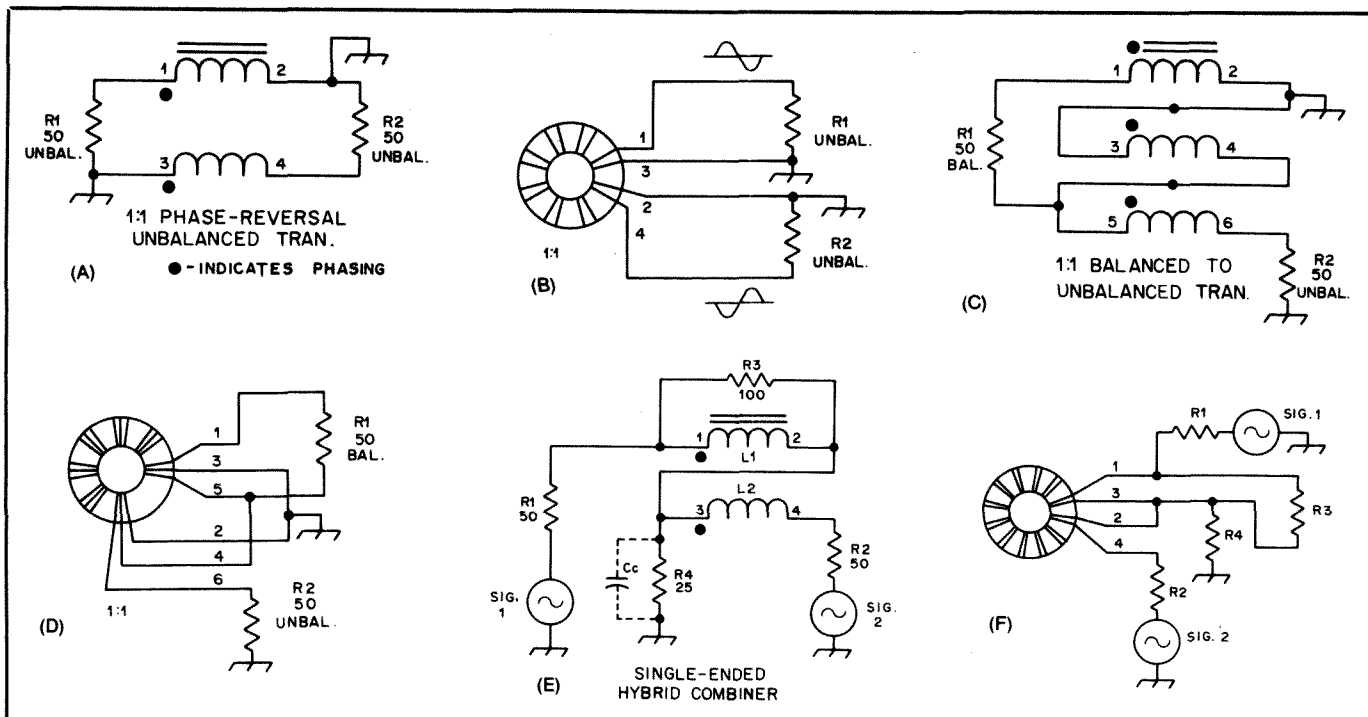

Fig. 25 — Assorted broadband transformers.

cellent for obtaining a host of impedance transformations. This transformer was developed by W2FMI for use in matching ground-mounted vertical antennas.

Phase-reversal, 1:1 balun and hybrid-

combiner transformers are shown in Fig. 25. The circuit at E of Fig. 25 is useful when it is necessary to feed two signals to a single load. When the input signals are on different frequencies, the power is split evenly

between R3 and R4. When the input voltages are on the same frequency (as with two transistor amplifiers feeding a single load), with the amplitudes and phase identical, all of the power is delivered to R4.

# Radio Receiving Principles

**H**ow good should receiver performance be? A suitable answer might be, "As good as is possible, consistent with the state of the amateur art and the money available to the purchaser." That opens up a wide area for debate, but the statement is not meant to imply that a receiver has to be costly or complex to provide good performance: Some very basic, inexpensive homemade receivers offer outstanding performance.

For many years the evolution of commercial amateur receivers seemed to stagnate except for the window dressing and frills added to the front panels. Emphasis was placed on "sensitivity" (whatever was really meant by that term) in the advertising. Some amateurs concluded (as a result of the strong push for sensitive receivers) that the mark of a good unit was seen when atmospheric noise on the HF bands could push the S-meter needle up to an S2 or S3. Very little thought, if any, was given to the important parameters of a receiver — high dynamic range, fine readout resolution and frequency stability. Instead, receivers were placed on the market with 5- or 10-kHz dial increments and excessive amounts of front-end gain. The excessive gain caused the mixer (or mixers) to collapse in the presence of moderate and strong signals.

Double-conversion superheterodyne receivers were for a long time the choice of manufacturers and amateurs. The second IF was often 100 or 50 kHz, thereby enabling the designer to get fairly reasonable orders of selectivity by means of high-Q IF transformers. That concept predated the availability of crystal-lattice and mechanical filters. The low-frequency second IF dictated the use of a double-conversion circuit in order to minimize image responses.

Single-conversion receivers offer much cleaner performance in terms of spurious responses and dynamic range. Although their performance is acceptable in many instances, there is considerable room for improvement. At least there is only one mixer to cause intermodulation-distortion (IMD) and overloading problems in a single-conversion superheterodyne receiver. A

strong doubly balanced mixer (DBM) and careful gain distribution in such a receiver can yield superb performance. Of course, the local oscillator should be stable and low in noise components to further enhance performance. Thus far, not many commercially built amateur receivers meet these criteria. In terms of dynamic range, some manufactured receivers exhibit an MDS (minimum discernible signal) of  $-145$  dBm (referenced to the noise floor); blocking of the desired signal does not occur (1 dB of compression) until the adjacent test signal is some 116-dB above the noise floor, and the two-tone IMD dynamic range is on the order of 85 dB. Greater detail concerning this measurement technique is given in Chapter 25. A receiver with the approximate figures just given is considered to be an acceptable one for use where fairly strong signals prevail. However, improvements over those numbers have been achieved by amateurs who designed and built their own receivers.

### VHF and UHF

Adequate receiving capability is essential in VHF and UHF communications. This is true whether the station is a transceiver or a combination of separate transmitting and receiving units, regardless of the modulation system used. Transceivers and FM receivers are treated separately in this Handbook, but their performance involves basic principles that apply to all receivers for frequencies above 30 MHz. Important attributes are good signal-to-noise ratio (low noise figure), adequate gain, stability and freedom from overloading and other spurious responses.

A VHF station often has an HF-band communications receiver, with a crystal-controlled converter for the desired VHF band ahead of it. The HF receiver serves as a tunable IF system, complete with detector, noise limiter, BFO and audio amplifier.

Choice of a suitable communications receiver for use with converters should not be made lightly. A good receiver for this purpose has all the characteristics of a good HF receiver. The special requirements of FM phone are discussed in Chapter 18.

Good mechanical design and frequency stability are important. Image rejection should be high in the converter output range. This may rule out 28 MHz with single-conversion receivers having 455-kHz IF systems.

This suggests strongly that amateurs consider designing and building their own receivers. Certainly, this is within the capability of many experimenters. The satisfaction derived from such an effort can't be measured. The following sections of this chapter are written for those who wish to acquire a better understanding of how a practical receiver operates. Design data and related philosophy are included for those who are inspired toward developing a homemade receiver.

### Sensitivity

One of the least understood terms among amateurs is sensitivity. In a casual definition the word refers to the ability of a receiver to respond to incoming signals. It is proper to conclude from this that the better the sensitivity, the more responsive the receiver will be to weak signals. The popular misconception is that the greater the receiver front-end gain, the higher the sensitivity. An amateur who subscribes to this concept can ruin the performance of a good receiver by installing a high-gain preamplifier ahead of it. Although this will cause the S meter to read much higher on all signals, it can actually degrade the receiver sensitivity if the preamplifier is of inferior design (noisy).

A true measure of receiver sensitivity is obtained when the input signal is referenced to the noise generated within the receiver. Since the significant noise generated inside a receiver of good design originates in the RF and mixer stages (sometimes in the post-mixer amplifier), a low-noise front end is vital to high sensitivity. The necessary receiver gain can be developed after the mixer — usually in the IF amplifier section. The internal noise is generated by the thermal agitation of electrons inside the tubes, transistors or ICs. It is evident from this discussion that a receiver of high sensitivity could be one with relatively low front-end gain. This thought should be kept in

Fig. 1 — Relationship between noise figure and noise temperature.

mind as we enter the discussion of dynamic range and noise figure.

### Noise Temperature, Noise Factor and Noise Figure

The lower the receiver noise figure (NF), the more sensitive it is. Receiver noise figures are established primarily in the RF amplifier and/or mixer stages. Low-noise active devices (tubes or transistors) should be used in the receiver front end to help obtain a low noise figure. The unwanted noise, in effect, masks the weaker signals and makes them difficult to copy. Noise generated in the receiver front end is amplified in the succeeding stages along with the signal energy. Therefore, in the interest of sensitivity, internal noise should be kept as low as possible.

Don't confuse external noise (man-made and atmospheric, which comes in on the antenna) with receiver noise during discussions of noise figure. Although the ratio of the external noise to the incoming signal level has a lot to do with reception, external noise does not relate to this general discussion. It is because external noise levels are quite high on 160, 80, 40 and 20 meters that emphasis is seldom placed on a low receiver noise figure for those bands. However, as the operating frequency is increased from 15 meters up through the microwave spectrum, the matter of receiver noise becomes a primary consideration. At these higher frequencies the receiver noise almost always exceeds that from external sources, especially at 2 meters and above.

Receiver noise is produced by the movement of electrons in any substance (such as resistors, transistors and FETs) that has

a temperature above absolute zero ( $-273^{\circ}\text{C}$  or  $0\text{ K}$ ). Electrons move in a random fashion colliding with relatively immobile ions that make up the bulk of the material. The final effect is that in most substances there is no net current in any particular direction on a long-term average, but rather a series of random pulses. These pulses produce what is called thermal agitation noise, thermal noise or Johnson noise.

As the currents caused by electron movement increase with temperature, so does the noise power. Also, as the pulses are random, they spread out over a broad frequency spectrum. As it turns out, if we examine the power contained in a given passband, the value of that power is independent of the center frequency of the passband. This is expressed as

$$p = kTB$$

where  $p$  is the thermal noise power,  $k$  is Boltzmann's constant ( $1.38 \times 10^{-23}$  joule per K),  $T$  is absolute temperature in kelvins and  $B$  is the bandwidth in hertz. Notice that the power is directly proportional to temperature, and at  $0\text{ K}$  the noise power is zero.

Active devices normally exhibit noise temperatures different from their ambient temperatures. The thermal noise produced by a semiconductor device will limit its ability to respond to input signals below the level of the internally generated noise. Noise temperature, noise factor and noise figure are all measures of this device noise. The results are expressed in terms of temperature, ratios and decibels, respectively.

Consider a 50-ohm termination connected to the input of a device with the termination cooled to absolute zero. There would be no noise produced by this source, and the noise output from the device would be that of the internally generated noise. If the termination were now heated to a temperature that would raise the output noise of the device by 3 dB (thermal agitation noise equal to the internally generated noise of the device) and the temperature of the termination measured, the effective input noise temperature ( $T_E$ ) of the device would be this value. The noise temperature specification is independent of bandwidth and is directly proportional to noise power. For example, if we were to halve the noise temperature we would double the signal-to-noise ratio.

In order to convert a noise temperature measurement to noise figure, an intermediate calculation is required — noise factor ( $f$ ). Noise factor is by definition the ratio of the total output noise power to the input noise power when the termination is at the standard temperature of  $290\text{ K}$  ( $17^{\circ}\text{C}$ ). The noise power caused only by the input noise of the termination is simply the noise power of the source multiplied by the gain of the device. Mathematically

$$N_{\text{power input}} = GkBT_0$$

where  $G$  is the gain of the device and  $T_0$  is  $290\text{ K}$ . The total noise caused by the input noise of the termination and the internally generated noise is simply the sum of the two noise sources multiplied by the gain of the device, or

$$N_{\text{power total}} = GkB(T_0 + T_E)$$

where  $T_E$  is the effective input noise temperature and  $T_0$  is  $290\text{ K}$ . The noise factor ( $f$ ) is calculated as

$$f = \frac{N_{\text{power total}}}{N_{\text{power input}}}$$

where  $T_E$  is the effective input noise temperature and  $T_0$  is  $290\text{ K}$ . Noise figure can then be calculated as follows:

$$NF = 10 \log_{10} f = 10 \log_{10} \left( 1 + \frac{T_E}{T_0} \right)$$

where noise figure is expressed in decibels. Should the noise figure of the device be known and it is desired to find the noise temperature, the equation can be rearranged as follows:

$$T_E = 290 [\text{antilog}(NF/10) - 1] \text{K}$$

where noise figure is expressed in decibels. A graph illustrating the relationship between noise figure and noise temperature is given in Fig. 1.

Noise factor can also be represented in terms of signal-to-noise ratios as

$$f = \frac{S/N \text{ at input}}{S/N \text{ at output}}$$

and noise figure can be found from

$$NF = 10 \log_{10} f = 10 \log_{10} \frac{S/N \text{ at input}}{S/N \text{ at output}}$$

A receiving system consists of an interconnection of individual stages, some noisier than others. Each stage's noise contribution to the reduction of signal-to-noise ratio can be expressed as a noise figure. How much the noise figure of a particular stage affects system noise figure depends on the gain of the stages between that stage and the antenna. That is, if a stage's gain is sufficiently large, its noise figure will tend to override or "mask" the noise contribution of the stage following it. Mathematically, the noise factor of a receiving system can be expressed as

$$F = f_1 + \frac{f_2 - 1}{G_1} + \frac{f_3 - 1}{G_1 G_2} + \dots + \frac{f_n - 1}{G_1 \dots G_{n-1}}$$

where

$f_n$  = noise factor of the  $n^{\text{th}}$  stage  
 $G_n$  = gain of the  $n^{\text{th}}$  stage.

Brief analysis of this equation shows that the first stage of a receiving system is the most important with regard to noise figure. If the gain of this and succeeding stages is greater than unity, the denominator of each successive term becomes greater. The numerical value of terms beyond the second or third approaches zero and can be ignored.

It might seem that the more gain an RF amplifier has, the better the signal-to-noise ratio and therefore the better the reception. This is not necessarily true. The primary function of an RF amplifier is to establish the noise figure of the system. One good RF stage is usually adequate unless the mixer is a passive type with loss instead of gain. Two RF stages are the usual maximum requirement.

Once the system noise figure is established, any further gain necessary to bring a signal to audible levels may be obtained from intermediate-frequency stages or in the audio channel. Use the minimum gain necessary to set the overall receiver noise figure; this will help avoid overloading and spurious signals in subsequent stages.

Further examination of the equation points out the desirability of mounting the first stage of the receiver system at the antenna for VHF and UHF. The transmission line from the antenna to the receiver can be considered as a stage in the receiving system. The first stage of a receiving system makes the major contribution of noise figure to the system, so it is highly desirable that the first stage be a low-noise amplifier with gain. A transmission line is a "lossy" amplifier, and if placed at the first stage of a receiving system, automatically limits the system noise figure to that of the transmission line, at best. If the first RF amplifier is placed before the lossy transmission line stage, at the antenna, the amplifier gain will tend to mask the noise added by the transmission line.

### Noise-Figure Measurements

Amateurs can use a thermal noise source for determining receiver noise figure. The resistance of the noise-generator output must match that of the receiver input, 50 ohms to 50 ohms, for example. Fig. 2 shows a setup for making these measurements. The first reading is taken with the noise generator turned off. The receiver audio gain is adjusted for a convenient noise reading in decibels, as observed on the audio power meter. The noise generator is turned on next, and its output is increased until a convenient power ratio, expressed by  $N_2/N_1$ , is observed. The ratio  $N_2/N_1$  is referred to as the "Y-factor", and this noise figure measurement technique is commonly called the Y-factor method. From the Y-factor and output power of the noise generator, the noise figure can be calculated

$$NR = ENR - 10 \log_{10} (Y - 1)$$

where

NF = noise figure in decibels

ENR = excess noise ratio of the noise generator in decibels

Y = output noise ratio,  $N_2/N_1$ .

The excess noise ratio of the generator is

$$ENR = 10 \log_{10} \left( \frac{P_2}{P_1} - 1 \right)$$

where

$P_2$  = noise power of the generator

$P_1$  = noise power from a resistor at 290 kelvins.

If a thermionic diode such as a 5722 tube is used as the noise source, and if the circuit is operated in the "temperature-limited mode" (portion of the tube curve where saturation occurs, dependent on cathode temperature and plate voltage), the (excess) decibels can be calculated by

$$(\text{excess}) \text{ dB} = 10 \log_{10} (20 R_d I_d)$$

where

$R_d$  = the noise source output resistance

$I_d$  = the diode current in amperes.

Most manufacturers of amateur communications receivers rate the noise characteristics with respect to signal input. A common expression is  $S + \text{Noise/Noise}$ , or the signal-to-noise ratio. Usually the sensitivity is given as the number of microvolts required for an  $S + \text{Noise/Noise}$  ratio of 10 dB. Sensitivity can also be expressed in terms of the minimum discernible signal (MDS) or noise floor of the receiver. (See Chapter 25.)

Typically, the noise figure for a good receiver operating below 30 MHz runs about 5 to 10 dB. Lower noise figures can be obtained, but they are of no real value because of the external noise arriving from the antenna. It is important to remember also that optimum noise figure in an RF amplifier does not always coincide with maximum stage gain, especially at VHF and higher. This is why actual noise measurements must be used to peak for best noise performance.

### Selectivity

Many amateurs regard the expression "selectivity" as equating to the ability of a receiver to separate signals. This is a fundamental truth, particularly with respect to IF selectivity which has been established by means of high-Q filters (LC, crystal, monolithic or mechanical). But in a broader sense, selectivity can be employed to reject unwanted signal energy in any part of a receiver — the front end, IF section, audio circuit or local-oscillator chain. Selectivity is a relative term, since the degree of bandwidth can vary from a few hertz to more than a megahertz, depending on the design objectives. Therefore, it is not uncommon to hear terms like "broadband

Fig. 2 — Block diagram of a noise measurement setup.

Fig. 3 — A curve and equation for determining the unloaded Q of a tuned circuit.

filter" or "narrow-band filter."

The degree of selectivity is determined by the bandwidth of a filter network. The bandwidth is normally specified for the minus 3-dB points on the filter response curve; the frequencies where the filter output power is half the peak output elsewhere in the passband. The difference in frequency between a minus 3-dB point and the filter center frequency is known as  $\Delta f$ . The bandwidth of the filter then becomes  $2 \Delta f$ . Fig. 3 illustrates this principle and shows how the unloaded Q of a tuned circuit or resonator relates to the bandwidth characteristic.

If a tuned circuit is used as a filter, the higher its loaded Q, the greater the selectivity. To make the skirts of the response curve steeper, several high-Q resonators can be used in cascade. This aids the selectivity by providing greater rejection of signals close in frequency to the desired one. The desirable effect of cascaded filter sections can be seen in Fig. 4. The circuit is that of a tunable Cohn type of three-pole filter for use in the front end of a 160-meter receiver. The response curve is included to illustrate the selectivity obtained.

An ideal receiver with selectivity applied to various significant parts of the circuit might be structured something like this:

a) Selective front end for rejecting out-of-band signals to prevent overloading and spurious responses.

Fig. 4 — A tunable Cohn-type filter is shown at A. L5 and L6 are the bottom-coupling inductors (1.45  $\mu$ H). L1 and L4 are 70 pH and L2, L3 are 140  $\mu$ H. A response curve for the tunable filter is given at B.

b) Selective IF circuit (two IF filters: one for 2.4-kHz SSB bandwidth and one for 300-Hz CW and RTTY bandwidth).

c) RC active or passive audio filter for audio selectivity to reduce wideband noise and provide audio selectivity in the range from 300 to 2700 Hz (SSB), 2100 to 2300 Hz (or 1250 to 1450 Hz), for RTTY and a very narrow bandwidth, such as 750 to 850 Hz, for CW.

d) Selective circuits or filters in the local oscillator chain to reject all mixer injection energy other than the desired frequency.

This illustrates clearly that selectivity means more than the ability of a receiver to separate one amateur signal from another that is nearby in frequency. Specifically, it means that selectivity can be used to select one frequency or band of frequencies while rejecting others.

#### Selectivity at VHF

Ever-increasing occupancy of the radio spectrum brings with it a parade of receiver overload and spurious responses. Overloading problems can be minimized by the use of high-dynamic-range receiving techniques, but spurious responses such as

Fig. 5 — Round and square helical resonators, showing principal dimensions. Diameter, D (for side, S) is determined by the desired unloaded Q. Other dimensions are expressed in terms of D (or S) as described in the text.

the image frequency must be filtered out before mixing occurs. Conventional tuned circuits cannot provide the selectivity necessary to eliminate the plethora of signals found in most urban and many suburban neighborhoods. Other filtering techniques must be used.

Although some amateurs use quarter-wavelength coaxial cavities on 50, 144 and 220 MHz, the helical resonators shown in Fig. 5 are usually a better choice as they are smaller and easier to build. In the frequency range from 30 to 100 MHz, where it's difficult to build high-Q inductors, and because coaxial cavities are very large, the helical resonator is an excellent choice. At 50 MHz, for example, a capacitively tuned, quarter-wavelength coaxial cavity with an unloaded Q of 3000 would be about 4 inches in diameter and nearly 5 feet long. On the other hand, a helical resonator with the same unloaded Q is about 8.5 inches in diameter and 11.3 inches long. Even at 432 MHz, where coaxial cavities are common, the use of a helical resonator will result in substantial size reductions. The following design information on helical resonators originally appeared in a June 1976 *QST* article by W1HR.

The helical resonator has often been described simply as a coil surrounded by a shield, but it is actually a shielded, resonant section of helically wound transmission line with relatively high characteristic impedance and low axial propagation velocity. The electrical length is about 94 percent of an axial quarter wavelength, or 84.6 electrical degrees. One lead of the helical winding is connected directly to the shield, and the other end is open circuited as shown in Fig. 5. Although the shield may be any shape, only round and square shields will be considered in this section.

#### Design

The unloaded Q of a helical resonator is determined primarily by the size of the shield. For a round resonator with a copper coil on a low-loss form, mounted in a

copper shield, the unloaded Q is given by

$$Q_u = 50 D \sqrt{f_o}$$

where D = inside diameter of the shield in inches and  $f_o$  = frequency in MHz.

If the shield can is square, assume D to be 1.2 times the width of one side. This formula, which includes the effects of losses and imperfections in practical materials, yields values of unloaded Q which are easily attained in practice. Silver plating of the shield and coil will increase the unloaded Q by about three percent over that predicted by the equation. At VHF and UHF, however, it is more practical to increase slightly the shield size (i.e., increase the selected  $Q_u$  by about three percent before making the calculation). The fringing capacitance at the open-circuited end of the helix is about 0.15D pF (i.e., approximately 0.3 pF for a shield 2 inches in diameter).

Once the required shield size has been determined, the total number of turns, N, winding pitch, P, and characteristic impedance,  $Z_o$ , for round and square helical resonators with air dielectric between the helix and shield, are given by

$$N = \frac{1908}{f_o D} \quad P = \frac{f_o D^2}{2312} \quad Z_o = \frac{99,000}{f_o D}$$

$$N = \frac{1590}{f_o S} \quad P = \frac{f_o S^2}{1606} \quad Z_o = \frac{82,500}{f_o S}$$

In these equations, dimensions D and S are in inches, and  $f_o$  is in megahertz. The design nomograph for round helical resonators in Fig. 6, which can be used with slide-rule accuracy, is based on these formulas.

Although there are many variables to consider when designing helical resonators, certain ratios of shield size and length, and coil diameter and length, will provide optimum results. For helix diameter,  $d = 0.55D$ , or  $d = 0.66S$ . To determine helix length,  $b = 0.825D$ , or  $b = 0.99S$ . For shield length,  $B = 1.325D$  and  $H = 1.60S$ .

Calculation of these dimensions is simplified by the design chart of Fig. 7. Note that these ratios result in a helix with a length 1.5 times its diameter, the condition for maximum Q. The shield is about 60 percent longer than the helix — although it can be made longer — to completely contain the electric field at the top of the helix and the magnetic field at the bottom.

It should be mentioned that the winding pitch, P, is used primarily to determine the required conductor size. During actual construction the length of the coil is adjusted to that given by the equations for helix length. Conductor size ranges from 0.4P to 0.6P for both round and square resonators and is plotted graphically in Fig. 8.

Fig. 6 — Design nomograph for round helical resonators. After selecting unloaded  $Q_u$ , required shield diameter is indicated by index line from  $Q_u$  scale to frequency scale (dashed index line here indicates a shield of about 3.8 inches for an unloaded  $Q$  of 500 at 7 MHz). Number of turns,  $N$ , winding pitch,  $P$ , and characteristic impedance,  $Z_o$ , are determined by index line from the frequency scale through previously determined shield diameter on right-hand side of the chart (index line indicates  $P = 0.047$  inch,  $N = 70$  turns, and  $Z_o = 3600$  ohms).

Obviously, an area exists (in terms of frequency and unloaded  $Q$ ) where the designer must make a choice between a conventional cavity (or lumped LC circuit) and a helical resonator. At the higher frequencies, where cavities might be considered, the choice is affected by shape factor: a coaxial resonator is long and relatively small in diameter, while the length of a helical resonator is not much greater than its diameter. A second consideration is that point where the winding pitch,  $P$ , is less than the radius of the helix (otherwise the structure tends to be nonhelical). This condition occurs when the helix has fewer than three turns ("upper limit" on the design nomograph of Fig. 6).

### Construction

To obtain as high an unloaded  $Q$  as possible, the shield should not have any seams parallel to the axis of the helix. This is usually not a problem with round resonators because large-diameter copper tubing is used for the shield, but square resonators require at least one seam and usually more. However, the effect on unloaded  $Q$  is minimal if the seam is silver soldered carefully from one end to the other.

Best results are obtained when little or no dielectric is used inside the shield. This is usually no problem at VHF and UHF because the conductors are large enough that a supporting coil form is not required. The lower end of the helix should be soldered to the inside of the shield at a

Fig. 7 — Helical resonator design chart. After the shield diameter has been determined, helix diameter,  $d$ , helix length,  $b$ , and shield length,  $B$ , can be determined with this graph. Index line indicates that a shield diameter of 3.8 inches requires helix mean diameter of 2.1 inches, helix length of 3.1 inches, and shield length of 5 inches.

point directly opposite from the bottom of the coil.

Although the external field is minimized by the use of top and bottom covers, the top and bottom of the shield may be left open with negligible effect on frequency or unloaded  $Q$ . If covers are provided, however, they should make good electrical contact with the shield. In those resonators where the helix is connected to the bottom

Fig. 8 — Helix conductor size vs. winding pitch,  $P$ . A winding pitch of 0.047 inch for example, dictates a conductor diameter between 0.019 and 0.028 inch (number 22 or 24 AWG).

cover, that must be soldered solidly to the shield to minimize losses.

### Tuning

A helical resonator designed from the nomograph of Fig. 6, if carefully built, will resonate very close to the design frequency. Resonance can be adjusted over a small range by slightly compressing or expanding the helix. If the helix is made slightly longer than that called for in Fig. 7, the resonator can be tuned by pruning the open end of the coil. However, neither of these methods is recommended for wide frequency excursions because any major deviation in helix length will degrade the unloaded  $Q$  of the resonator.

Most helical resonators are tuned by

Fig. 9 — Insertion loss of all tuned resonant circuits is determined by the ratio of loaded to unloaded Q as shown here.

means of a brass tuning screw or high quality air-variable capacitor across the open end of the helix. Piston capacitors also work well, but the Q of the tuning capacitor should ideally be several times the unloaded Q of the resonator. Varactor diodes have sometimes been used where remote tuning is required, but varactors can generate unwanted harmonics and other spurious signals if they are excited by strong, nearby signals.

When a helical resonator is to be tuned by a variable capacitor, the shield size is based on the chosen unloaded Q at the operating frequency. Then the number of turns, N, and the winding pitch, P, are based on resonance at  $1.5f_0$ . Tune the resonator to the desired operating frequency,  $f_0$ .

#### Insertion Loss

The insertion loss (dissipation loss), IL, in decibels, of all resonant circuits is given by

$$IL = 20 \log_{10} \left( \frac{1}{1 - Q_d/Q_u} \right) \text{ dB}$$

where

$Q_d$  = loaded Q

$Q_u$  = unloaded Q.

This is plotted in Fig. 9. For the most practical cases ( $Q_d > 5$ ), this can be closely approximated by  $IL \approx 9.0 (Q_d/Q_u) \text{ dB}$ . The selection of a loaded Q for a tuned circuit is dictated primarily by the required selectivity of the circuit. However, to keep dissipation loss to 0.5 dB or less (as is the case for low-noise VHF receivers), the unloaded Q must be at least 18 times the loaded Q. Although this may be difficult to achieve in practice, it points up the necessity of considering both selectivity and insertion loss before choosing the unloaded Q of any resonant tuned circuit.

#### Coupling

Signals may be coupled into and out of helical resonators with inductive loops at the bottom of the helix, direct taps on the coil or any combination of these. Although

Fig. 10 — Response curve for a single-resonator 432-MHz filter showing the effects of capacitive and inductive input/output coupling. Response curve can be made symmetrical on each side of resonance by combining the two methods (inductive input and capacitive output, or vice versa).

the correct tap point can be calculated easily, coupling by loops and probes must be determined experimentally. When only one resonator is used, the input and output coupling is often provided by probes. For maximum isolation the probes are positioned on opposite sides of the resonator.

When coupling loops are used, the plane of the loop should be perpendicular to the axis of the helix and separated a small distance from the bottom of the coil. For resonators with only a few turns, the plane of the loop can be tilted slightly so it is parallel with the slope of the adjacent conductor. Helical resonators with inductive coupling (loops) will exhibit more attenuation to signals above the resonant frequency (as compared to attenuation below resonance), whereas resonators with capacitive coupling (probes) exhibit more attenuation below the passband, as shown for a typical 432-MHz resonator in Fig. 10. This characteristic may be a consideration when choosing a coupling method. The passband can be made more symmetrical by using a combination of coupling methods (inductive input and capacitive output, for example).

If more than one helical resonator is required to obtain a desired band-pass characteristic, adjacent resonators may be coupled through apertures in the shield wall between the two resonators. Unfortunately, the size and location of the aperture must be found empirically, so this method of coupling is not very practical unless you're building a large number of identical units.

Since the loaded Q of a resonator is determined by the external loading, this must be considered when selecting a tap (or position of a loop or probe). The ratio of this external loading,  $R_b$ , to the characteristic impedance,  $Z_0$ , for a quarter-wavelength resonator is calculated from

$$K = \frac{R_b}{Z_0} = 0.785 \left( \frac{1}{Q_d} - \frac{1}{Q_u} \right)$$

Even when filters are designed and built properly, they may be rendered totally ineffective if not installed properly. Leakage around a filter can be quite high at VHF and UHF, where wavelengths are short. Proper attention to shielding and good grounding is mandatory for minimum leakage. Poor coaxial cable shield connection into and out of the filter is one of the greatest offenders with regard to filter leakage. Proper dc lead bypassing throughout the receiving system is good practice, especially at VHF and above. Ferrite beads placed over the dc leads may help to reduce leakage even further.

Proper termination of a filter is a necessity if minimum loss is desired. Most VHF RF amplifiers optimized for noise figure do not have a 50-ohm terminating input impedance. As a result, any filter attached to the input of an RF amplifier optimized for noise figure will not be properly terminated, and the filter's loss may rise substantially. As this loss is directly added to the RF amplifier's noise figure, prudent consideration should be made of filter choice and placement in the receiver.

#### Dynamic Range

Here is another term which seems to confuse some amateurs and even some receiver manufacturers. The confusion concerns true dynamic range (as treated briefly at the start of this chapter) and the AGC control range in a receiver. That is, if a receiver AGC circuit has the capability of controlling the overall receiver gain by some 100 dB from a no-signal to a large-signal condition, a misinformed individual might claim that the dynamic range of the receiver is 100 dB. A receiver with a true dynamic range of 100 dB would be a very fine piece of equipment, indeed!

Dynamic range relates specifically to the amplitude levels of multiple signals that can be accommodated during reception. This is expressed as a numeric ratio, generally in decibels. The present state of the receiver art provides optimum dynamic ranges of up to 100 dB. This is the maximum dynamic range attainable when the distortion products are at the sensitivity limit of the receiver. Simply stated, dynamic range is the decibel difference (or ratio) between the largest tolerable receiver input signal (without causing audible distortion products) and the minimum discernible signal (sensitivity).

Poor dynamic range can cause a host of receiving problems when strong signals appear within the front-end passband. Notable among the maladies is cross modulation of the desired signal. Another effect is desensitization of the receiver from a strong unwanted signal. Spurious signals may appear in the receiver tuning range when a strong signal is elsewhere in the band. This is caused by IMD products from the mixer. Clearly, strong signals cause undesired interference and distortion of the desired signal when a receiver's dynamic

range is poor. Design features of importance to high-dynamic-range receivers will appear in this chapter.

### TRF Receivers

Tuned-radio-frequency receivers have little value in Amateur Radio today, but in the early days they were suitable for the reception of spark and AM signals. They consisted mainly of a couple of stages of selective RF amplification, an AM detector and an audio amplifier. Variations were developed as regenerative and super-regenerative receivers.

The straight regenerative detector was simply a self-oscillating detector that provided increased sensitivity (similar in function to a product detector) and a beat note for CW reception. Amplitude-modulated signals could be copied, if they were loud, when the regeneration control was set for a nonoscillating condition. For weak-signal AM reception the regeneration control was advanced to increase the detector sensitivity, and the signal was tuned in at zero beat, thereby eliminating the heterodyne from the carrier. Present-day uses for the TRF receiver are restricted mainly to reception of AM broadcast signals, for hi-fi reception and for field-strength indicators of CW or AM signals.

Superregenerative receivers were quite popular among VHF and UHF amateurs in the '30s, '40s and early '50s. The principle of operation was an oscillating detector that had its oscillation interrupted (quenched) by a low-frequency voltage slightly above the audible range (20 to 50 kHz being typical). Some superregenerative detectors employed a so-called self-quenching trait, brought about by means of an RC network of the appropriate time constant. The more esoteric "supergenny" or "rushbox" detectors used an outboard quench oscillator. This circuit was more sensitive than the straight regenerative detector, but was best suited for reception of AM and wide-band FM signals. Because of the quenching action and frequency, the detector response was extremely broad, making it unsuitable for narrow-band signals versus audio recovery. High-Q input tuned circuits helped make them more selective, but a typical superregenerative receiver that used a tuned cavity at the detector input could accommodate only ten 1000- $\mu$ V, 30-percent-modulated AM signals in a range from 144 to 148 MHz without signal overlap. These tests were performed in the ARRL laboratory with the 10 signals separated from one another by equal amounts.

A major problem associated with the use of regenerative and superregenerative receivers was oscillator (detector) radiation. The isolation between the detector and the antenna was extremely poor, even when an RF amplifier was employed ahead of the detector. In many instances the radiated energy could be heard for several miles, causing intense interference to other

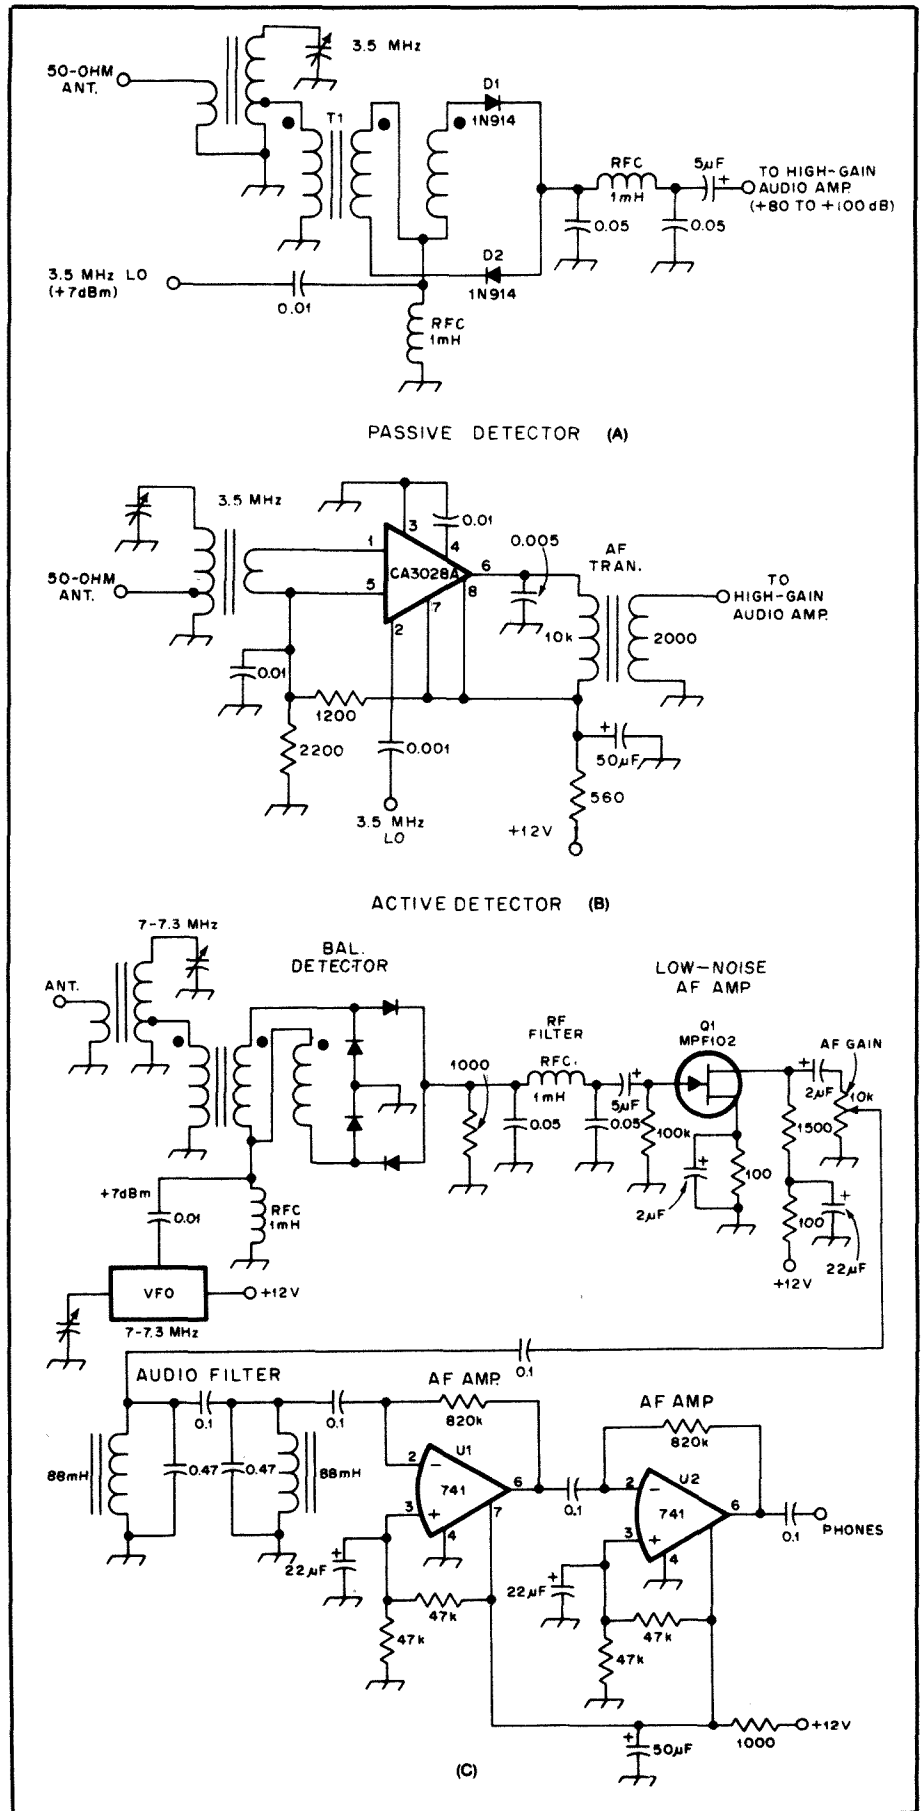

Fig. 11 — Typical detectors that can be used in the front ends of direct-conversion receivers. A passive diode is shown in A. The active detector (B) provides considerable conversion gain. An example of a practical direct-conversion receiver is shown in C.

amateurs in the community.

### Direct-Conversion Receivers

A more satisfactory simple receiver for CW or SSB is called the direct-conversion or synchrodyne type. Although there is a distinct possibility of signal radiation, it is considerably lower in level than with regenerative receivers. This results from better isolation between the antenna and the source of oscillation. A modern direct-conversion receiver uses a separate oscillator and a balanced or doubly balanced detector. Both features help to reduce unwanted radiation.

The detection stage of this receiver is actually a product detector that operates at the desired signal frequency. The product-detector circuits described in Chapter 18 are suitable in this kind of receiver. A tuned RF amplifier is useful ahead of the detector at 14 MHz and higher, but it is seldom necessary from 160 through 40 meters. This is because the atmospheric and man-made noise from the resonant antenna usually exceeds that of the detector below 14 MHz. When no RF stage is used, it is desirable to include a tuned network ahead of the detector.

Fig. 11 shows typical front ends for direct-conversion receivers. One circuit (A) employs a passive detector. The other (B) contains an active detector. Circuit B is desirable in the interest of increased gain. More information about product detectors can be found in Chapter 18.

The circuit of Fig. 11A shows a singly balanced passive detector. Front-end selectivity is provided by a tuned circuit. T1 is a broadband, trifilar-wound toroid transformer. It is tapped on the input tuned circuit at the approximate 50-ohm point. An RF filter is used after D1 and D2 to prevent LO energy from being passed on to the audio amplifier.

Fig. 11B illustrates an active singly balanced IC detector. The input impedance across pins 1 and 5 is roughly 1000 ohms. However, the secondary winding of the input tuned circuit can be made lower than 1000 ohms to reduce the signal amount to the detector. This will ensure improved dynamic range through a deliberate mismatch. Such a practice is useful when an RF amplifier precedes the detector. For maximum sensitivity when no RF amplifier is included, it is more practical to use a 1000-ohm transformation from the 50-ohm antenna (larger link at the detector input). An audio transformer is used at the detector output. The primary winding should have low dc resistance to provide dc balance between the collectors of the differential-amplifier pair in the IC. Alternatively, a center-tapped primary can be used. If this is done, pin 8 should be connected to one end of the winding and the B+ fed to the center tap. The impedance between pins 6 and 8 is approximately 8000 ohms.

In order to obtain ample headphone volume during reception of weak signals,

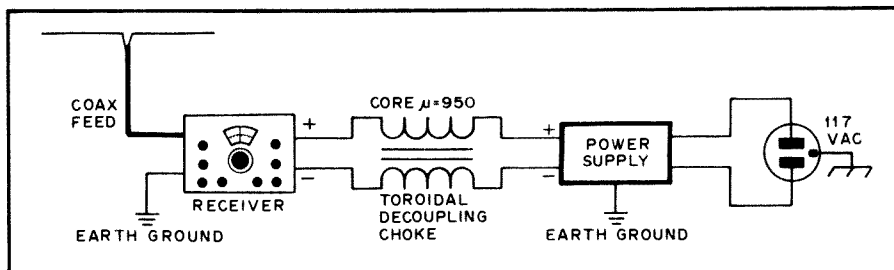

Fig. 12 — A method for eliminating common-mode hum in a direct-conversion receiver, as described by W7ZOI.

it is necessary to use an audio amplifier that has between 80 and 100 dB of gain. The first AF amplifier should be low-noise type, such as a JFET. The audio-gain control should follow the first audio amplifier. Selectivity for SSB and CW reception can be had by including a passive or RC active audio filter after the gain control. Fig. 11C contains a circuit that shows a typical direct-conversion receiver in its entirety. As was stated earlier, the detector is operating as a product detector rather than a mixer, and the VFO is serving as a BFO. The difference frequency between the incoming 7-MHz signal and the 7-MHz BFO injection voltage is at audio frequency (zero IF). This is amplified by Q1, filtered through a passive LC audio network, then amplified by two 40-dB op-amp stages. It is possible to copy AM signals with this type of receiver by tuning the signal in at zero beat.

Direct-conversion receivers of the type illustrated in Fig. 11 provide double-signal reception; that is, a CW beat note will appear either side of the zero beat. This is useful during sideband reception, wherein the upper sideband is received on one side of zero beat and the lower sideband will appear on the opposite side of zero beat. QRM will be greater, of course, with this kind of receiver because there is no rejection of the unwanted sideband. Some designers have contrived elaborate circuits that, by means of phasing networks, provide single-signal reception. Unfortunately, the circuit becomes nearly as complex as that of superheterodyne. The benefits obtained are probably not worth the effort.

Direct-conversion receivers are not especially suitable above 14 MHz because it is difficult to secure adequate BFO stability at so high a frequency. A practical solution to the problem is the employment of a heterodyne BFO chain in which a 5-MHz VFO is heterodyned with crystal-controlled oscillators. Direct-conversion receivers are ideal for use in simple transceivers because the BFO can be used also as the frequency source for the transmitter, provided the appropriate frequency offset is included between transmit and receive to permit copy of SSB and CW signals without readjusting the BFO.

### Characteristic Faults

A major difficulty connected with direct-

conversion receivers is microphonics. The effect is noted when the operating receiver is bumped or moved. An annoying ringing sound is heard in the receiver output until the mechanical vibration ceases. The simple act of peaking the front end or adjusting the volume control can set off a microphonic response. This trait is caused by the extremely high gain needed in the audio amplifier. Slight electrical noises in the receiver front end, caused by small vibrations, are amplified many times by the audio channel. They are quite loud by the time they reach the speaker or phones. The best precautionary measure to reduce microphonics is to make all of the detector and BFO circuit leads and components as rigid as possible. Addition of an RF amplifier stage ahead of the detector will also help by virtue of increasing the front-end gain. This reduces the amount of audio gain needed to copy a signal, thereby diminishing the loudness of the microphonics.

The other common problem inherent in direct-conversion receivers is hum (Fig. 12). The fault is most pronounced when an ac power supply is used. The hum becomes progressively worse as the operating frequency is increased. For the most part, this is caused by ac ground loops in the system. The ac modulates the BFO voltage, and the hum-modulated energy is introduced directly into the detector, as well as being radiated and picked up by the antenna. The most practical steps toward a cure are to affix an effective earth ground to the receiver chassis and power supply, use a battery power supply and feed the antenna with coaxial cable. End-fed wire antennas increase the possibility of hum if they are voltage fed (high impedance at the receiver end). Decoupling the ac power supply leads (dc leads to the receiver) is also an effective preventive measure for hum. The cure described by Wes Hayward, W7ZOI, is to add a toroidal decoupling choke, bifilar wound, in the plus and minus dc leads from the power supply. This will prevent high-impedance RF paths between the power supply and receiver. The effect is to prevent BFO energy from entering the power supply, being modulated by the rectifier diodes and reradiated by the ac line. This form of buzz is called "common-mode hum."

# Superheterodyne Receivers

Nearly all of the present-day communications receivers are structured as superheterodyne types. Fig. 13 shows a simple block diagram of a single-conversion superheterodyne circuit. This basic design has been popular since the 1930s, and only a few general circuit enhancements have been introduced in recent years. Sophisticated versions of this type of receiver use alternatives to the circuits indicated in the block diagram. The local oscillator, for example, might utilize a phase-locked loop or synthesizer LO chain rather than a straight VFO. Digital readout is used in many models in place of the more traditional analog readout method. RF noise blankers (often very complex) are chosen by some designers in preference to simple shunt audio noise limiters. An assortment of techniques is being used to improve the overall selectivity of these receivers — elaborate IF filtering, RC active or LC passive audio filters. However, the basic circuit concept remains unchanged. The advancement of greatest significance in recent years is the changeover from vacuum tubes to semicon-

ductors. This has increased the life span of the equipment, improved overall efficiency, aided stability (through reduced heating) and contributed to greater ruggedness and miniaturization.

Some manufacturers still produce double- or multiconversion superheterodyne receivers, but the circuits are similar to that of Fig. 13. Multiconversion receivers have a second mixer and LO chain for the purpose of making the second IF lower than the first. This helps to increase the overall selectivity in some designs, but it often degrades the receiver dynamic range through the addition of a second mixer. Multiconversion receivers are more prone to spurious responses than are single-conversion designs, owing to the additional oscillator and mixing frequencies involved. The "cleanest" performance is obtained from properly designed single-conversion receivers.

## Circuit Function

In the example of Fig. 13 it is assumed that the receiver is adjusted to receive the 20-meter band. Front-end selectivity is pro-

vided by the resonant networks before and after the RF amplifier stage. This part of the receiver is often called the preselector, meaning that it affords a specific degree of front-end selectivity at the operating frequency. The RF amplifier increases the level of the signal from the antenna before it reaches the mixer. The amount of amplification is set by the designer, consistent with the overall circuit requirements (gain distribution). Generally, the gain will be from a few decibels to as much as 25 dB.

When the incoming signal reaches the mixer it is heterodyned with the local-oscillator frequency to establish an IF (intermediate frequency). The IF can be the sum or the difference of the two frequencies. In the example given, the IF is the difference frequency, or 9 MHz.

An IF filter (crystal lattice or ceramic monolithic) is used after the mixer. At low intermediate frequencies (455 kHz and similar), mechanical filters are often used. The IF filter sets the overall receiver selectivity. For SSB reception it is usually 2.4 kHz wide at the 3-dB points of the filter response curve. For CW reception it is be-

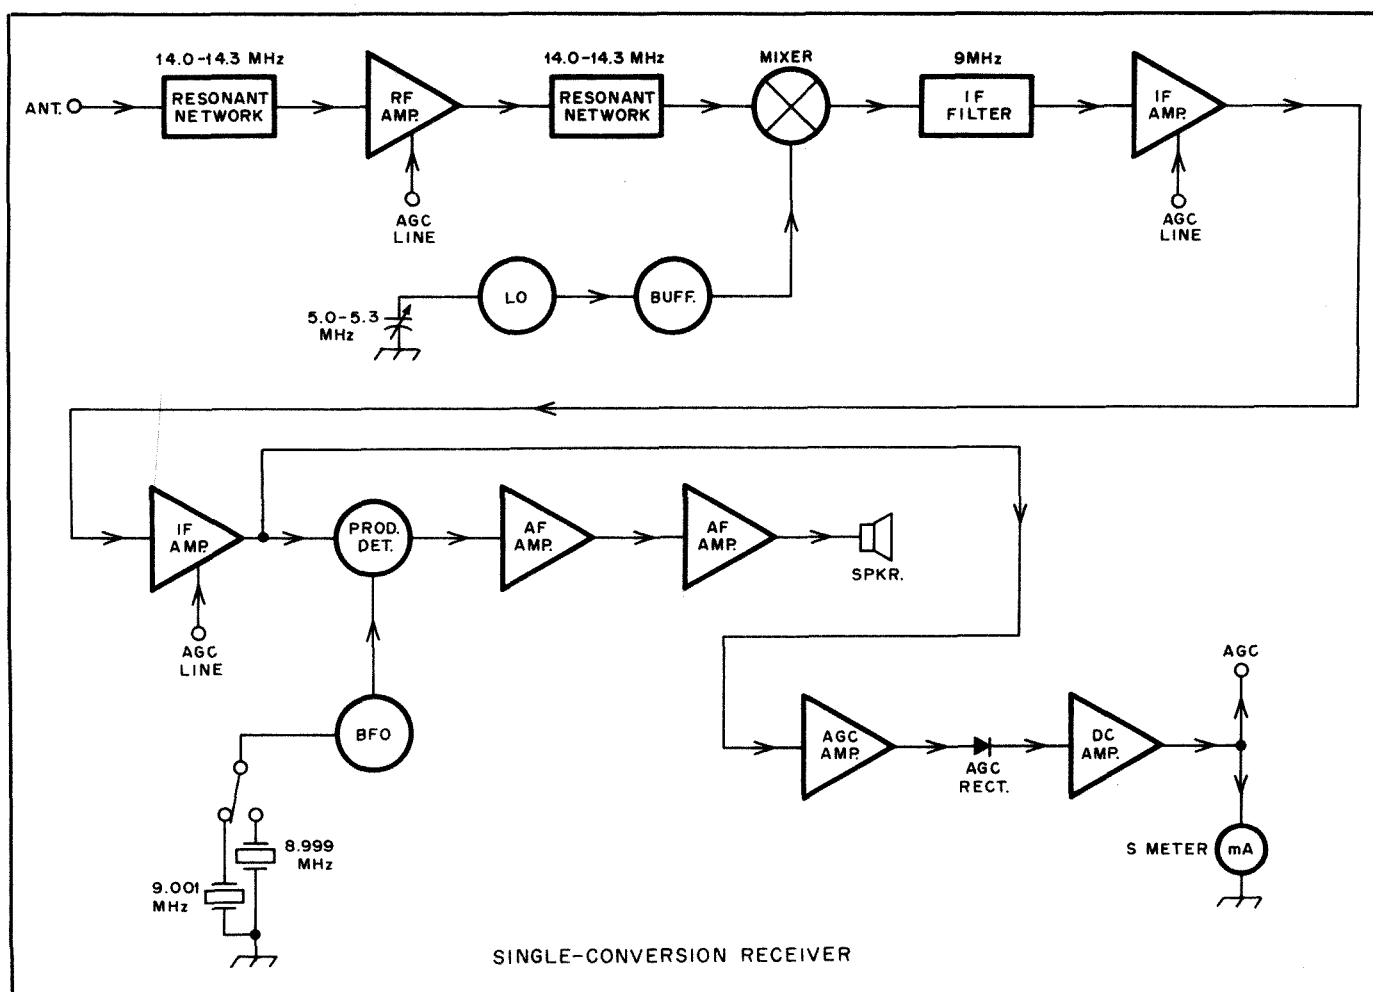

Fig. 13 — Block diagram of a single-conversion superheterodyne receiver for 20 meters. The arrows indicate the direction of signal and voltage components.

Fig. 14 — Layout of a typical amateur superheterodyne receiver.

tween 200 and 500 Hz in bandwidth, depending on the design objective and the operator preference. A good bandwidth for CW and RTTY reception is 300 Hz. Wider filters are available for AM and FM reception.

Output from the IF filter is increased by one or more amplifier stages. The overall gain of most IF strips varies from 50 to 100 dB. The amount of signal gain is determined by the design objective, the type of amplifier devices used and the number of gain stages.

The amplified IF energy is routed to a product detector, where it is mixed with the beat-frequency oscillator output. This produces an audio frequency voltage, which is amplified and fed to a speaker or headphones. The BFO is adjusted for reception of the upper or lower sideband, depending on which is appropriate at the time. In either case the BFO frequency is offset slightly from the center frequency of the IF filter. For SSB reception it is usually offset approximately 1.5 kHz, in which case it falls on the slope of the IF response curve. For CW reception the BFO is offset approximately 800 Hz from the IF filter center frequency to produce an 800-Hz peak audio tone in the speaker. Other values of CW offset are common, but 800 Hz is preferred by many CW operators.

The overall gain of the receiver can be adjusted manually (by means of a panel-mounted control) or automatically (by means of an AGC circuit). Energy can be sampled from the IF amplifier output or the audio amplifier. Depending on the method used, the resultant AGC is called *IF derived* or *audio derived*. There are many arguments pro and con about which

method is best. They shall not be considered here. In Fig. 13 the AGC voltage is sampled from the IF strip, amplified by the AGC amplifier and then rectified to provide a dc control voltage. A dc amplifier is used to drive the AGC terminals of the RF and IF amplifiers. It can also be used to operate an S meter for observing relative signal-strength levels. When the incoming signal is weak the gain-controlled stages operate fully. As the incoming signal becomes stronger the AGC circuit starts lowering the gain of the RF and IF stages, thereby leveling the audio output at the speaker. A well-designed AGC system will provide a uniform level of audio output (at a given AF-gain control setting) over an incoming signal-level variation of 100 dB. The net effect is to prevent overloading of some of the receiver stages and to protect the operator from the startling effect of tuning from a weak signal to an extremely loud one. Fig. 14 shows the front panel and controls for a typical amateur-band superheterodyne receiver.

### Local Oscillators

A good communications receiver contains oscillators that operate in a stable and spectrally pure manner. Poor oscillator performance can spoil the best of receivers even though all other parts of the circuit are functioning in elegant fashion. Not only should the oscillator be stable with regard to short- and long-term drift, it should have minimum noise in the output (at least 80 dB below the peak value of the fundamental energy) and be reasonably free of spurious responses. Concerning the latter, it is not difficult to design an oscillator that has all harmonics attenuated by 60 or 70

dB. Another important characteristic of an oscillator is quick starting when operating voltage is applied.

Oscillator instability can result from a host of poor design practices. To improve the stability characteristics it is useful to observe the following:

- 1) Use well-filtered regulated operating voltages.
- 2) Use temperature-stable, fixed-value capacitors in the frequency-determining part of the circuit. Polystyrene and silver mica capacitors are recommended.
- 3) Ensure that all mechanical and electrical components are secured rigidly in their part of the circuit. This will lessen the chance for mechanical instability.
- 4) Build the oscillator on firm, flex-free material.
- 5) When practical, enclose the oscillator in its own shield compartment and use RF filtering in the dc supply leads. The more constant the ambient temperature surrounding the oscillator, the greater will be the frequency stability.

Precautions should be taken to ensure that the oscillator in a receiver looks into a constant load impedance. Even minute load changes will cause phase shifts which can affect the oscillator frequency. The effect is more pronounced with VFOs than it is with crystal-controlled oscillators. Because of these conditions it is good design practice to couple very lightly to the oscillator stage. The power level can be increased by adding one or more buffer/amplifiers before the oscillator signal is applied to the mixer or detector.

Changes in operating voltage will result in frequency shifts. It is for this reason that regulated voltage is recommended for oscillators. Zener diodes are adequate for the purpose.

Magnetic cores, such as those in slug-tuned coils, change their properties with variations in ambient temperature, thereby causing inductance changes that can severely affect the oscillator frequency. Furthermore, mechanical instability can result if the slugs are not affixed securely in the coil forms.

Oscillator noise can be held to an acceptable level by employing high-Q tuned circuits. The higher the tank Q, the narrower the bandwidth and, hence, the lower the noise output voltage. Excessive LO noise will have a serious effect on mixer performance.

High amounts of harmonic current in the LO-chain output can cause unwanted mixer injection. If the receiver front-end selectivity is not of high magnitude, spurious signals from outside the band of interest will be heard along with the desired ones. Harmonic energy can degrade the performance of some kinds of mixers, making it worthwhile to use suitable filtering at the LO-chain output.

### Receiver Front Ends

The designer has a number of options

available when planning the input section of a receiver. The band-pass characteristics of the input tuned circuits are of considerable significance if strong out-of-band signals are to be rejected — an ideal design criterion. Many of the commercial receivers available to the amateur use tuned circuits that can be adjusted from the front panel of the equipment. The greater the network Q, the sharper the frequency response and, hence, the better the adjacent-frequency rejection. For a given network design the bandwidth doubles for each octave higher. That is, an 80-meter front-end network may have a 3-dB bandwidth of 100 kHz for a given Q and load factor. At 40 meters the same type of network would be 200-kHz wide at the 3-dB points of the response curve. This is the reason that most receivers have a tunable front-end section (preselector). If fixed-tuned filters were used, at least two such filters would be necessary to cover from 3.5 to 4 MHz or 1.8 to 2.0 MHz. This would complicate the design and increase the equipment cost.

Fig. 15 shows the two concepts just discussed. The circuit at A covers all of the 80-meter band, and if selective enough offers some in-band rejection. A pair of Butterworth band-pass filters might be used at FL1 and FL2 of Fig. 15B to cover all of the 80-meter band. A lot of additional components would be required, and the in-band rejection of unwanted signals would be less than in the case of circuit A. The principal advantage of the circuit at B is that front-panel peaking adjustments would not be necessary once the trimmers in the filters were set for the desired response. A similar tuned circuit for either example in Fig. 15 would be used between the RF amplifier and the mixer.

Regardless of the type of LC input network used, a built-in step attenuator is worth considering. It can be used for measuring changes in signal level, or to reduce overloading effects when strong signals appear in the receiver passband. Fig. 16 shows how this can be done. The example at A is suitable for simple receivers when calibration in decibels is not a requisite, and when maintaining an impedance match between the tuned circuit and the antenna is not vital. The circuit at B is preferred because the pads are of 50-ohm impedance. In the circuit shown three steps are available: 6, 12 and 18 dB, depending on how the switches are thrown. The resistance values specified are the closest standard ones to the actual values needed to provide precisely 6 or 12 dB of attenuation. For amateur work the accuracy is adequate. Front-end attenuators are useful when VHF converters are used ahead of the station receiver. If the converters have a significant amount of overall gain they can degrade the dynamic range of the main receiver when strong signals are present. The attenuators can be set to simulate a condition of unity gain through the converter, thereby aiding receiver dynamic

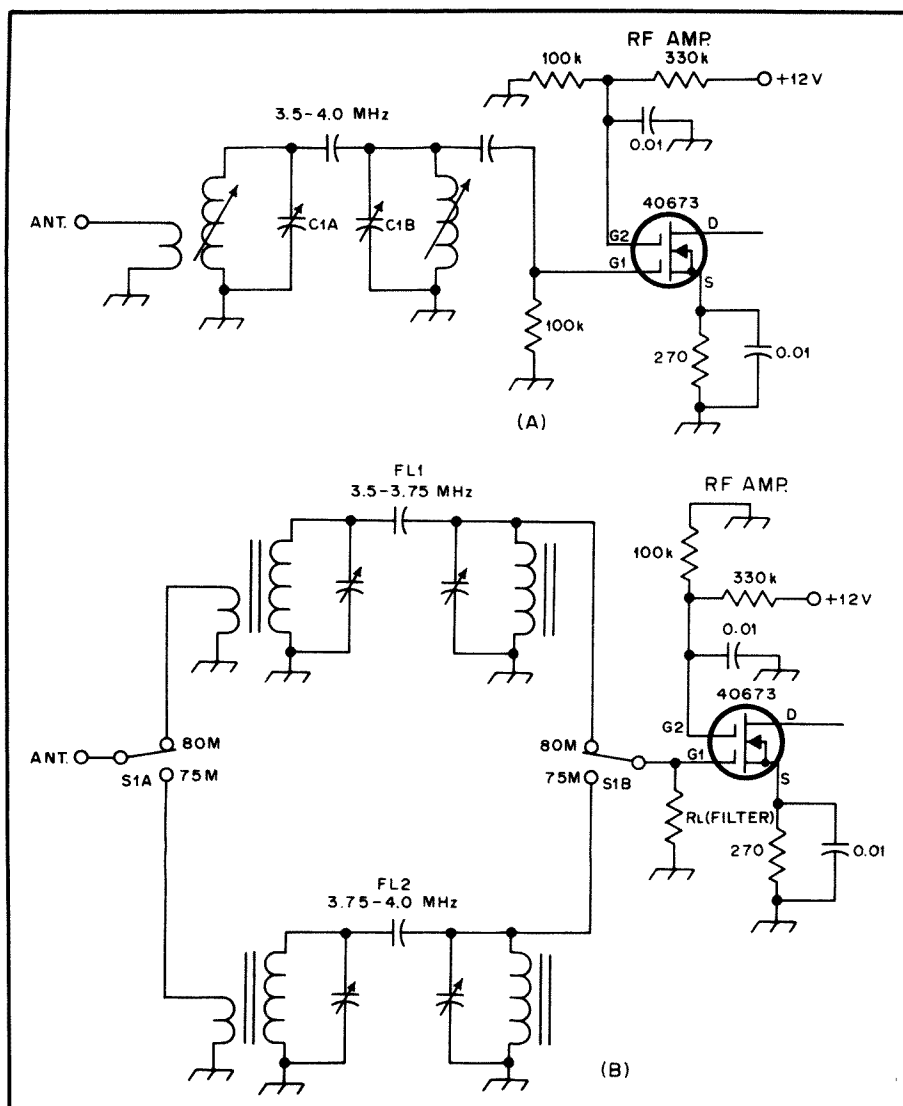

Fig. 15 — Method for selecting band-pass filters for 75 and 80 meters at the input to an RF amplifier.

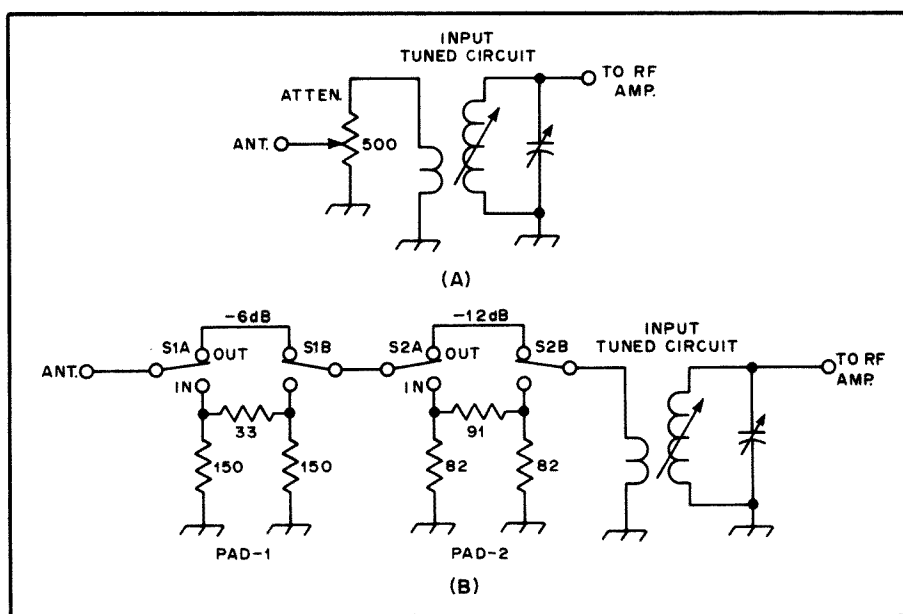

Fig. 16 — Front-end attenuators. A simple type is given at A and a step-attenuator version is shown at B.

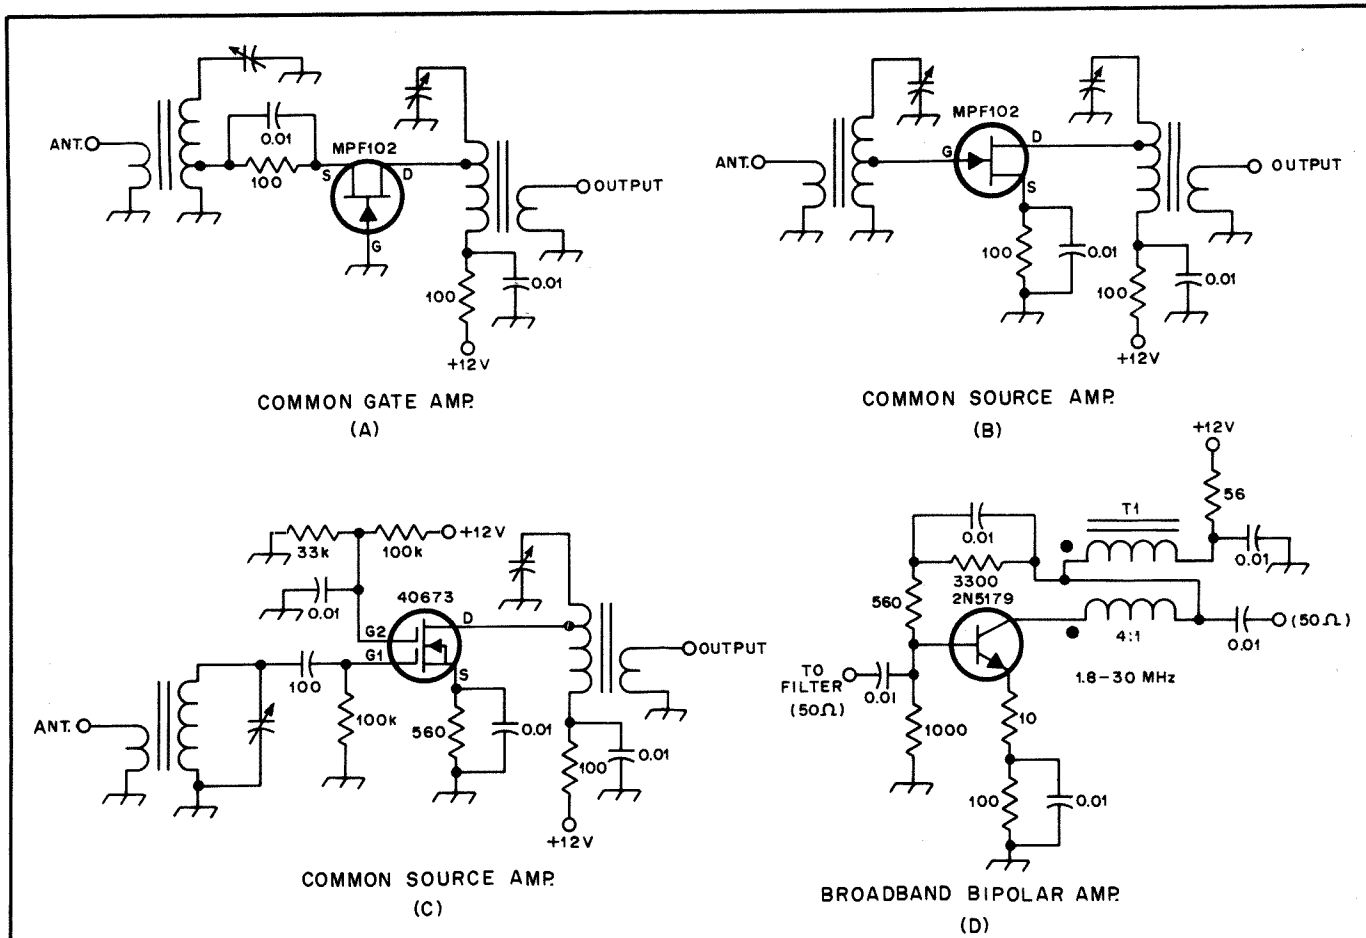

Fig. 17 — Narrowband RF amplifiers are shown from A to C. A fed-back broadband RF amplifier is shown at D.

range. It is worth remembering, however, that an attenuator used at the input of a receiver when no converter is attached will degrade receiver sensitivity and noise figure. A receiver used frequently for antenna and received-signal decibel measurements might have several 3-dB pads included, thereby providing greater resolution during measurements.

### RF Amplifiers

It was implied earlier in the chapter that RF amplifiers are useful primarily to improve the receiver noise figure. When atmospheric and man-made noise levels exceed that of the mixer it should be possible to realize better dynamic range by not having an RF amplifier. The gain of the RF stage, when one is used, should be set for whatever level is needed to override the mixer noise. Sometimes that is only a few decibels. A good low-noise active device should be employed as the RF amplifier in such instances.

A well-designed receiver should not have AGC applied to the RF amplifier. The best noise figure and RF-stage dynamic range will result when AGC is not applied. This is because the AGC voltage changes the operating characteristics of the RF amplifier from Class A to a less-linear mode.

Fig. 17 shows some typical RF amplifiers for use in amateur receivers. Tube-type circuits have not been included because they do not offer any particular advantage over solid-state amplifiers.

The circuit at A in Fig. 17 is likely to be the least subject to self-oscillation of the four examples given. The common-gate hookup helps to ensure stability if the gate lead is kept as short as is physically possible. The gain from a common-gate amplifier of this type is lower than that of a common-source amplifier. However, gains up to 15 dB are typical. The drain of the FET need not be tapped down on the drain coil, but if it is there will be less loading on the tuned circuit, thereby permitting somewhat greater tuned-circuit selectivity: The lower the drain tap, the less the stage gain.

All of the FET amplifiers in Fig. 17 are capable of providing low-noise operation and good dynamic range. The common-source circuits at illustrations B and C can provide up to 25 dB of gain. However, they are more prone to instability than is the circuit at A. Therefore, the gates are shown tapped down on the gate tank: Placing the input at a low impedance point on the tuned circuit will discourage self-oscillation. The same is true of the drain tap. JFETs will hold up under considerable

RF input voltage before being damaged. Laboratory test of the MPF102 showed that 80 volts P-P (gate to source) was required to destroy the device. However, in the interest of good operating practices the P-P voltage should be kept below 10. Tapping the gate down on the input tuned circuit will result in lower levels of P-P input voltage, in addition to aiding stability.

A broadband bipolar-transistor RF amplifier is shown in Fig. 17 at D. This type of amplifier will yield approximately 16 dB of gain up to 148 MHz, and it will be unconditionally stable because of the degenerative feedback in the emitter and the negative feedback in the base circuit. A broadband 4:1 transformer is used in the collector to step the impedance down to approximately 50 ohms at the amplifier output. A 50-ohm characteristic exists at the input to the 2N5179 also. A band-pass filter should be used at the input and output of the amplifier to provide selectivity. The 4:1 transformer helps to ensure a collector load of 200 ohms, which is preferred in an amplifier of this type. This style of amplifier is used in CATV applications where the transformation from collector to load is 300 to 75 ohms.

### Stability

Excessive gain or undesired feedback

may cause amplifier instability. Oscillation may occur in unstable amplifiers under certain conditions. Damage to the active device from overdissipation is only the most obvious effect of oscillation. Deterioration of noise figure, spurious signals generated by the oscillation, and reradiation of the oscillation through the antenna, causing RFI to other services, can also occur from amplifier instability.

Neutralization or other forms of feedback may be required in RF amplifiers to reach stability. Amplifier neutralization is achieved by feeding energy from the amplifier output circuit back to the input in such an amount and phase as to cancel out the effects of device internal capacitance and other unwanted input-output coupling. Care in termination of both the input and output can produce stable results from an otherwise unstable amplifier. Attention to proper grounding and proper isolation of the input from the output by means of shielding can also yield stable operating conditions.

#### Overloading and Spurious Signals

Normally, the RF amplifier is not a significant contributor to overloading problems in VHF receiving systems. The RF amplifiers in the first or second stage of a receiving system operate in a linear service, and if properly designed require a substantial signal input to cause deviation from linearity. Overloading usually occurs in the naturally nonlinear mixer stages. Images and other responses to out-of-band signals can be reduced or eliminated by proper filtering at the amplifier input.

In general, unwanted spurious signals and overloading increase as the signal levels rise at the input to the offending stage. Consequently, minimum gain prior to the stage minimizes overloading. Since noise figure may suffer at reduced gain, a compromise between optimum noise figure and minimum overloading must often be made. Especially in areas of high amateur activity, sacrificing noise figure somewhat may result in increased weak-signal reception effectiveness if the lower noise-figure system is easily overloaded.

#### Typical Circuits for VHF and Above

Common circuits for the RF amplifiers used at VHF and UHF are illustrated in Figs. 18 through 21. The termination impedances of both the input and output of these examples are low (50 ohms), suiting them well to preamplifier service. Preamplifiers are useful for improving the noise figure of existing equipment.

The choice of active device has a profound effect on the weak-signal performance of an RF amplifier. Although tubes can be used on the VHF and UHF bands, their use is seldom seen, as solid-state devices provide far better performance at lower cost. Bipolar transistors can provide excellent noise figures up through 4 GHz if chosen and used properly. The

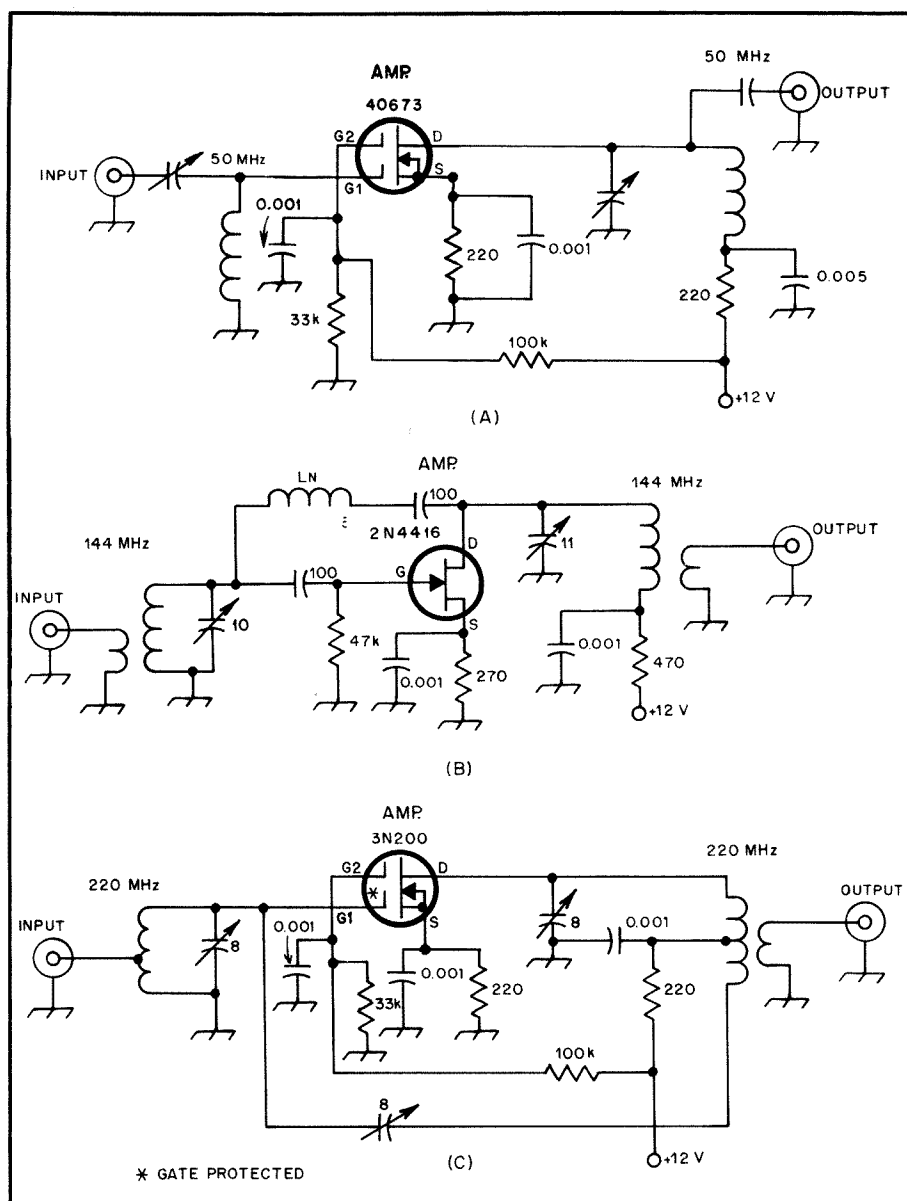

Fig. 18 — Typical grounded-source RF amplifiers. The dual-gate MOSFET, A, is useful below 500 MHz. The junction FET, B, and neutralized MOSFET, C, work well on all VHF bands. Except where given, component values depend on frequency.

JFET is usable through 450 MHz, although the most commonly available ones drop off in performance quickly beyond that frequency. Dual-gate MOSFETs also are usable through 450 MHz. The GaAsFET provides superior noise figures past 1300 MHz.

Most RF amplifiers for use below 225 MHz use FETs rather than bipolars. Unless bipolar transistors are run at relatively high standing currents they are prone to overloading from strong signals. Additionally, their lower terminating impedances can present somewhat awkward design considerations to the builder. The FET minimizes these problems while presenting an acceptable noise figure.

Above 225 MHz, inexpensive FETs cannot provide the low noise figure attainable from bipolars. The wavelength at these higher frequencies also allows the con-

venient use of tuned lines rather than conventional coils, easing the possible design difficulties of the lower terminating impedances of bipolars.

The input network of an RF amplifier should be as low in loss as possible to assure a low noise figure, since any loss before the first stage is effectively added to the noise figure. High-selectivity circuits often have significant losses and should be avoided at the front end. L networks usually provide the least loss while achieving proper impedance matching. High-quality components should also be employed in the input circuit to further reduce losses.

It should be pointed out that the terminating impedance of transistors for optimum noise figure is usually not the same as that for optimum power transfer (gain). This complicates the design and tuning procedures somewhat, but careful

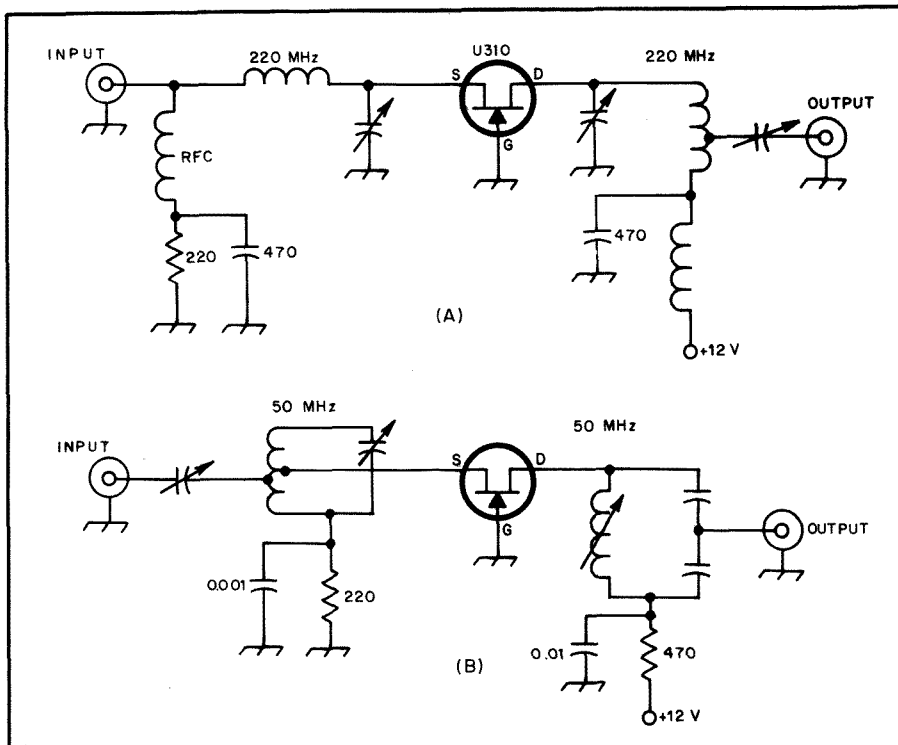

Fig. 19 — Grounded-gate-FET preamplifier tends to have lower gain and broader frequency response than other amplifiers described.

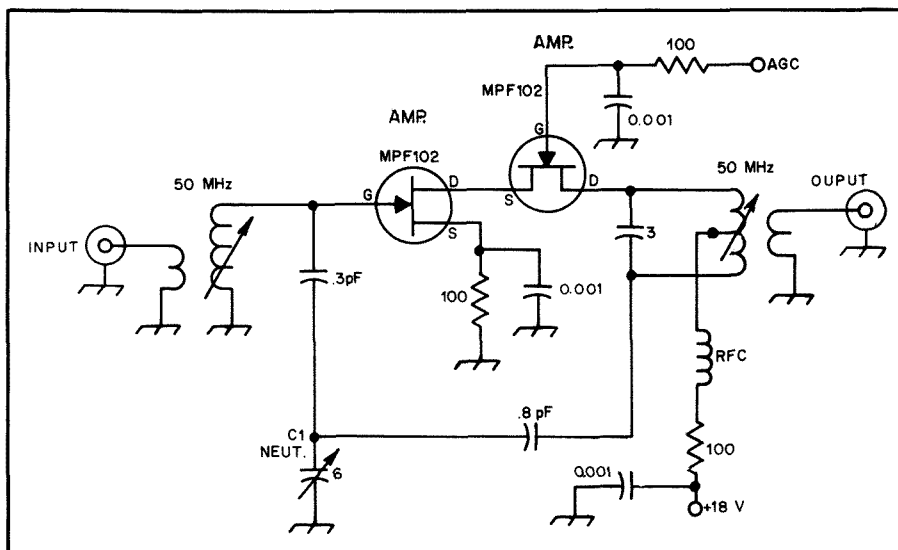

Fig. 20 — Cascode amplifier circuit combines grounded-source and grounded-gate stages, for high gain and low noise figure. Though JFETs are shown, the cascode principle is useful with MOSFETs as well.

measurements and adjustment can compensate for these shortcomings. The dual-gate MOSFET has different internal geometry, so optimum noise match is virtually identical to optimum gain match. This means that adjusting a dual-gate MOSFET amplifier for maximum gain usually provides best noise figure.

Some examples of common-source amplifiers are shown in Fig. 18. Many properly designed dual-gate MOSFET amplifiers do not require neutralization to achieve stability and best noise figure. An

example of this approach is shown in Fig. 18A. Neutralization may be required; Fig. 18C shows capacitive neutralization applied to a dual-gate-MOSFET amplifier. Common-source JFET amplifiers usually require neutralization to attain satisfactory operation. Inductive neutralization as shown in Fig. 18B is commonly used.

Using the gate as the common stage element introduces negative feedback and eliminates the need for neutralization in a common-gate amplifier, as shown in Fig. 19. The feedback reduces the stage

gain and lowers the input impedance, increasing the bandwidth of the stage. An additional benefit of common-gate amplifiers is reduced susceptibility to overload as compared to common-source amplifiers.

The cascode circuit of Fig. 20 combines the common-source and the common-gate amplifiers, securing some of the advantages of each. Increased gain over a single stage is its greatest asset.

Fig. 21 shows typical bipolar amplifiers for the UHF range. Fig. 21A illustrates a common-emitter amplifier, analogous to the common-source FET amplifier. The common-base amplifier of Fig. 21B can similarly be compared to a common-gate FET amplifier.

### Front-End Protection

The first amplifier of a receiver is susceptible to damage or complete burnout through application of excessive voltage to its input element by way of the antenna. This can be the result of lightning discharges (not necessarily in the immediate vicinity), RF leakage from the station transmitter through a faulty send-receive relay or switch, or RF power from a nearby transmitter and antenna system. Bipolar transistors often used in low-noise UHF amplifiers are particularly sensitive to this trouble. The degradation may be gradual, going unnoticed until the receiving sensitivity has become very poor.

No equipment is likely to survive a direct hit from lightning, but casual damage can be prevented by connecting diodes back-to-back across the input circuit. Either germanium or silicon VHF diodes can be used. Both have the thresholds of conduction well above any normal signal level, about 0.2 volt for germanium and 0.6 volt for silicon. The diodes used should have fast switching times. Diodes such as the 1N914 and hot-carrier types are suitable. A check on weak-signal reception should be made before and after connection of the diodes.

### MIXERS

Conversion of the received energy to a lower frequency, so it can be amplified more efficiently than would be possible at the signal frequency, is a basic principle of the superheterodyne receiver. The stage in which this is done may be called a converter or frequency converter, but we will use the more common term, mixer, to avoid confusion with converter, as applied to a complete VHF receiving accessory. Mixers perform similar functions in both transmitting and receiving circuits.

The mixer is one of the most important parts of a high-performance receiver. It is at this point where the greatest consideration for dynamic range exists. For best receiver performance the mixer should receive only enough preamplification to overcome the mixer noise. When excessive amounts of signal energy are permitted to reach the mixer, there will be desensitization, cross-modulation and IMD products

in the mixer. When these effects are severe enough the receiver can be rendered useless. Therefore, it is advantageous to utilize what is often called a "strong mixer." That is, one which can handle high signal levels without being affected adversely.

Generally speaking, diode-ring passive mixers fare the best in this regard. However, they are fairly noisy and require considerably more LO injection than is the case with active mixers. For the less sophisticated types of receivers, it is adequate to use single-ended active mixers, provided the gain distribution between the antenna and mixer is proper for the mixer device used. Field-effect transistors are preferred by most designers; bipolar-transistor mixers are seldom used.

The primary advantage of an active mixer is that it has conversion gain rather than loss. This means that the stages following the mixer need not have as much gain as when diode mixers are used. A typical doubly balanced diode mixer will have a conversion loss of some 8 dB, whereas an FET active mixer may exhibit a conversion gain as great as 15 dB. The cost of gain stages is relatively small. This consideration easily justifies the use of strong passive mixers in the interest of high dynamic range.

An LC, crystal-lattice, or mechanical type of band-pass filter is almost always used after the mixer or the post-mixer amplifier. This helps to establish the overall selectivity of the receiver. It also rejects unwanted mixer products that fall outside the passband of the filter.

In the interest of optimum mixer performance, the LO energy supplied to it should be reasonably clean with respect to unwanted frequencies. Many designers, for this reason, use a band-pass filter between the LO output and the mixer input. Excessive LO noise will seriously degrade receiver performance. LO noise should be 80 dB or more below the peak output level. Excessive noise will appear as noise sidebands in the receiver output.

A receiver for 50 MHz or higher usually has at least two mixer stages: one in the VHF or UHF converter, and usually two or more in the communications receiver that follows it. We are primarily concerned here with the first mixer.

The ideal mixer would convert any input signal to another chosen frequency with no distortion, and would have a noise figure of 0 dB. Unfortunately, a mixer such as that exists only in a dream world. The mixer that has a 0-dB noise figure (or equivalent loss) has yet to be conceived. This means that the proper use of RF amplification and perhaps post-mixer amplification is necessary for maximum receiver performance with regard to sensitivity. Poor sensitivity is the least difficult of the mixer failings to mend.

Because the mixer operates in a nonlinear mode, reduction of distortion becomes a major design problem. As the mixer input

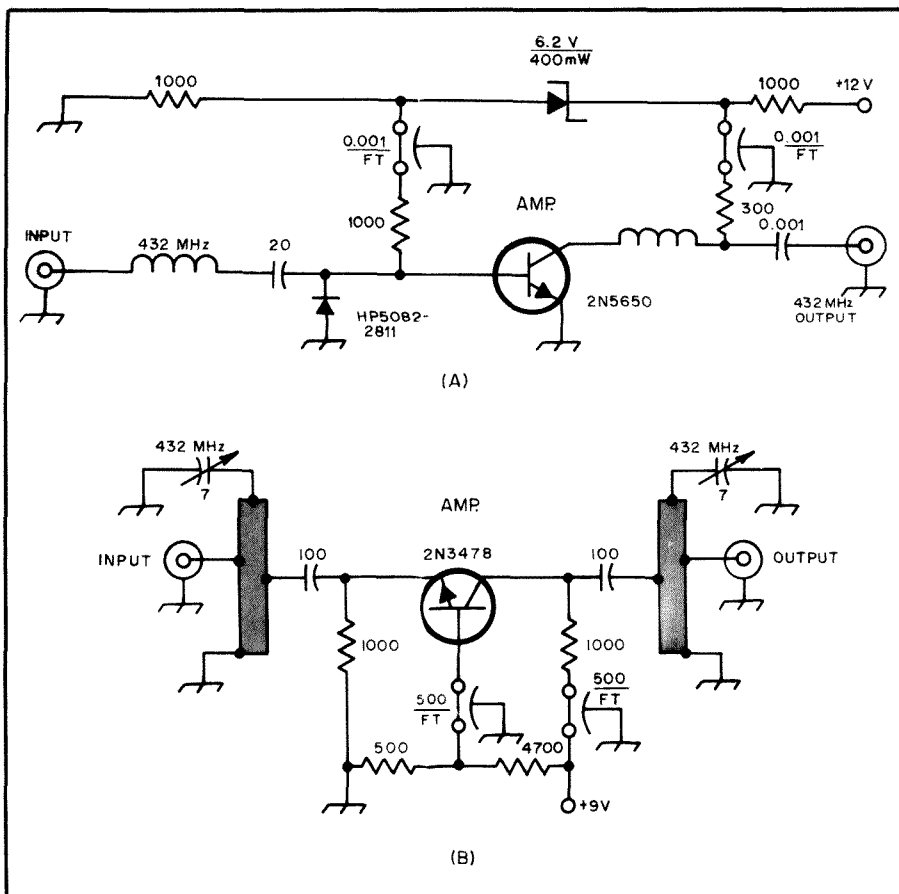

Fig. 21 — Examples of VHF amplifiers using bipolar transistors.

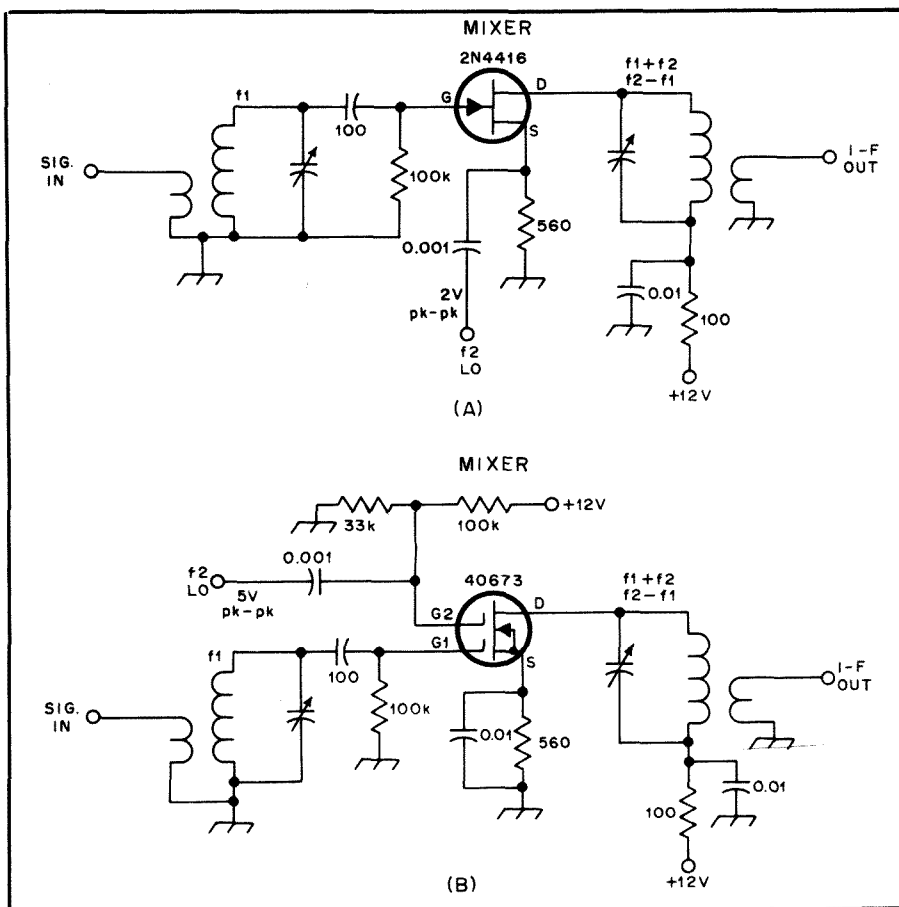

Fig. 22 — Two styles of active mixers using FETs.

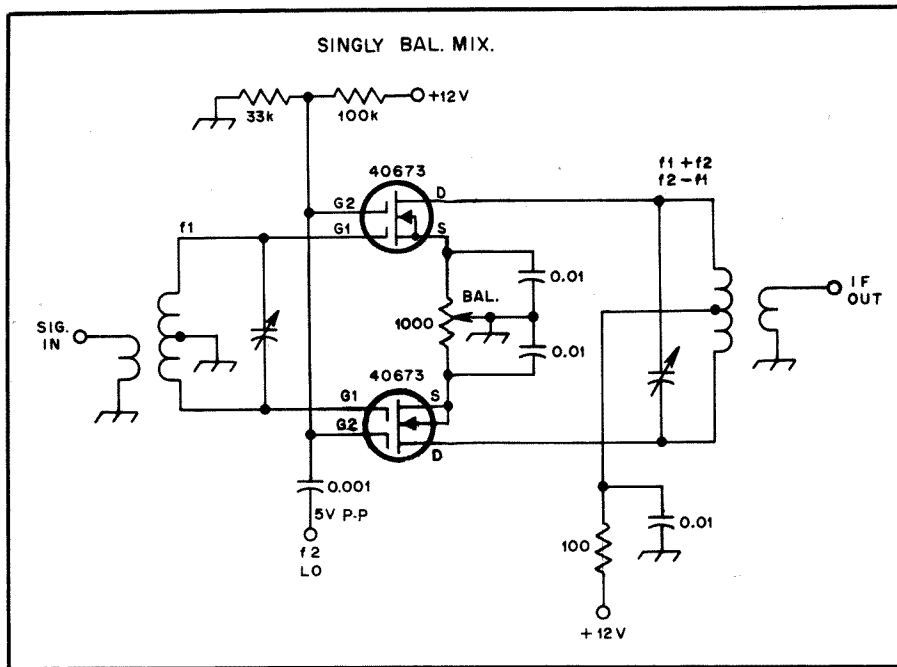

Fig. 23 — An active singly balanced FET mixer.

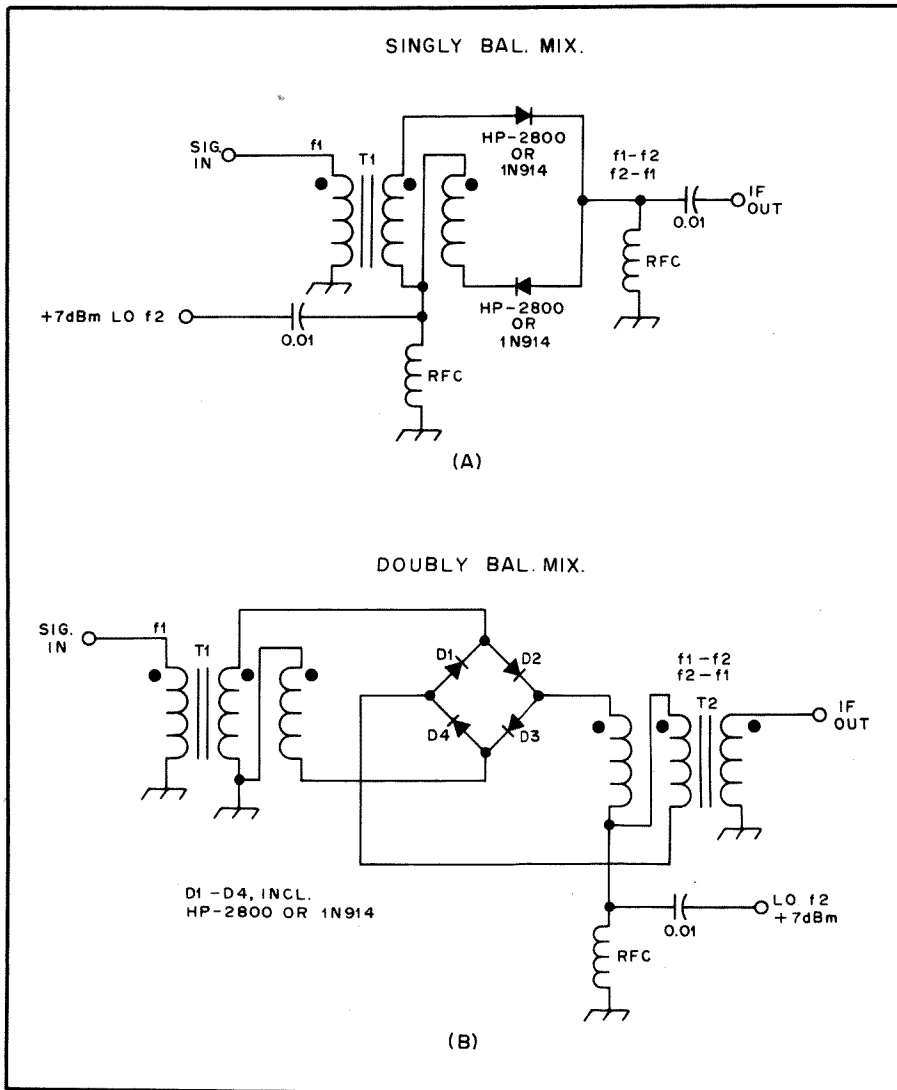

Fig. 24 — Singly and doubly balanced diode mixers.

level is increased, a point is reached where the output no longer increases linearly with input. A phenomenon known as compression occurs. When the compression point is reached, the sensitivity of the mixer is reduced for every signal in the passband. This is manifested as desensing. Different types of mixers characteristically reach their compression points at different input levels, so proper mixer choice can minimize this type of distortion. Any amplifier before the mixer will increase the input levels to the mixer, lowering the point where the input level to the receiving system will cause compression. Therefore, a builder should not use more gain than is necessary to establish system noise figure prior to the mixer.

If more than one signal is present in the passband going into the mixer, they may mix to produce spurious responses known as intermodulation distortion (IMD) products. As the input levels increase further, higher-order IMD products may appear, seemingly filling the passband. Proper mixer operating conditions will alleviate IMD problems and also reduce gain-compression problems.

A third type of distortion is cross modulation. This is most readily observed on AM signals. When the carrier is on, cross modulation is evidenced by modulation characteristics of another signal being superimposed on the received carrier. Techniques to improve IMD characteristics also improve cross-modulation performance.

A problem inherent in all mixing systems is image generation. Whenever two signals are mixed, components are produced at the sum and difference of the two signal frequencies and at multiples of these frequencies. For receiving applications amateurs typically want to detect only one of the mixing products, usually the first-order mixing product. Filtering must be applied to separate the desired signal from the rest. Post-mixer filtering is not adequate, as input images can be mixed to the same intermediate frequency as the desired signal. Input filtering discriminates against these images and prevents unwanted out-of-band signals from overloading the mixer.

#### Typical HF Mixer Circuits

Fig. 22 shows two single-ended active mixers that offer good performance. The example at A employs a JFET with LO injection supplied to the source across a 560-ohm resistor. This injection mode requires somewhat more LO power than would be used if injection was done at the gate. However, there is less occasion for LO pulling when source injection is used, and there is better isolation between the LO and antenna than would be the case with gate injection.

The circuit at B in Fig. 22 is similar in general performance to that at A. The major difference is that a dual-gate MOSFET is used to permit injection of the LO energy at gate 2. Since there is con-

siderable signal isolation between gates 1 and 2, LO pulling is minimized, and antenna-to-LO isolation is good.

A singly balanced active mixer is illustrated in Fig. 23. Two 40673 dual-gate MOSFETs are connected in push-pull, but with the LO frequency injected in parallel at gate 2 of each device. A potentiometer is used in the sources of the transistors to permit circuit balance. This mixer offers performance superior to that of the mixers shown in Fig. 22.

One of the least complicated and inexpensive mixers is the two-diode version (singly balanced) seen in Fig. 24A. A trifilar-wound broadband toroidal transformer is used at the mixer input. The shortcoming of this mixer over the one at B is that signal isolation between all three mixer ports is not possible. A better version is that at B in Fig. 24. In this case all three mixer ports are well isolated from one another. This greatly reduces the probability of spurious responses in the receiver. Conversion loss with these mixers is approximately 8 dB. The impedance of the mixer ports is approximately 50 ohms.

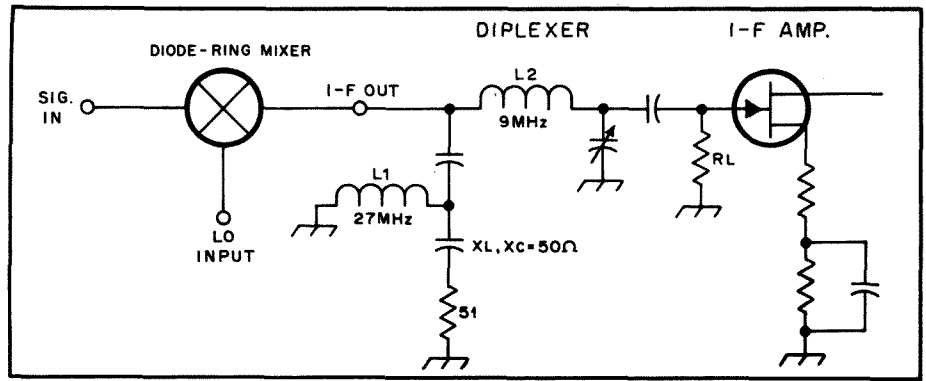

Fig. 25 — Method for diplexing the mixer output to improve the IMD characteristics.

Improved IMD characteristics can be had from a diode-ring mixer, by placing a diplexer after the mixer as shown in Fig. 25. The diplexer consists of a high-pass network (L1) and a low-pass one (L2). L2 is tuned to the IF and serves as a matching network between 50 ohms and  $R_L$ , the FET gate resistor. L1 and the associated series capacitors are tuned to three times the IF and terminated in 50 ohms. This

gives the mixer a proper resistive termination without degrading the 9-MHz IF. The high-pass network has a loaded Q of 1.

### IC Mixers

Although numerous ICs are available for use as mixers, only three are shown here. Fig. 26 shows a CA3028A singly balanced active mixer. The diagram at B shows the inner workings of the IC. The LO is in-

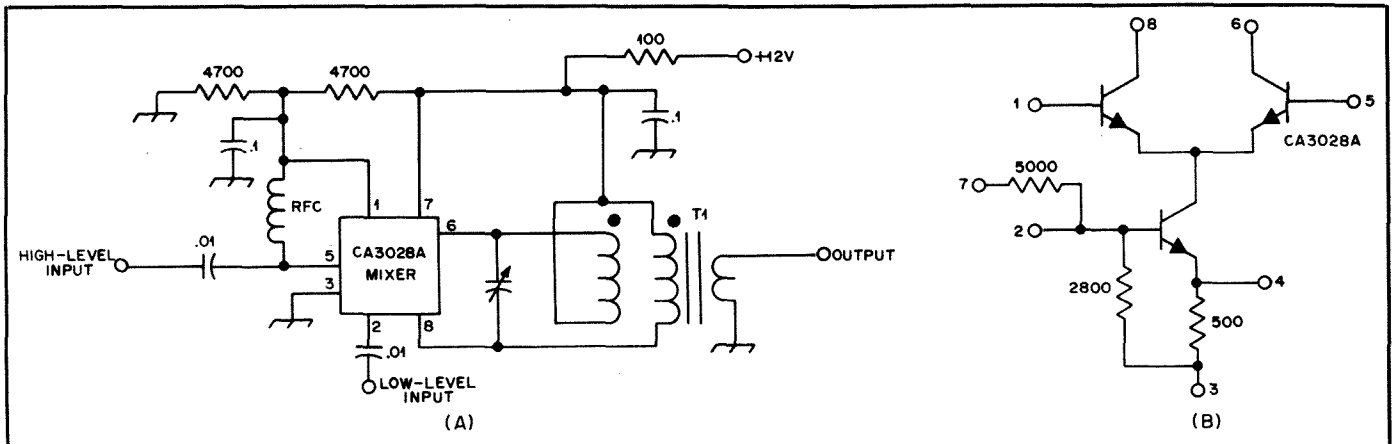

Fig. 26 — CA3028A singly balanced mixer. The circuit for the IC is given at B.

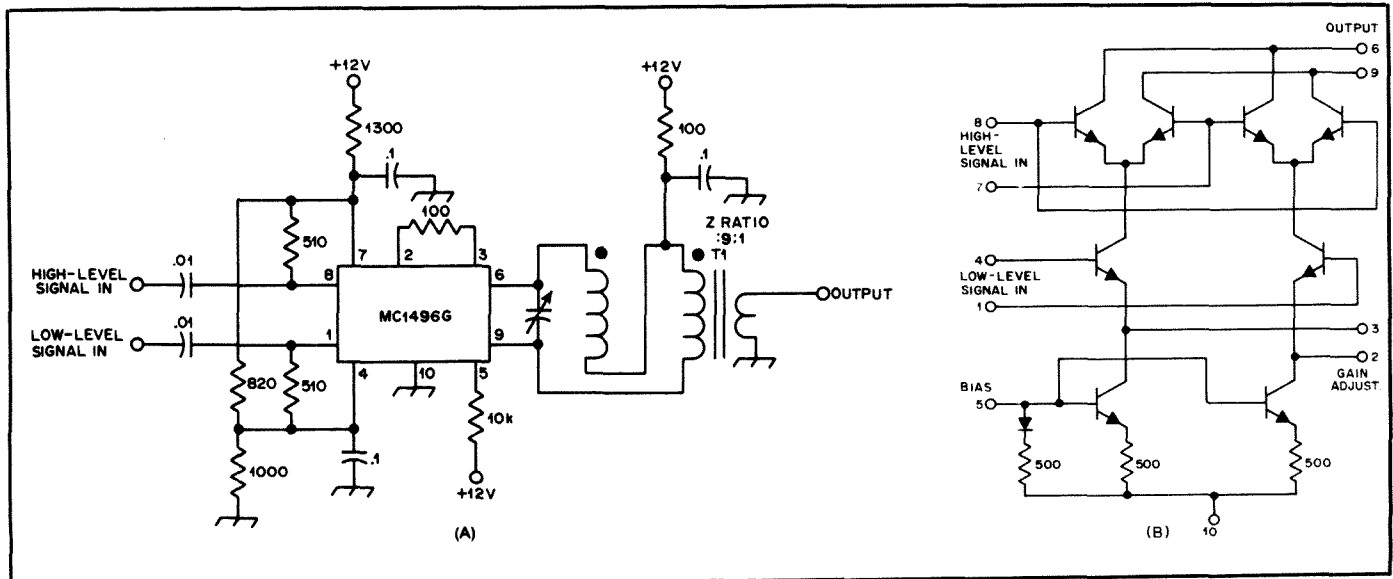

Fig. 27 — MC1496G doubly balanced mixer and circuit of the IC.

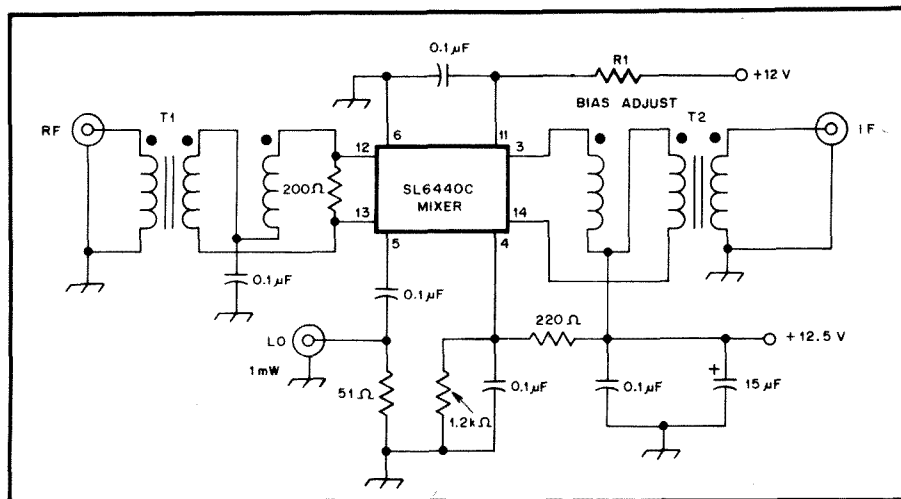

Fig. 28 — Plessey SL6400C doubly balanced mixer. R1 is selected for a bias current of about 12 mA. T1 and T2 are broadband transformers wound on ferrite toroidal cores.

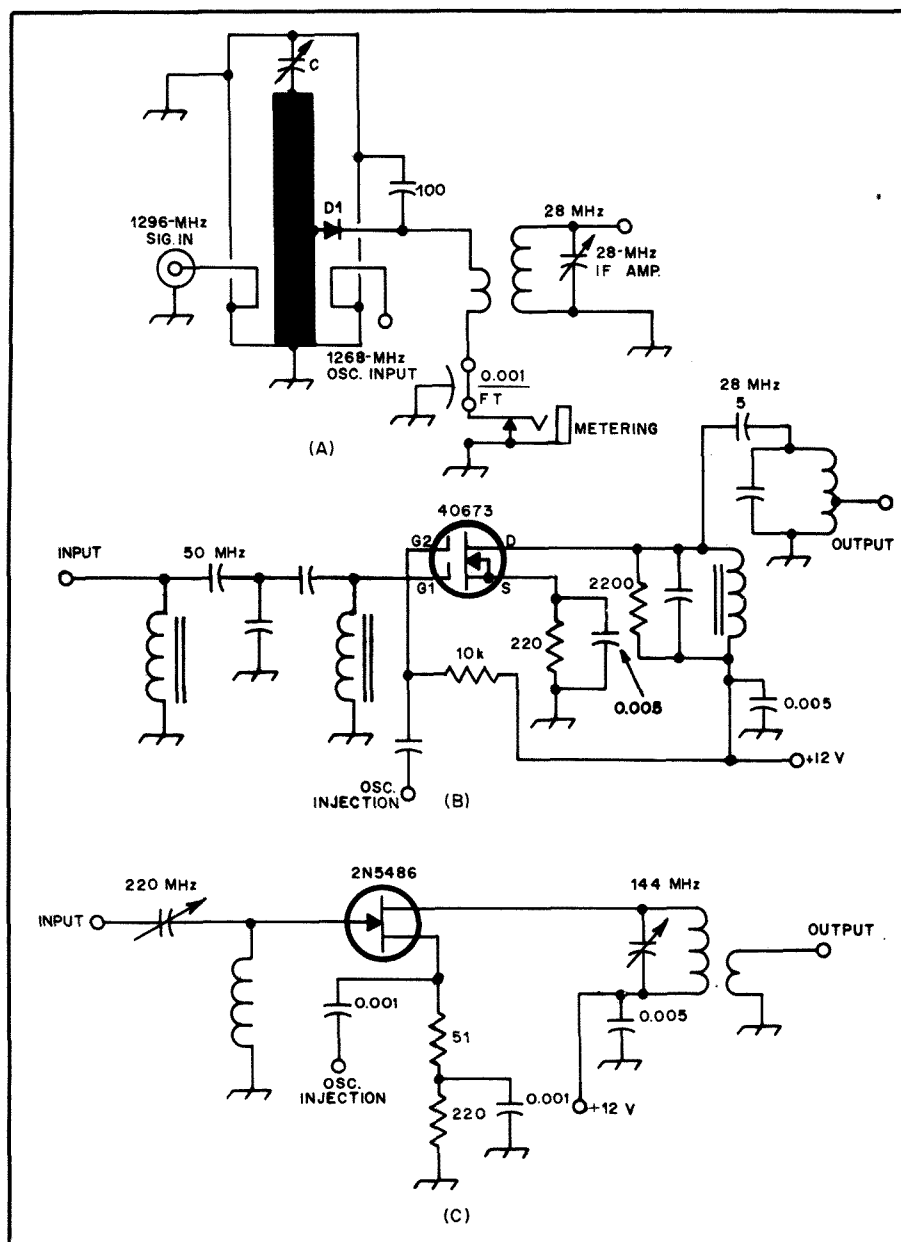

Fig. 29 — Examples of single-ended mixers. The diode mixer, A, is usable through the microwave region. FET mixers, B and C, offer conversion gain and low noise figure.

jected at pin 2 of the IC. Conversion gain is on the order of 15 dB.

Fig. 27A illustrates a doubly balanced IC active mixer that employs an MC1496G. A schematic diagram of the IC is shown at B. The performance of this mixer is excellent, but it is not as strong a mixer as that of Fig. 24. However, it has good conversion gain and a fairly low noise figure.

The Plessey SL6400C programmable high-level doubly balanced mixer is shown in Fig. 28 in a broadband circuit. This configuration produces a conversion gain of 8 dB and a third-order output intercept of approximately +22 dBm. The single-sideband noise figure was found to be 11 dB. If the mixer input and output ports are terminated in 50 ohms, rather than 200 ohms as shown in Fig. 28, the typical conversion gain will be -1 dB.

### Single-ended Mixers for VHF and UHF

The simplest type of mixer is the diode mixer. The signal and the heterodyning frequency are fed into the mixer, and the mixer output includes both the sum and the difference frequencies of the two. In the case of the circuit shown in Fig. 29A the difference frequency is retained, so the 1296-MHz input signal is converted down to 28 MHz. The sum frequency is filtered out by the 28-MHz tuned circuits.

A quality diode (such as the hot-carrier type) has a fairly low noise figure up through the microwave region. Since most active mixers fall off in performance above 500 MHz, the diode mixer is the one most commonly found in amateur microwave service. Unfortunately, all diode mixers have conversion loss. The loss must be added to the noise figure of the stage following the mixer to determine the system noise figure. A low-noise stage following the mixer is necessary for good weak-signal reception. The noise figure of most communications receivers is far higher than what is needed for a low-noise-figure system; if not, RF amplification is used.

Bipolar transistors are not good square-law type devices, and thus are not favored for single-ended applications. Their major use is in switching-type mixers of the balanced variety.

Field-effect transistors have good square-law response and are very popular VHF mixers. The dual-gate MOSFET is a common mixer found in VHF amateur equipment. The MOSFET can provide considerable conversion gain, while at the same time maintaining a reasonable noise figure. MOSFET overload characteristics are suitable for the vast majority of applications. Local-oscillator energy can be applied at one of the MOSFET gates, effectively isolating the local oscillator from the other signals. The gate impedance is high, so relatively little injection is needed for maximum conversion gain. A typical example is shown in Fig. 29B.

JFETs are close to the MOSFET in mixer performance but are more difficult to apply

in practical hardware. As with the MOSFET, input impedance to a JFET mixer is high, and substantial conversion gain is available. JFET bias for mixer service is critical and must be adjusted for best results. The output impedance of a JFET is lower than a dual-gate MOSFET; typically around 10 k $\Omega$ . Although other possibilities exist, local-oscillator injection should be made at the JFET source for best results. The source is a low-impedance point, so considerably more local-oscillator power is required than if a dual-gate MOSFET were used as the mixer. Noise figures as low as 4 dB are possible with circuits like that shown in Fig. 29C.

The injection level of the local oscillator affects mixer performance. Raising the LO level increases conversion gain in an FET mixer. The local-oscillator signal should be as large as possible without pushing the FET into its pinchoff region. The gate junction of the FET should never conduct in mixer applications. Increased IMD products result from either of these conditions and should be avoided. The local-oscillator energy should be as pure as possible. Distorted injection energy not only increases IMD production but also increases stage noise figure.

Proper termination of the output of an FET mixer optimizes overload performance. If the impedance seen at the drain of an FET mixer is too high at any of the mixer product frequencies, large voltage excursions can occur on the FET drain. If the voltage excursion on the drain is large enough, output distortion will be evident. Often these high-voltage excursions occur at frequencies outside the desired passband, causing distortion from signals not even detectable by the receiver. A resistor within the output matching network may be used to limit the broadband impedance to a suitably low level.

### Balanced Mixers

Use of more than one device in either a singly or doubly balanced mixer offers many advantages over a single-ended mixer. The balance prevents energy injected into a mixer port from appearing at another port. The implications of this are significant when minimum mixer distortion is sought. The port-to-port isolation inhibits any signals other than the mixing products from reaching subsequent stages where they might be mixed and cause undesirable products. The usually large local-oscillator signal is kept away from the RF amplifier stages where it might cause gain compression because of its magnitude. Any amplitude-modulated noise found on the local-oscillator signal is suppressed at the mixer output, where it might be later detected. In a singly balanced mixer only one port, usually the local-oscillator input, is isolated from the other two. A doubly balanced mixer isolates all three ports from each other.

The most common balanced mixer uses

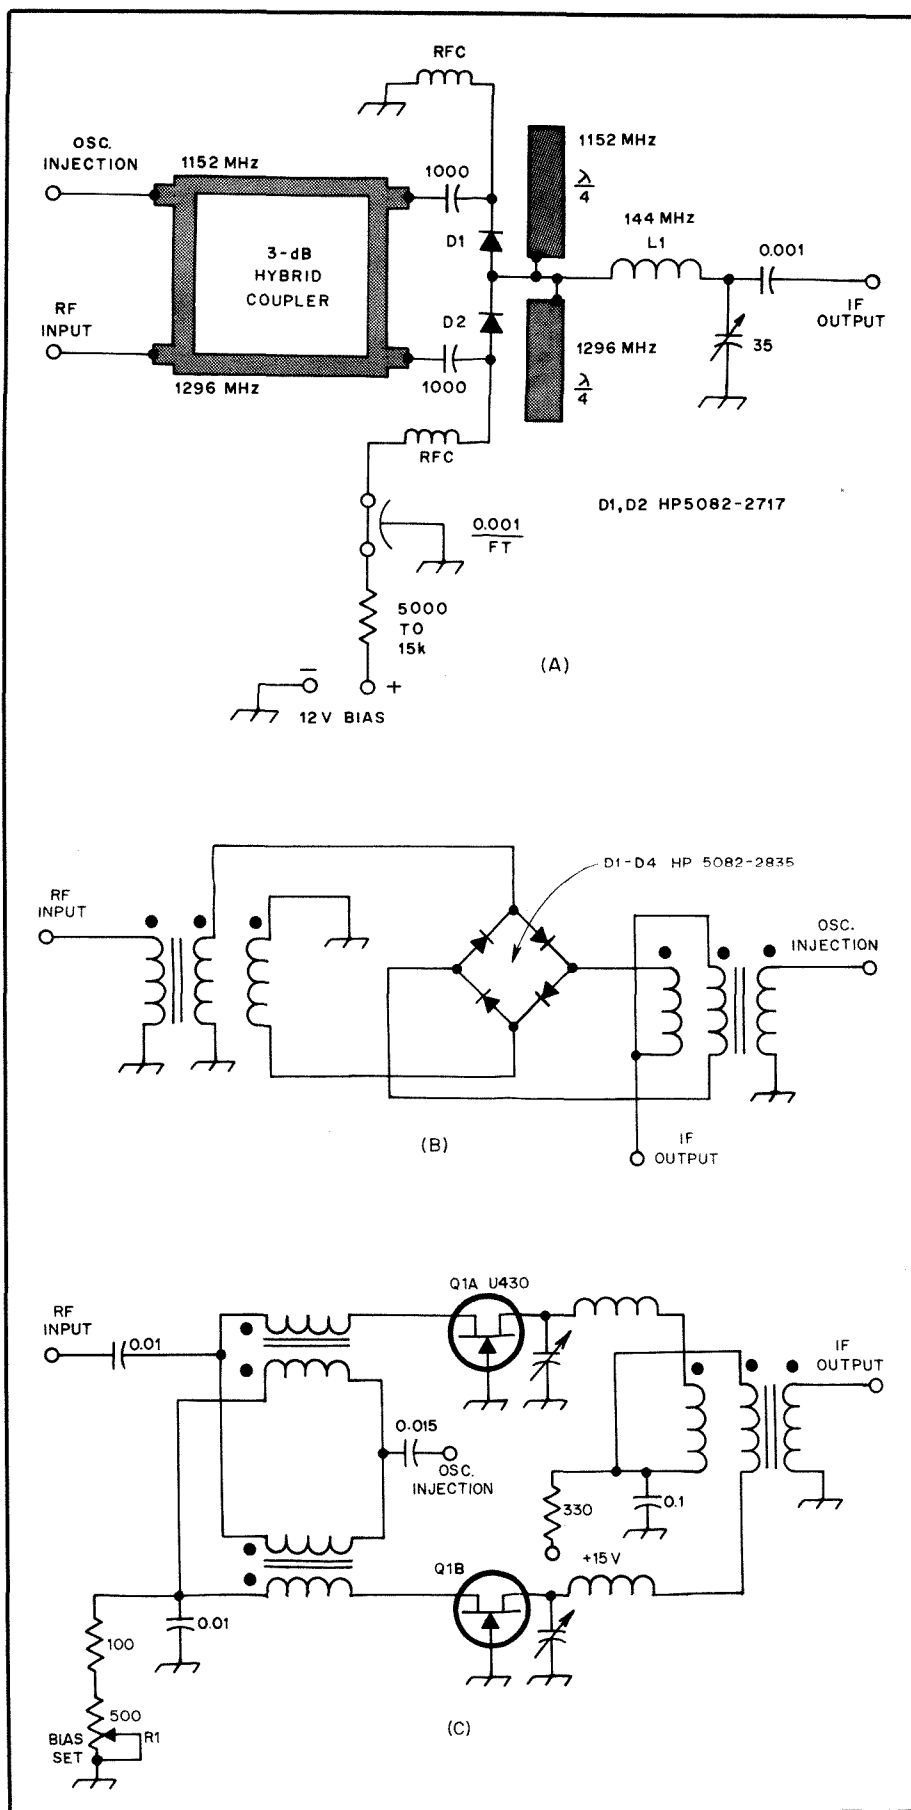

Fig. 30 — Balanced mixers for VHF and UHF. The singly balanced mixer, A, provides isolation of the local oscillator from the output. The doubly balanced diode mixer, B, has all ports isolated from each other, and is broadband throughout VHF. A special dual JFET is used at C to give high dynamic range with low noise figure.

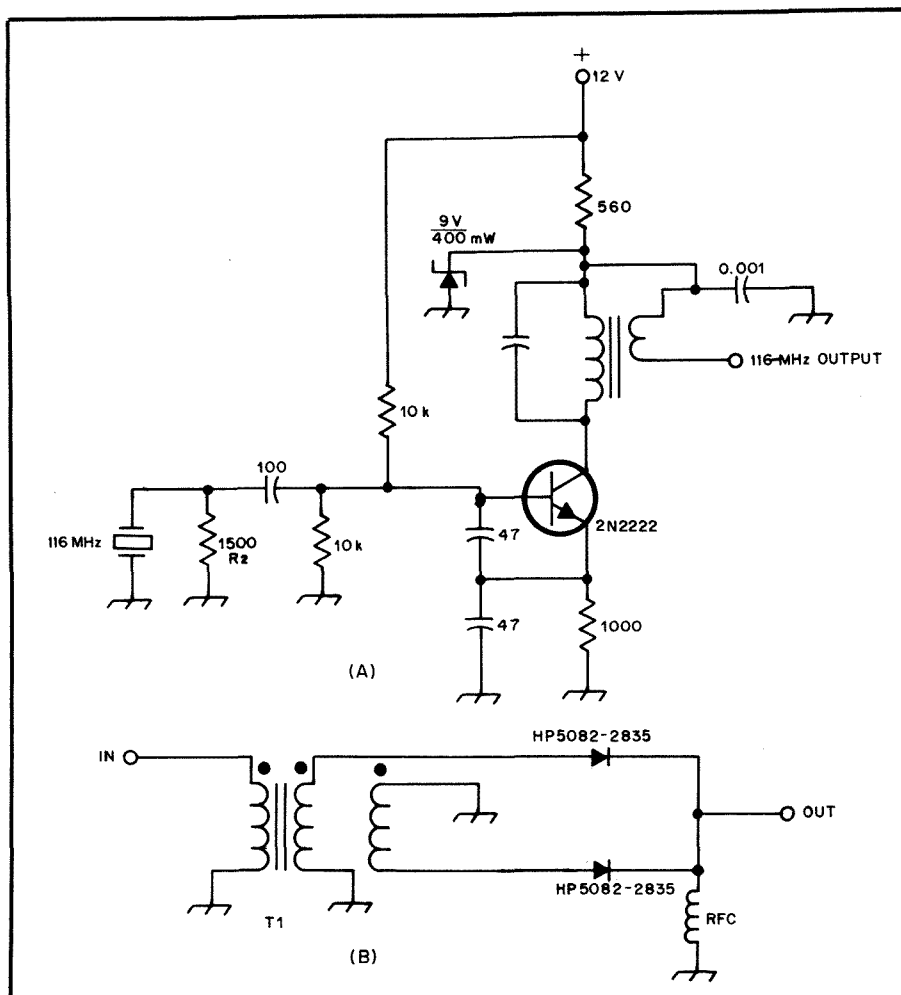

Fig. 31 — Typical crystal oscillator for VHF use, A, The diode frequency doubler, B, provides good rejection of the fundamental signal.

diodes. The disadvantages presented earlier with respect to single-ended diode mixers apply here also. A singly balanced diode mixer is shown in Fig. 30A. Hot-carrier diodes are normally used for D1 and D2, as they can handle high currents, have a low noise figure, and are available for use up through several gigahertz.

The doubly balanced mixer is more common today. Commercial modules, very reasonably priced, are often used instead of homemade circuits. Large-scale manufacturing can usually offer electrical balance not so easily attained with the homemade units. Isolation of 35 to 40 dB is typical at VHF, with only 6 to 7 dB of conversion loss. High local-oscillator injection is needed to reach optimum performance with these mixers. Proper broadband termination of all the mixer ports is necessary to prevent unwanted signals from being reflected into the mixer "rat race," only to emerge at another port. The IF port (shown in Fig. 30B) is the most critical with respect to termination and should be terminated at  $50 + j0$  ohms. Transmission line transformers provide the necessary phase shift, as half the bridge is fed 180 degrees out of phase with respect to the

other half. These can be wound on ferrite toroidal forms to effect a broadband response. Careful winding of the transformers improves balance in the circuit, which in turn improves port-to-port isolation.

Active devices can be used very effectively in balanced mixers. Both FETs and bipolars can be used successfully. Active balanced mixers offer all the benefits of balanced diode mixers, plus the added advantage of conversion gain rather than loss. Because of this conversion gain, less RF amplification is needed to establish a lower system noise figure than would be needed with a diode mixer. Low gain prior to the mixer keeps mixer-input levels low, maximizing mixer overload resistance. High-dissipation active devices can be used, yielding better mixer performance than is available from diode balanced mixers. Fig. 30C shows a dual FET which has been specially designed for mixer applications. R1 allows for electrical balance adjustment in the circuit. A sharp null in local oscillator output at the mixer output can be observed when R1 is set to the optimum point, showing that electrical balance has been achieved.

## Injection Stages

Oscillator and multiplier stages supplying heterodyning energy to the mixer should be as stable and free of unwanted frequencies as possible. Proper application of crystal control gives the stability needed. Two major factors influence oscillator stability: temperature and operating voltage. As the temperature of a component changes, its internal geometry is altered somewhat as the constituent materials expand or contract. This typically results in internal capacitance changes that affect the resonant frequency of the tuned circuits controlling the oscillator frequency. Use of quality components that have good temperature characteristics helps in this regard. Minimum power should be extracted from the oscillator as excessive heat dissipation within either the crystal or the transistor will cause internal capacitance changes in those devices, moving the resonant frequency. Voltage to the transistor should be regulated for best stability. Simple Zener-diode regulation is sufficient, or a three-terminal regulator IC can be used.

Any unwanted injection frequencies will mix with signals present in the mixer, creating spurious outputs at the mixer output. A clean local oscillator will prevent these unwanted outputs. The oscillator chain output can be heavily filtered to cut down the harmonic content of the oscillator. Good planning and design will minimize the unwanted energy, making the filtering job less demanding. A high-frequency crystal in the oscillator minimizes the number of times that the fundamental oscillator frequency has to be multiplied to reach the converter injection frequency. Proper use of doublers rather than triplers can eliminate any odd oscillator frequency multiples, so a low-pass filter at the output has to filter only the fourth harmonic and beyond. A band-pass filter would be needed at the output of a tripler to eliminate the second harmonic and the higher ones. Finally, good shielding and power-line filtering should be used throughout to prevent any line noise from reaching the mixer or causing RFI problems elsewhere.

Fig. 31A shows a typical circuit useful for providing the 116-MHz injection energy necessary to convert a 144-MHz signal down to 28 MHz. R<sub>Z</sub> dampens the crystal action somewhat, assuring that the proper overtone is the actual oscillation frequency. The collector tank network is parallel tuned and can be wound on a toroidal core to reduce radiation. The output is link coupled from the tank, minimizing harmonic coupling. This oscillator would be followed by a buffer to bring the signal up to that level needed and to purify the oscillator signal further.

A similar oscillator could be used in a 220-MHz converter. Since crystals are not available at 192 MHz, the frequency required for conversion to 28-MHz converter

output, the most logical approach is to use a 96-MHz oscillator and double its output. Fig. 31B shows a diode frequency doubler suitable for the application. The phase-shifting transformer can be made from a trifilar winding on a ferrite core. Hot-carrier diodes allow the use of a doubler like this up through at least 500 MHz. There is a loss of about 8 dB through the doubler, so amplification is needed to raise the injection signal to the appropriate level. Fundamental energy is down by as much as 40 dB from the second harmonic with a balanced diode doubler such as this. All of the odd harmonics are well down in amplitude also, without using tuned circuits. A low-pass filter can be used to eliminate the undesired harmonics from the output.

## DOUBLY BALANCED MIXERS

Advances in technology have provided the amateur builder with many new choices of hardware to use in the building of receivers, converters or preamplifiers. The broadband doubly balanced mixer (DBM) package is a fine example of this progress. As amateurs gain an understanding of the capabilities of this device, they are incorporating this type of mixer in many pieces of equipment, especially receiving mixers. The combined mixer/amplifier described here was presented originally in March 1975 *QST* by K1AGB.

### Mixer Comparisons

Is a DBM really better than other types? What does it offer, and what are its disadvantages? To answer these questions, another look at more conventional active (voltages applied) mixing techniques and some of their problems is in order. Briefly, common single-device active mixers with gain at VHF and UHF are beset with problems of noise, desensitization and insufficient local-oscillator (LO) isolation from the RF and IF "ports." As mixers, most devices have noise figures in excess of those published for them as RF amplifiers and will not provide sufficient

sensitivity for weak-signal work. To minimize noise, mixer-device current is generally maintained at a low level. This can reduce dynamic range and increase overload potential. Gain contributions of RF amplifiers (used to establish a low system noise figure) further complicate the overload problem. LO-noise leakage to the RF and IF ports adversely affects system performance. Mixer dynamic range can be limited by conversion of this noise to the IF, placing a lower limit on mixer system sensitivity. Generally 20 dB of mixer mid-band interport isolation is required, and most passive DBMs can offer greater than 40 dB.

A commercially manufactured doubly balanced diode mixer offers performance predictability, circuit simplicity and flexibility. Closely matched Schottky-barrier hot-carrier diodes, commonly used in most inexpensive mixers of this type, provide outstanding strong-signal mixer performance (up to about 0 dBm at the RF input port) and add little (0.5 dB or so) to the mixer noise figure. Essentially, diode conversion loss from RF to IF, listed in Table 1, represents most of the mixer contribution to system noise figure. Midband isolation between the LO port and the RF and IF ports of a DBM is typically > 35 dB — far greater than that achievable with conventional single-device active-mixing schemes. This isolation is particularly advantageous in dealing with low-level local-oscillator harmonic and noise content. Of course, selection of LO devices with low audio noise figures, and proper RF filtering in the LO output, will reduce problems from this source.

Often-listed disadvantages of a diode DBM are (a) conversion loss, (b) LO power requirements, and (c) IF-interface problems. The first two points are closely interrelated. Conversion loss necessitates some low-noise RF amplification to establish a useful weak-signal system noise figure. Additional LO power is fairly easy to generate, filter and measure. If we accept the fact that more LO power is

necessary for the DBM than is used in conventional single-device active mixing circuits, we leave only two real obstacles to be overcome in the DBM, those of conversion loss and IF output interfacing.

To minimize conversion loss in a DBM, the diodes are driven by the LO beyond their square-law region, producing an output spectrum which in general includes the terms<sup>2</sup>

- 1) Fundamental frequencies  $f_{LO}$  and  $f_{RF}$
- 2) All of their harmonics
- 3) The desired IF output,  $f_{LO} \pm f_{RF}$
- 4) All higher order products of  $n f_{LO} \pm m f_{RF}$ , where  $n$  and  $m$  are integers.

The DBM, by virtue of its symmetry and internal transformer balance, suppresses a large number of the harmonic modulation products. In the system described here,  $f_{LO}$  is on the low side of  $f_{RF}$ ; therefore, numerically, the desired IF output is  $f_{RF} - f_{LO}$ . Nonetheless, the term  $f_{LO} + f_{RF}$  appears at the IF output port equal in amplitude to the desired IF signal, and this unused energy must be effectively terminated to obtain no more than the specified mixer-conversion loss. This is not the image frequency,  $f_{LO} - f_{IF}$ , which will be discussed later.

In any mixer design, all RF port signal components must be bypassed effectively for best conversion efficiency (minimum loss). Energy not "converted" by mixing action will reduce conversion gain in active systems, and increase conversion loss in passive systems such as the diode DBM. RF bypassing also prevents spurious resonances and other undesired phenomena from affecting mixer performance. In this system, RF bypassing at the IF output port will be provided by the input capacitance of the IF interface. The DBM is not a panacea for mixing ills, and its effectiveness can be reduced drastically if all ports are not properly terminated.

<sup>2</sup>See appendix at the end of this section on mixers.

Fig. 32 — The IF port of a doubly balanced mixer, matched at  $f_{LO} - f_{RF}$  and reactive at  $f_{LO} + f_{RF}$ . In this configuration conversion loss, RF compression and desensitization levels can vary  $\pm 3$ dB while harmonic modulation and third-order IMD products can vary  $\pm 20$  dB.

### DBM-Port Termination

Most DBM performance inconsistencies occur because system source and load impedances presented to the mixer are not matched at all frequencies encountered in normal operation. The terminations (attenuator pads) used in conjunction with test equipment by manufacturers to measure published performance characteristics are closely matched over a wide range of frequencies. Reactive mixer terminations can cause system problems, and multiple reactive terminations can usually compound these problems to the point where performance is very difficult to predict. Let's see how we can deal with reactive terminations.

#### The IF Port

The IF port is very sensitive to mismatch conditions. Reflections from the mixer/IF-amplifier interface (the pi network in Fig. 33) can cause the conversion loss to vary as much as 6 dB. Also greatly affected are third-order intermodulation-product ratio and the suppression of spurious signals, both of which may vary  $\pm 10$  dB or more. It is ironic that the IF port is the most sensitive to a reactive termination, as this is a receiving system point where sharp-skirted filters are often desired.

Briefly, here is what happens with a reactive IF port termination. Fig. 32 shows a DBM with "high side" LO injection and an IF termination matched at  $f_{LO} - f_{RF}$  but reactive to  $f_{LO} + f_{RF}$ . The latter term re-enters the mixer, again combines with the LO, and produces terms that exit at the RF port, namely  $2f_{LO} + f_{RF}$ , a dc term, and  $f_{LO} + f_{RF} - f_{LO}$  (the original RF-port input frequency). This condition affects conversion loss, as mentioned earlier, in addition to RF-port VSWR, depending on the phase of the reflected signal. The term  $2f_{LO} + f_{RF}$  also affects the harmonic spectrum resulting in spurious responses.

One solution to the IF interface problem is the use of a broadband 50-ohm resistive termination, like a pad, to minimize reflec-

tions. In deference to increased post-conversion system noise figure, it seems impractical to place such a termination at the mixer IF output port. While a complementary filter or diplexer (high-pass/low-pass filters appropriately terminated) can be used to terminate both  $f_{RF} + f_{LO}$  and  $f_{RF} - f_{LO}$ , a simpler method can be used if  $f_{RF} + f_{LO}$  is less than 1 GHz and  $(f_{RF} + f_{LO})/(f_{RF} - f_{LO}) \geq 10$ . Place a short-circuit termination to  $f_{RF} + f_{LO}$ , like a simple lumped capacitance, directly at the mixer IF terminal. This approach is easiest for the amateur to implement and duplicate, so a form of it was tried — with success. In our circuit, C1 serves a dual purpose. Its reactance at  $f_{RF} + f_{LO}$  is small enough to provide a low-impedance "short-circuit" condition to this term for proper mixer operation. Additionally, it is part of the input reactance of the mixer IF amplifier interface. Fortunately, the network impedance-transformation ratio is large enough, and in the proper direction, to permit a fairly large amount of capacitance (low reactance) at the mixer IF-output port. The capacitor, in its dual role, must be of good quality at VHF/UHF (specifically  $f_{RF} + f_{LO}$ ), with short leads, to be effective. The mixer condition  $(f_{RF} + f_{LO})/(f_{RF} - f_{LO}) \geq 10$  is met at 432 and 220 MHz with a 404/192 MHz LO (28-MHz IF) and on 144 MHz with a 130-MHz LO (14-MHz IF). At 50 MHz, with a 36-MHz LO, we are slightly shy of the requirement, but no problems were encountered in an operating unit. The pi-type interface circuit assures a decreasing impedance as IF operation departs from mid-band, lessening IMD problems.

#### The LO Port

The primary effect of a reactive LO source is an increase in harmonic modulation and third-order IMD products. If the drive level is adequate, no effect is noted on conversion loss, RF compression and desensitization levels. A reactive LO source can be mitigated by simply padding the LO port with a 3- or 6-dB pad and increasing the LO drive a like amount. If excess LO power is not available, matching the LO source to the mixer will improve performance. This method is acceptable for single-frequency LO applications, when appropriate test equipment is available to evaluate matching results. For simplicity, a 3-dB pad was incorporated at the LO-input port as an interface in both versions of the mixer. Thus the LO port is presented with a reasonably broadband termination, and is relatively insensitive to applied frequency, as long as it is below about 500 MHz. This implies that frequencies other than amateur assignments may be covered — and such is indeed the case when ap-

<sup>1</sup>Presentation and calculation format of these terms is based on "low-side" LO injection; see the appendix for explanation.

R2 16 ohm, 1/4 W	11 ohm, 1/4 W

Ferrite beads can be replaced by a 10-ohm, 1/4-W carbon resistor at one end of the choke, if desired.

SM = Silver Mica.

propriate LO frequencies and RF amplifiers are used. Remotely located LOs, when adjusted for a 50-ohm load, can be connected to the mixer without severe SWR and reflective-loss problems in the transmission line.

Broadband mixers exhibit different characteristics at different frequencies, owing to circuit resonances and changes in diode impedances resulting from LO power-level changes. Input impedances of the various ports are load dependent, even though they are isolated from each other physically, and by at least 35 dB electrically. At higher frequencies, this effect is more noticeable, since isolation tends to drop as frequency increases. For this reason, it is important to maintain the LO power at its appropriate level, once other ports are matched.

#### The RF Port

A reactive RF source is not too detrimental to system performance. This is good, since the output impedance of most amateur preamplifiers is seldom 50 ohms resistive. A 3-dB pad is used at the RF port in the 50- and 144- to 14-MHz mixers, and a 2-dB pad is used in the 220/432- to 28-MHz units, although they add directly to mixer noise figure. RF inputs between about 80 and 200 MHz are practical in the 14-MHz-IF-output model, while the 28-MHz-output unit is most useful from 175 to 500 MHz. Mixer contribution to system noise figure will be almost completely overcome by a low-noise RF amplifier with sufficient gain and adequate image rejection.

## Image Response

Any broadband mixing scheme will have a potential image-response problem. In most amateur VHF/UHF receiver systems (as in these units), single-conversion techniques are employed. The LO is placed below the desired RF channel for noninverting down-conversion to IF. Conversion is related to both IF and LO frequencies. Because of the broadband nature of the DBM, input signals at the RF image frequency (numerically  $f_{LO} - f_{RF}$  in our case) will legitimately appear inverted at the IF-output port, unless proper filtering is used to reduce them at the mixer RF-input port. For example, a 144-MHz converter with a 28-MHz IF output (116-MHz LO) will have RF image-response potential in the 84- to 88-MHz range. TV channel 6 wideband-FM audio will indeed appear at the IF-output port near 28 MHz unless appropriate RF-input filtering is used to eliminate it. While octave-bandwidth VHF/UHF "imageless mixer" techniques can improve system noise performance by about 3 dB (image noise reduction), and image signal rejection by 20 dB — and much greater with the use of a simple gating scheme — such a system is a bit esoteric for our application. Double- or multiple-conversion techniques can be used to advantage, but they further complicate an otherwise simple system. Image noise and signal rejection will depend on the effectiveness of the filtering provided in the RF-amplifier chain.

## Mixer Selection

The mixer used in this system is a Relcom M6F, with specifications of the M6F and suitable substitutes given in Table 1. While mixers are available with connectors at-

tached; they are more expensive. The MF6 and substitutes are designed for printed-circuit applications. Their short leads assure a proper interface between the mixer and the IF amplifier. The combining of mixer and IF amplifier in one converter package was done for that reason. Along these lines, the modular approach permits good signal isolation and enables the mixer-amplifier/IF system to be used at a variety of RF and LO-input frequencies, as mentioned earlier.

Most commonly available, inexpensive DBMs are not constructed to take advantage of LO powers much above +10 dBm (10 mW). To do so requires additional circuitry, which could degrade other mixer characteristics, specifically conversion loss and interport isolation. The advantage of higher LO power is primarily one of improved strong-signal-handling performance. At least one manufacturer advertises a moderately priced "high-level" receiving DBM that can use up to +23 dBm (200 mW) LO power, and still retain the excellent conversion loss and isolation characteristics shown in Table 1. The usefulness of mixers with LO power requirements above the commonly available +7 dBm (5 mW) level in amateur receiving applications may be a bit moot, as succeeding stages in most amateur receivers will likely overload before the DBM does. Overdesign is not necessary.

In general, mixer selection is based on the lowest practical LO level requirement that will meet the application, as it is more economical and results in the least LO leakage within the system. As a first-order approximation, LO power should be 10 dB greater than the highest anticipated input-signal level at the RF port. Mixers with LO

requirements of +7 dBm are adequate for amateur receiving applications.

## Application Design Guidelines

While the material just presented only scratches the surface in terms of DBM theory and utilization in amateur VHF/UHF receiving systems, some practical solutions to the mixer-port mismatch problem have been offered. To achieve best performance from most commercially manufactured broadband DBMs in amateur receiver service, the following guidelines are suggested:

- 1) Choose IF and LO frequencies that will provide maximum freedom from interference problems. Don't guess; go through the numbers!
- 2) Provide a proper IF-output termination (most critical).
- 3) Increase the LO-input power to RF-input power ratio to a value that will provide the required suppression of any in-band interfering products. The specified LO power (+7 dBm) will generally accomplish this.
- 4) Provide as good an LO match as possible.
- 5) Include adequate premixer RF-image filtering at the RF port.

When the mixer ports are terminated properly, performance usually in excess of published specifications will be achieved — and this is more than adequate for most amateur VHF/UHF receiver mixing applications.

## THE COMBINED DBM/IF AMPLIFIER

A low-noise IF amplifier (2 dB or less) following the DBM helps ensure an acceptable system noise figure when the mixer is preceded by a low-noise RF amplifier.

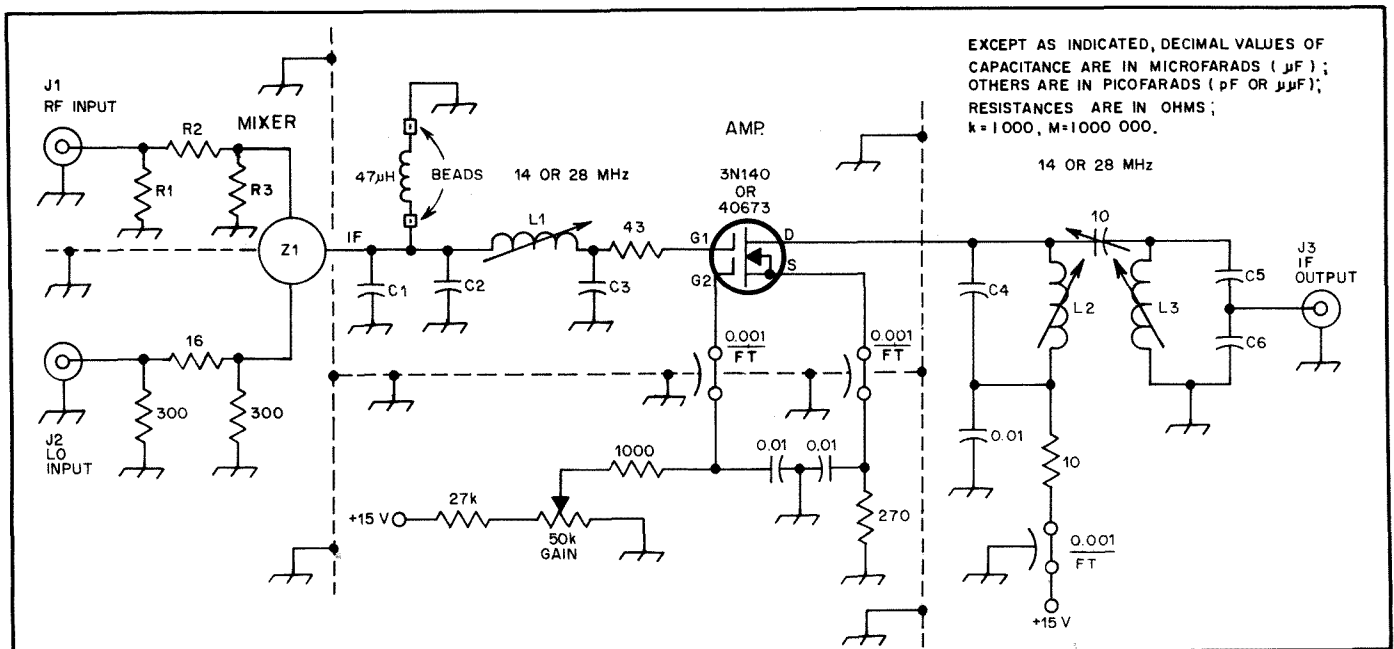

Fig. 33 — A schematic diagram for the doubly balanced mixer and IF post amplifier. The IF can be either 14 or 28 MHz. Parts values are given in Table 2.

A pi-network matching system used between the mixer IF-output port and gate 1 of the 3N140 transforms the nominal 50-ohm mixer-output impedance to a 1500-ohm gate-input impedance (at 28 MHz) specifically for best noise performance. The network forms a narrow-band mixer/IF-output circuit, which serves two other importance functions: It helps achieve the necessary isolation between RF and IF signal components, and serves as a 3-pole filter, resulting in a monotonic decrease in match impedances as the operating IF departs from midband. This action aids in suppression of harmonic-distortion products.

The combined DBM/IF amplifier is shown schematically in Fig. 33 and pictorially in the photographs. In the 14-MHz model, the 3N140 drain is tapped down on its associated inductance to provide a lower impedance for better strong-signal-handling ability. The 3N140 produces about 19 dB gain across a 700-kHz passband, flat within 1 dB between 13.8 and 14.5 MHz. A 2-MHz passband is used for the 28-MHz model, and the device drain is connected directly to the high-impedance end of its associated inductance. Both amplifiers were tuned independently of their mixers, and checked for noise figure as well as gain. With each IF amplifier pretuned and connected to its mixer, signals were applied to the LO- and RF-input ports. The pi-network inductance in the IF interface was adjusted carefully to see if performance had been altered. No change was noted. IF gain is controlled by the externally accessible potentiometer. Passband tuning adjustments in the drain circuit are best made with a sweep generator, but single-signal tuning techniques will be adequate. While there should be no difficulty with the non-gate-protected 3N140, a 40673 may be substituted directly if desired.

#### DBM/IF Amplifier IMD Evaluation

Classical laboratory IMD measurements were made on the DBM/IF amplifier using two -10 dBm signals, closely spaced in the 144-MHz range. The LO power used was +7 dBm. Conversion loss was 5 dB and the calculated third-order output intercept point was +15 dBm. In operation, as simulated by these test conditions, equivalent output signal levels at J3 would be strong enough to severely overload most amateur receivers.

A high-performance, small-signal, VHF/UHF receiving amplifier optimized for IMD reduction and useful noise figure is only as good as any succeeding receiving-system stage, in terms of overload. The DBM/IF-amplifier combination presented significantly reduces common first-mixer overload problems, leaving the station receiver as the potentially weak link in the system. When properly understood and employed, the broadband DBM followed by a selective low-noise IF amplifier can be a useful tool for the amateur VHF/UHF

receiver experimenter.

## APPENDIX

### Mixer Terminology

$f_{RF}$  — RF input frequency

$f_{LO}$  — local-oscillator input frequency

$f_{IF}$  — IF output frequency

By convention, mixing signals and their products are referred to the LO frequency for calculations. In the mixer system,  $f_{RF}$  is always above  $f_{LO}$ , so we will refer our signals to  $f_{RF}$ , with the exception of Fig. 32 which used the  $f_{LO}$  reference.

### Overload

A generic term covering most undesired operating phenomena associated with device nonlinearity.

### Harmonic Modulation Products

Output responses caused by harmonics of  $f_{LO}$  and  $f_{RF}$  and their mixing products.

### RF Compression Level

The absolute single-signal RF input-power level that causes conversion loss to increase by 1 dB.

### RF Desensitization Level

The RF input power of an interfering signal that causes the small-signal conversion loss to increase by 1 dB, i.e., reducing a weak received signal by 1 dB.

### Intermodulation Products

Distortion products caused by multiple RF signals and their harmonics mixing with each other and the LO, producing new output frequencies.

### Mixer Intermodulation Intercept Point

Because mixers are nonlinear devices, all signals applied will generate others. When two signals (or tones),  $F_1$  and  $F_2$ , are applied simultaneously to the RF-input port, additional signals are generated and appear in the output as  $f_{LO} \pm (nF_1 + mF_2)$ . These signals are most troublesome when  $n + m$  is a low odd number, as the resulting product will lie close to the desired output. For  $n = 1$  (or 2) and  $m = 2$  (or 1), the result is three (3), and is called the two-tone/third-order intermodulation products. When  $F_1$  and  $F_2$  are separated by 1 MHz, the third-order products will lie 1 MHz above and below the desired output. Intermodulation is generally specified under anticipated operating conditions since performance varies over the broad mixer-frequency ranges. Intermodulation products may be specified at levels required (i.e., 50 dB below the desired outputs for two 0-dBm input signals) or by the intercept point.

The intercept point is a fictitious point determined by the fact that an increase of level of two input tones by 10 dB will cause the desired output to increase by 10 dB, but the third-order output will increase by 30

dB. If the mixer exhibited no compression, there would be a point at which the level of the desired output would be equal to that of the third-order product. This is called the third-order-intercept point.

### Noise Figure

Noise figure (NF) is a relative measurement based on excess noise power available from a termination (input resistor) at a particular temperature (290 K). When measuring the NF of a doubly balanced mixer with an automatic system, such as the HP-342A, a correction may be necessary to make the meter reading consistent with the accepted definition of receiver noise figure.

In a broadband DBM, the actual noise bandwidth consists of two IF passbands, one on each side of the local-oscillator frequency ( $f_{LO} + f_{IF}$  and  $f_{LO} - f_{IF}$ ). This double-sideband (DSB) IF response includes the RF channel and its image. In general, only the RF channel is desired for further amplification. The image contributes nothing but receiver and background noise.

When making an automatic noise-figure measurement using a wideband noise source, the excess noise is applied through both sidebands in a broadband DBM. Thus the instrument meter indicates NF as based on both sidebands. This means that the noise in the RF and image sidebands is combined in the mixer IF-output port to give double contribution (3 dB greater than under SSB conditions). For equal RF-sideband responses, which is a reasonable assumption, and in the absence of preselectors, filters or other image rejection elements, the automatic NF meter readings are 3 dB lower than the actual NF for DBM measurements.

The noise figure for receivers (and most DBM) is generally specified with only one sideband for the useful signal. As mentioned in the text, most DBM diodes add no more than 0.5 dB (in the form of NF) to conversion loss, which is generally measured under single-signal RF-input (SSB) conditions. Assuming DBM conversion efficiency (or loss) to be within specifications, there is an excellent probability that the SSB NF is also satisfactory. Noise-figure calculations in the text were made using a graphical solution of the well known noise-figure formula:

$$f_T = f_1 + \frac{f_2 - 1}{g_1}$$

converted to decibels.

### Improved Wideband IF Responses

The following information was developed in achieving broad-band performance in the mixer-to-amplifier circuitry. In cases where only a small portion of a band is of interest the original circuit values are adequate. For those who need to receive over a considerable portion of a band, say 1 to 2 MHz, a change of some component

will provide improved performance over a broad range while maintaining an acceptable noise figure.

Ther term "nominal 50-ohm impedance" applied to diode DBM ports is a misnomer, as their reflective impedance is rarely 50 ohms +  $j_0$ , and a VSWR of 1 is almost never achieved. Mixer performance specified by the manufacturer is measured in a 50-ohm broadband system, and it is up to the designer to provide an equivalent termination to ensure that the unit will meet specifications. Appropriate matching techniques at the RF and LO ports will reduce conversion loss and LO-power requirements. Complex filter synthesis can improve the IF output match. However, if one does not have the necessary equipment to evaluate these efforts, they may be wasted. Simple, effective, easily reproduced reduced circuitry was desired as long as the trade-offs were acceptable. Measurements indicate this to be the case.

The most critical circuit in the combined unit is the interface between mixer and IF amplifier. It must be low-pass in nature to satisfy VHF signal component bypassing requirements at the mixer IF port. For best mixer IMD characteristics and low conversion loss, it must present to the IF port a nominal 50-ohm impedance at the desired frequency, and this impedance value must not be allowed to increase as IF operation departs from midband. The impedance at the IF-amplifier end of the interface network must be in the optimum region for minimum cross-modulation and low noise. A dual-gate device offers two important advantages over most bipolars. Very little, if any, power gain is sacrificed in achieving best noise figure, and both parameters (gain and NF) are relatively independent of source resistance in the optimum region. As a result, the designer has a great deal of flexibility in choosing a source impedance. In general, a 3:1 change in source resistance results in only a 1-dB change in NF. With minimum cross-modulation as a prime system consideration, this 3:1 change (reduction) in source resistance implies a 3:1 improvement in cross-modulation and total harmonic distortion.

Tests in the 3N201 dual-gate MOSFET have shown device noise performance to be excellent for source impedances in the 1000- to 2000-ohm region. For optimum noise and good cross-modulation performance, the nominal 50-ohm mixer-IF-output impedance is stepped up to about 1500 ohms for IF-amplifier gate 1, using the familiar low-pass pi network. This is a mismatched condition for gate 1, as the device input impedance for best gain in the HF region is on the order of 10 k $\Omega$ . Network loaded-Q values in the article are a bit higher than necessary, and a design for lower  $Q_L$  is preferred. Suggested modified component values are listed in Fig. 34. High-frequency attenuation is reduced somewhat, but satisfactory noise and bandwidth perfor-

Fig. 34 — Suggested changes in the mixer-to-3N140 pi-network interface circuit, producing lower  $Q_L$  and better performance.

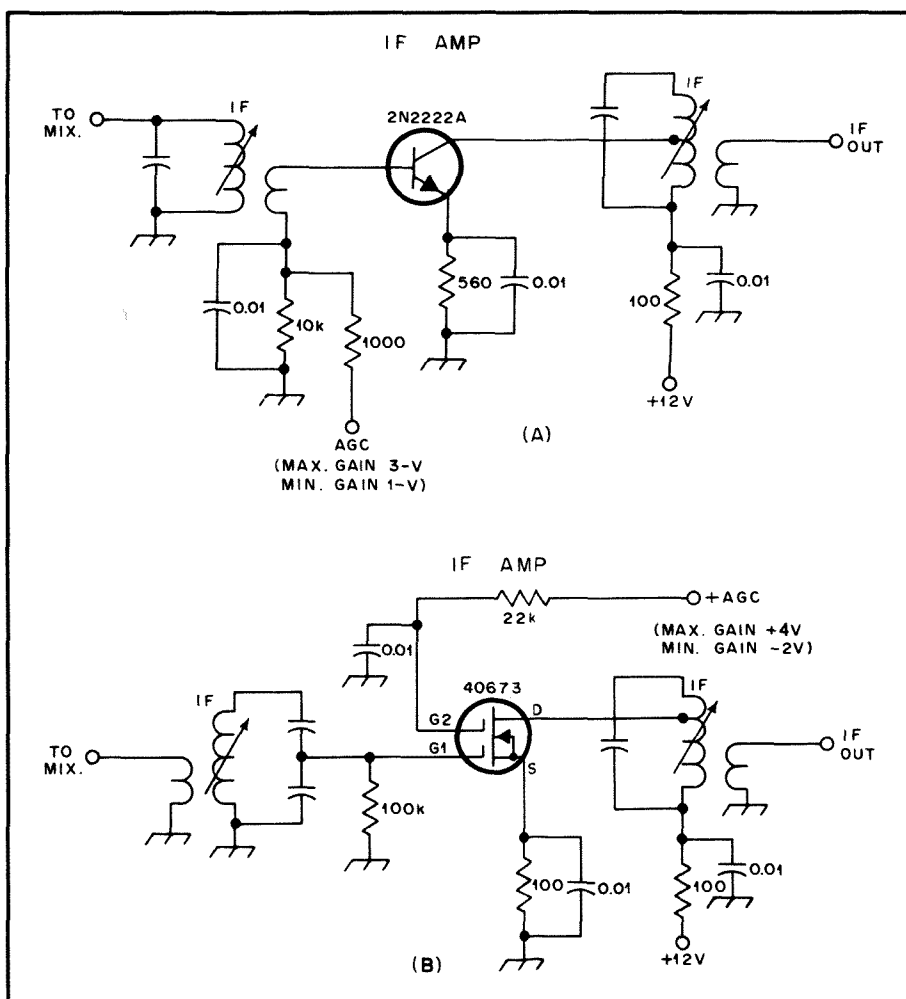

Fig. 35 — Methods for applying AGC to a bipolar IF amplifier (A) and a dual-gate-MOSFET IF stage (B).

mance are more easily obtained. Coil-form size is the same, so no layout changes are required for the modification. Components in the interface must be of high Q and few in number to limit their noise contribution through losses. The 28-MHz values provide satisfactory interface network performance over a 2-MHz bandwidth. A higher  $Q_L$  in the 28-MHz interface can be useful if one narrows the output network and covers only a few hundred kilohertz bandwidth, as is commonly done in 432-MHz weak-signal work.

Device biasing and gain control methods

were chosen for simplicity and adequate performance. Some sort of gain adjustment is desirable for drain-circuit overload protection. It is also a handy way to "set" the receiver S meter. A good method for gain adjustment is reduction of the gate-2 bias voltage from its initial optimum-gain bias point (greater than +4 V dc), producing a remote-cutoff characteristic (a gradual reduction in drain current with decreasing gate bias). The initial gain-reduction rate is higher with a slight forward bias on gate 1, than for  $V_{g1s} = 0$ . Input- and output-circuit detuning resulting from gain reduc-

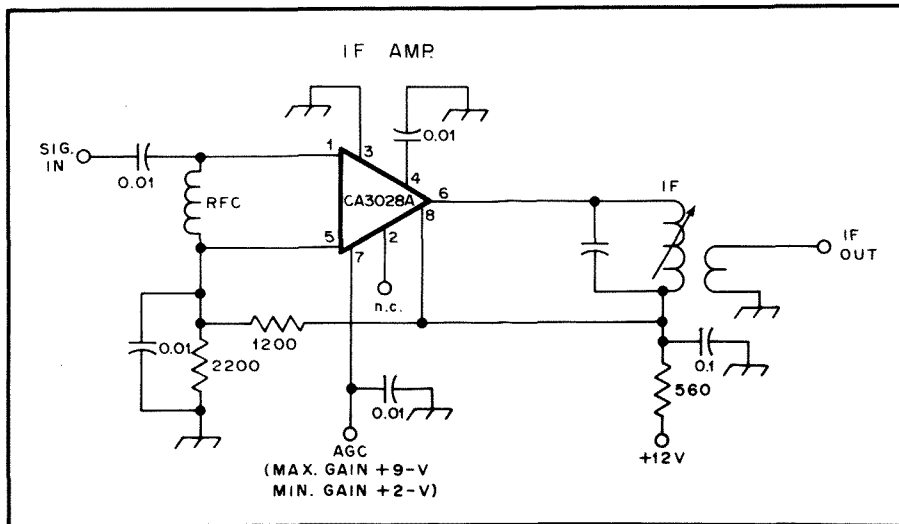

Fig. 36 — An IC type of IF amplifier with AGC applied.

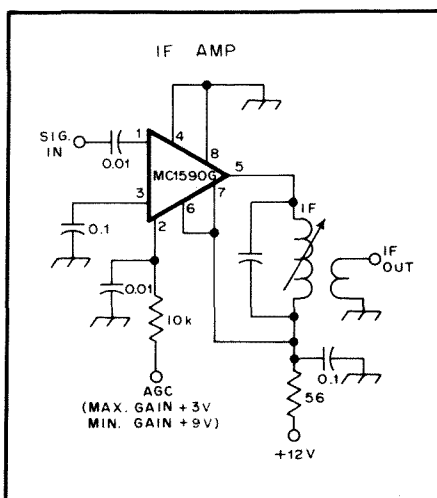

Fig. 37 — AGC is applied to an MC1590G IC.

tion (Miller effect) are inconsequential as the gate-1 and drain susceptances change very little over a wide range of  $V_{g2s}$  and  $I_D$  at both choices of IF. Best intermodulation figure for the 3N201 was obtained with a small forward bias on gate 1. The bias-circuit modification shown in Fig. 34 may be tried, if desired.

### IF Amplifiers

The amount of amplification used in a receiver will depend on how much signal level is available at the input to the IF strip. Sufficient gain is needed to ensure ample audio output consistent with driving headphones or a speaker. Another consideration is the amount of AGC-initiated IF gain range. The more IF stages used (a maximum of two is typical), the greater the gain change caused by AGC action. The range is on the order of 80 dB when two CA3028A ICs are used in the IF strip. A pair of MC1590G ICs will provide up to 120 dB of gain variation with AGC applied.

Nearly all modern receiver circuits utilize ICs as IF amplifiers. Numerous types of ICs are available to provide linear RF and IF amplification at low cost. The CA3028A and MC1590G ICs are the most popular ones for amateur work because they are easy to obtain and are inexpensive. With careful layout techniques either device will operate in a stable manner. Bypassing should be done as near to the IC pins as possible. Input and output circuit elements must be separated to prevent mutual coupling which can cause unstable operation. If IC sockets are used they should be of the low-profile variety with short socket conductors.

Fig. 35 contains examples of bipolar transistor and FET IF amplifiers. Typical component values are given. A CA3028A IC, connected for differential-amplifier operation, is shown in Fig. 36 as an IF amplifier. Up to 40 dB of gain is possible with this circuit. The IC is useful up to 120 MHz and has a low noise figure.

A Motorola MC1590G IC will provide up to 50 dB of gain when used as an IF amplifier. An example of the circuit is given in Fig. 37. AGC operates in the reverse of that which is applied to a CA3028A. With the CA3028A, the gain will be maximum with maximum AGC voltage. An MC1590G delivers maximum gain at the low AGC voltage level.

With both amplifiers (Figs. 36 and 37) the input impedance is on the order of 1000 ohms. The output impedance is close to 4000 ohms. These values are for single-ended operation, as shown. The values are doubled when either device is operated in push-pull with respect to input and output tuned circuits.

### Choice of Frequency

The selection of an intermediate frequency is a compromise between conflicting factors. The lower the IF the higher the selectivity and gain, but a low IF brings the

image nearer the desired signal and hence decreases the image ratio. A low IF also increases pulling of the oscillator frequency. A high IF improves the image ratio and reduces pulling, but the gain is lowered and selectivity is harder to obtain by simple means.

An IF of the order of 455 kHz gives good selectivity and is satisfactory from the standpoint of image ratio and oscillator pulling at frequencies up to 7 MHz. The image ratio is poor at 14 MHz when the mixer is connected to the antenna, but adequate when there is a tuned RF amplifier between the antenna and mixer. At 28 MHz and at very high frequencies, the image ratio is very poor unless several RF stages are used. Above 14 MHz, pulling is likely to be bad without very loose coupling between mixer and oscillator. Tuned-circuit shielding also helps.

With an IF of about 1600 kHz, satisfactory image ratios can be secured on 14, 21 and 28 MHz with one RF stage of good design. For frequencies of 28 MHz and higher, a common solution is to use double conversion, choosing one high IF for image reduction (9 MHz is frequently used) and a lower one for gain and selectivity.

In choosing an IF it is wise to avoid frequencies on which there are strong signals, such as broadcast bands, since such signals may get into the IF amplifier by conduction or radiation pickup. Shifting the IF or better shielding are solutions to this interference problem.

### Fidelity: Sideband Cutting

If the selectivity is too great to permit uniform amplification over the band of frequencies occupied by the modulated signal, some of the sidebands are "cut." While sideband cutting reduces fidelity, it is frequently done to favor communications effectiveness.

### IF Selectivity

Assuming that all stages are properly designed, IF selectivity is the most significant selectivity in a receiver. This selectivity separates signals and reduces QRM. At intermediate frequencies above 500 kHz it is common practice to use crystal filters. These can be designed with just one crystal (Fig. 38A), or with two or more crystals. Fig. 38B illustrates a two-crystal, half-lattice filter. A cascaded half-lattice filter is shown at C of Fig. 38. Table 4 lists various crystal filters manufactured by Spectrum International.

The single-crystal example shown at A of Fig. 38 is best suited for simple receivers intended mainly for CW use. CI is adjusted to provide the bandpass characteristic shown adjacent to the circuit. When the BFO frequency is placed on the part of the low-frequency slope (left) which gives the desired beat note relative to  $f_o$  (approximately 800 Hz), single-signal reception will result. To the right of  $f_o$  in Fig. 38A the response drops sharply to reduce output on

the unwanted side of zero beat, thereby making single-signal reception possible. If no IF filter were used, or if the BFO frequency fell at  $f_0$ , nearly equal response would exist on either side of zero beat (double-signal response) as is the case with direct-conversion receivers. QRM on the unwanted-response side of the IF passband would interfere with reception. The single-crystal filter shown is capable of at least 30 dB of rejection on the high-frequency side of zero beat. The filter termination,  $R_T$ , has a marked effect on the response curve. It is necessary to experiment with the resistance value until the desired response is obtained. Values can range from 1500 to 10,000 ohms.

A half-lattice filter is shown at B in Fig. 38. The response curve is symmetrical, and there is a slight dip at center frequency. The dip is minimized by proper selection of  $R_T$ .  $Y_1$  and  $Y_2$  are separated in frequency by the amount needed to obtain CW or SSB selectivity. The bandwidth at the 3-dB points will be approximately 1.5 times the crystal-frequency spacing. For upper- or lower-sideband reception,  $Y_1$  and  $Y_2$  would be 1.5 kHz apart, yielding a 3-dB bandwidth of approximately 2.25 kHz. For CW work, a crystal spacing of 0.4 kHz would result in a bandwidth of roughly 600

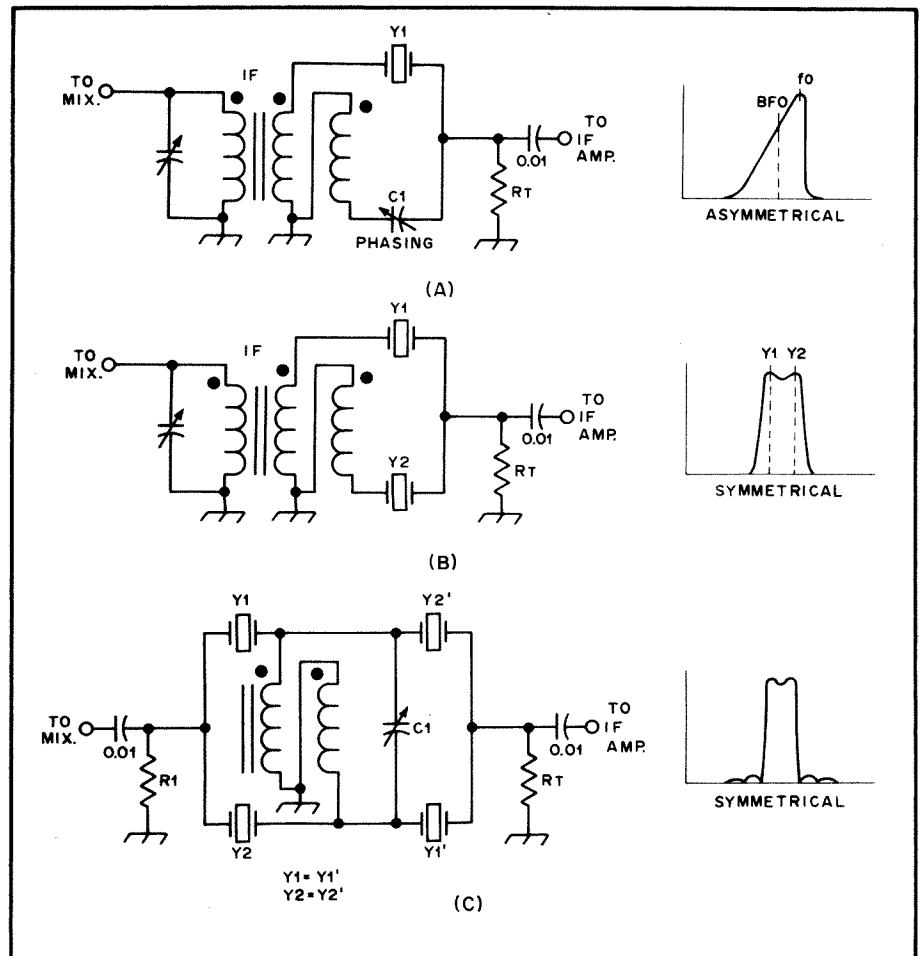

Fig. 38 — A comparison among crystal IF filters. The selectivity is increased as crystals are added.

Fig. 40 — Crystal IF filters can be used at both ends of the IF strip. FL2 greatly reduces wide-band IF noise.

Hz. The skirts of the curve are fairly wide with a single half-lattice filter, which uses crystals in the HF region.

The skirts can be steepened by placing two half-lattice filters in cascade, as shown in Fig. 38C.  $R_1$  and  $R_T$  must be selected to provide minimum ripple at the center of the passband. The same rule applies for frequency spacing between the crystals.  $C_I$  is adjusted for a symmetrical response.

The circuits of Fig. 38 can be built easily and inexpensively by amateurs. The transformers shown are tuned to center frequency. They are wound bifilar or trifilar on ferrite or powdered-iron cores of appropriate frequency characteristics.

A technique that has recently gained favor with amateurs is that of building crystal filters in the form of a ladder network, in which all crystals are cut to the same frequency. TV color-burst and CB crystals are commonly used to fabricate low-cost filters having high performance. The design procedure involves analysis of a quartz crystal in terms of its lumped-constant equivalent circuit. These lumped-constant values are then used to design a modern Chebyshev or Butterworth band-pass filter. Wes Hayward, W7ZOI, described the procedure in detail in "A Unified Approach to the Design of Crystal Ladder Filters" in May 1982 *QST* (pp. 21-27).

An illustration of how a mechanical filter operates is provided in Fig. 39. Perhaps the most significant feature of a mechanical filter is the high  $Q$  of the resonant metallic disks it contains. A  $Q$  figure of 10,000 is the nominal value obtained with this kind of resonator. If  $L$  and  $C$  constants were employed to acquire a bandwidth equivalent to that possible with a mechanical filter, the IF would have to be below 50 kHz. Table 3 lists various mechanical filters that are manufactured by Collins Radio Co.

Mechanical filters have excellent frequency-stability characteristics. This makes it possible to fabricate them for fractional bandwidths of a few hundred hertz. Bandwidths down to 0.1 percent can be obtained with these filters. This means that a filter having a center frequency of 455 kHz could have a bandwidth as small as 455 Hz. By inserting a wire through the centers of several resonator disks, thereby coupling them, the fractional bandwidth can be made as great as 10 percent of the center frequency. The upper limit is governed primarily by occurrence of unwanted spurious filter responses adjacent to the desired passband.

Mechanical filters can be built for center frequencies from 60 to 600 kHz. The main limiting factor is disk size. At the low end of the range, the disks become prohibitively large. At the high limit of the range, the disks become too small to be practical.

The principle of operation is shown in Fig. 39. As the incoming IF signal passes through the input transducer, the signal is converted to mechanical energy. This energy is passed through the disk resonators to filter out the undesired frequencies, then through the output transducer where the mechanical energy is converted back to the original electrical form.

The transducers serve a second function: They reflect the source and load impedances into the mechanical portion of the circuit, thereby providing a termination for the filter.

Mechanical filters require external resonating capacitors, which are used across the transducers. If the filters are not resonated, there will be an increase in insertion loss and degradation of the passband characteristics. Concerning the latter, there will be various unwanted dips in the nose response (ripple), which can lead to undesirable effects. The exact amount of

shunt capacitance will depend on the filter model used. The manufacturer's data sheet specifies the proper capacitor values.

Collins mechanical filters are available with center frequencies from 64 to 500 kHz and in a variety of bandwidths. Insertion loss ranges from 2 dB to 12 dB, depending on the style of filter used. Of greatest interest to amateurs are the 455-kHz mechanical filters with the prefix F455. They are available in bandwidths of 0.375, 1.2, 1.9, 2.5, 2.9, 3.8 and 5.8 kHz. Maximum insertion loss is 10 dB, and the characteristic impedance is 2000 ohms. Different values of resonating capacitance are required for the various models, ranging from 350 to 1100 pF. Although some mechanical filters are terminated internally, this series requires external source and load termination of 2000 ohms. The F455 filters are the least expensive of the Collins line.

Most modern receivers have selectable IF filters to provide suitable bandwidths for SSB and CW. Most commercial receivers use a 250- to 600-Hz bandwidth filter for CW and a 1.8- to 2.7-kHz bandwidth for SSB. CW or SSB filters are used to receive RTTY. The input and output ends of a filter should be well isolated from one another if the filter characteristics are to be realized. Leakage across a filter will negate the otherwise good performance of the unit. The problem becomes worse as the filter frequency is increased. Mechanical switches are not recommended above 455 kHz for filter selection because of leakage across the switch wafers and sections. Diode switching is preferred by most designers. The switching diodes for the filter that is out of the circuit are usually back-biased to ensure minimum leakthrough.

In the interest of reducing wideband noise from the IF amplifier strip, it is worthwhile to use a second filter that has exactly the same center frequency as the first. The second filter is placed at the end of the IF strip, ahead of the product detector. This is shown in Fig. 40. The technique was described by W7ZOI in March and April 1974 *QST*. The second filter, FL2, has somewhat wider skirts than the first, FL1. An RC active audio filter after the product detector has a similar effect, but the results are not quite as spectacular as when two IF filters are used. The overall signal-to-noise ratio is enhanced greatly by this method.

### Automatic Gain Control

Automatic regulation of the gain of the receiver in inverse proportion to the signal strength is an operating convenience in reception, because it tends to keep the output level of the receiver constant regardless of input-signal strength. The average rectified dc voltage, developed by the received signal across a resistance in a detector circuit, is used to vary the bias on the RF and IF amplifier stages. Since this voltage is

Various schemes from simple to extravagant have been conceived to develop AGC voltage in receivers. Some perform poorly because the attack time of the circuits is wrong for CW work, resulting in "clicky" or "pumping" AGC. The first significant advance toward curing the problem was presented by Goodman, W1DX, "Better AVC for SSB and Code Reception," January 1957 *QST*. He coined the term "hang" AVC, and the technique has been adopted by many amateurs who have built their own receiving equipment. The objective is to make the AGC take hold as quickly as possible to avoid the ailments mentioned earlier.

Fig. 41 illustrates the general concept of an AGC circuit. RF energy is sampled from the output of the last IF by means of light coupling. This minimizes loading on the tuned circuit of the IF amplifier. The IF energy is amplified by the AGC amplifier, then convert to dc by means of an AGC rectifier. R1 and C1 are selected to provide a suitable decay time constant (about 1 second for SSB and CW). Q1 and Q2 function as dc amplifiers to develop the voltage needed for AGC control of the IF (and sometimes, RF) amplifier stages. The developed AGC voltage can be used to drive an S meter. A level control can be placed at the input of the AGC amplifier to establish the signal input level (receiver front end), which turns on the AGC system. Most designers prefer to have this happen when a received signal level is between 0.25 and  $1\mu\text{V}$ . The exact parameters are based somewhat on subjectivity.

An RF-derived AGC system is seen in Fig. 43. It operates on a principle similar to that shown in Fig. 42, except that an op amp is used in place of the discrete bipolar dc amplifiers. Current changes are sampled across the 10-k $\Omega$  FET source resistor by

It certainly is not essential to have AGC in a receiver. If the operator is willing to adjust the gain manually, good performance is certain to result. AGC is mainly an operator convenience: It prevents loud signals from blasting out of the speaker or headphones when the operator tunes the band at a given AF-gain setting.

## Radio Receiving Principles 12-29

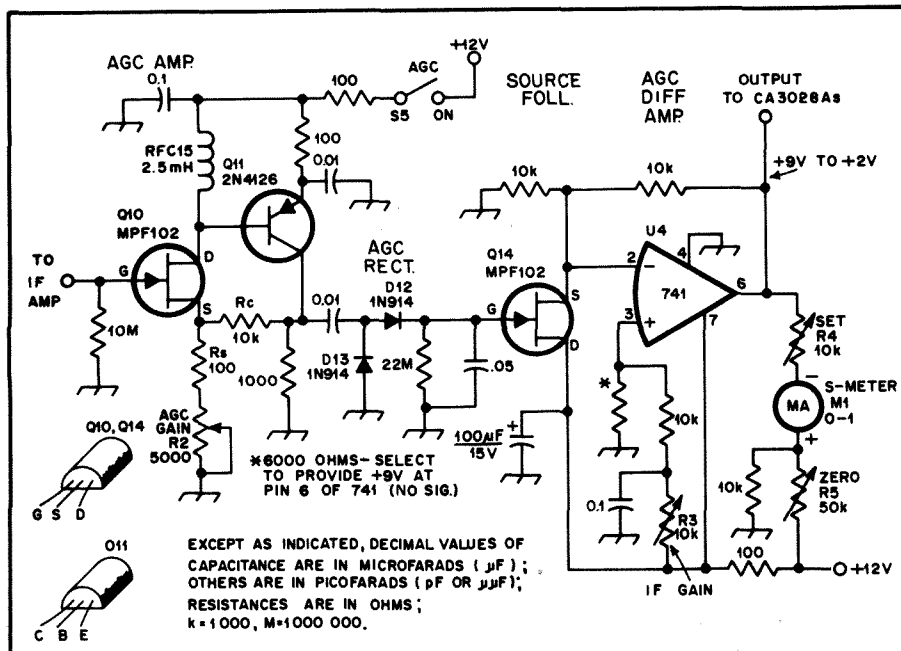

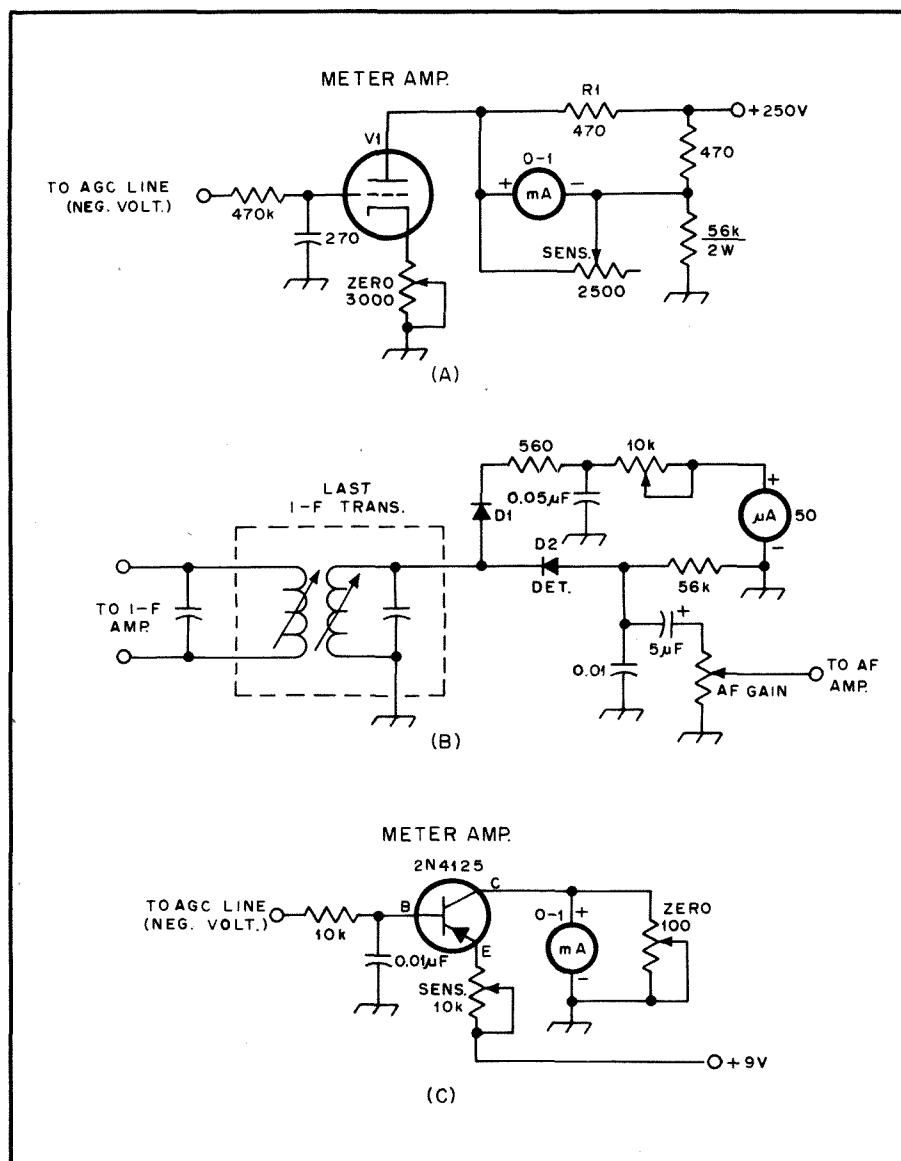

Fig. 43 — An AGC system for CA3028A IF amplifiers. An op amp is used as difference amplifier to provide AGC voltage while operating an S meter.

A BFO need not be crystal controlled. It can use a VFO circuit, or it can be tuned by means of a Varactor diode. Elimination of the crystals represents a cost savings to the builder, but frequency stability may not be as good as when crystal control is employed.

When the BFO is operated at frequencies above 3 MHz it is helpful to use a buffer stage after the oscillator to minimize the effects of pulling. Furthermore, if a passive product detector is used in the receiver, a substantial amount of BFO output power will be required — approximately +7 dBm. The buffer/amplifier helps to boost the oscillator output to satisfy this requirement.

## S Meters

Signal-strength meters are useful when there is a need to make comparative readings. Such might be the case when another operator asks for a comparison between two antennas being tested. Because S meters are relative-reading instruments, signal reporting based on the amount of needle deflection is generally without meaning. No two receivers render the same reading a given signal, unless by coincidence. This is because the gain distribution within an amateur receiver varies from band to band. Since most S meters are activated from the AGC line in a receiver, what might be S9 on one ham band could easily become S6 or 10 dB over S9 on another band. A receiver that rendered accurate readings on each band it covered would be extremely esoteric and complex.

An attempt was made by at least one receiver manufacturer in the early 1940s to establish some significant numbers for S meters. S9 was to be equivalent to 50 μV, and each S unit would have been equal to 6 dB. The scale readings above S9 were given in dB. The system never took hold in the manufacturing world, probably for the reasons given earlier.

In addition to the example shown in Fig. 43, some typical S-meter circuits are offered in Fig. 44. The example at C can be used with RF- or audio-derived AGC.

## NOISE REDUCTION

The only known approach to reducing tube, transistor and circuit noise is through

Fig. 44 — Various methods for using an S meter. At A, V1 is a meter amplifier. As the AGC voltage increases, the plate current decreases to lower the voltage drop across R1. An up-scale meter reading results as the current through the meter increases. At B, the negative-going AGC voltage is inverted and amplified by an operational amplifier circuit. R1 establishes the dB-per-S-unit sensitivity; R2 is the meter-zeroing adjustment. R3 and D1 compress the readings over S9. This circuit is well suited to an IF amplifier having a gain control characteristic that is linear in dB/volt, such as one using dual-gate MOSFETs. At C, the negative AGC voltage forward biases the transistor to cause an increase in collector current, thereby deflecting the meter upward with signal increases.

Fig. 45 — A simple audio limiter/clipper. R1 sets the bias on the diodes for the desired limiting level.

the choice of low-noise, front-end, active components and through more overall selectivity.

In addition to the active-device and circuit noise, much of the noise interference experienced in reception of high-frequency signals is caused by domestic or industrial electrical equipment and by automobile ignition systems. The interference is of two types in its effects. The first is "hiss," consisting of overlapping pulses similar in nature to the receiver noise. It is largely reduced by high selectivity in the receiver, especially for code reception. The second is the "pistol-shot" or "machine-gun" type, consisting of separated impulses of high amplitude. The hiss type of interference usually is caused by commutator sparking in dc and series-wound ac motors, while the shot type results from separated spark discharges (ac power leaks, switch and key clicks, ignition sparks and the like).

### Impulse Noise

Impulse noise, because of the short duration of the pulses compared with the time between them, must have high amplitude to contain much average energy. Hence, noise of this type strong enough to cause

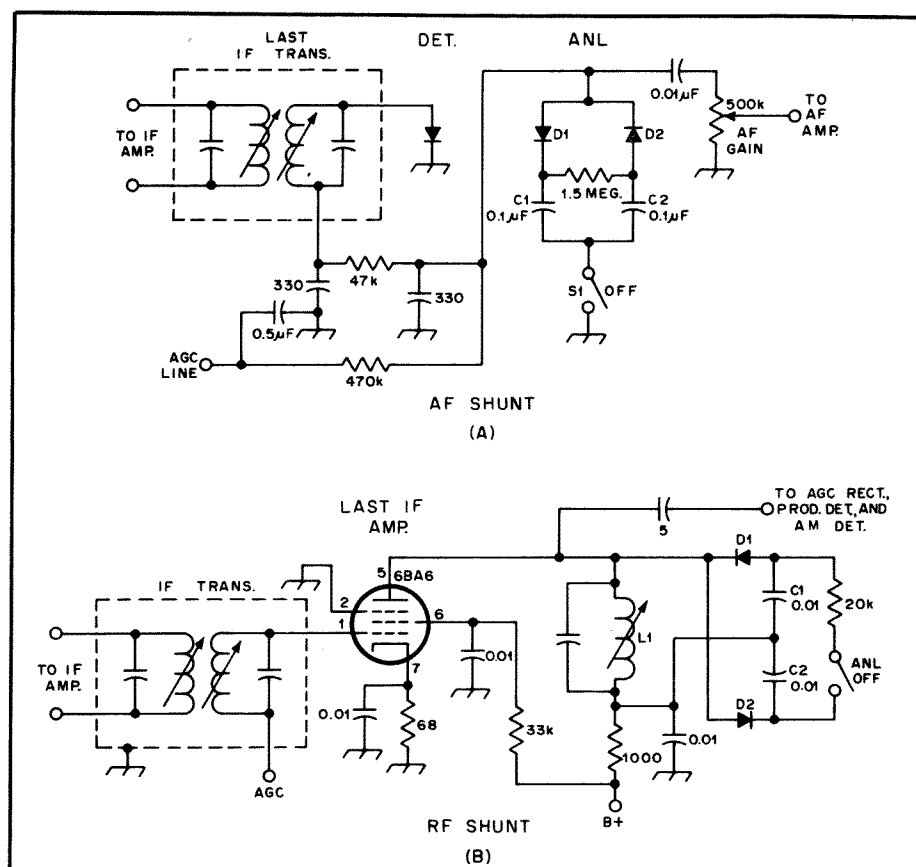

Fig. 46 — Examples of RF and audio ANL circuits. Positive and negative clipping takes place in both circuits. The circuit at A is self-adjusting.

much interference generally has an instantaneous amplitude much higher than that of the signal being received. The general principle of devices intended to reduce such noise is to allow the desired signal to pass through the receiver unaffected, but to make the receiver inoperative for amplitudes greater than that of the signal. The greater the amplitude of the pulse compared with its time of duration, the more successful the noise reduction.

Another approach is to "silence" (render

inoperative) the receiver during the short duration time of any individual pulse. The listener will not hear the "hole" because of its short duration, and very effective noise reduction is obtained. Such devices are called "blankers" rather than "limiters."

In passing through selective receiver circuits, the time duration of the impulses is increased, because of the bandwidth of the circuits. Thus, the more selectivity ahead of the noise-reducing device, the more dif-

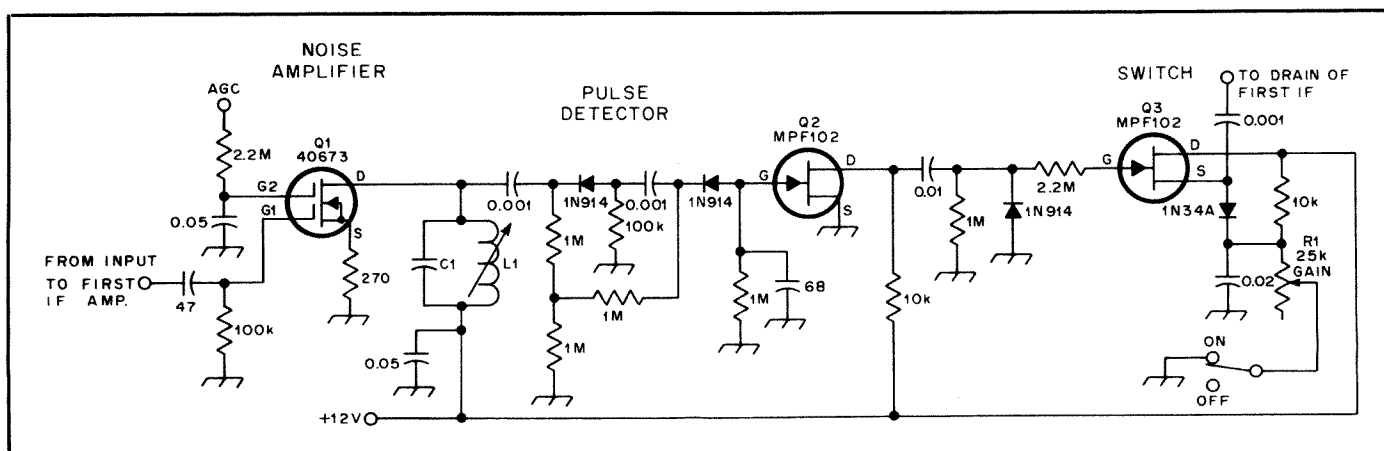

Fig. 47 — Diagram of a noise blander. C1 and L1 are tuned to the receiver IF.

difficult it becomes to secure good pulse-type noise suppression.

### Audio Limiting

A considerable degree of noise reduction in CW and RTTY reception can be accomplished by amplitude-limiting arrangements applied to the audio-output circuit of a receiver. Such limiters also maintain the signal output nearly constant during fading. These output-limiter systems are simple, and are readily adaptable to most receivers without any modification of the receiver itself. However, they cannot prevent noise peaks from overloading previous stages.

### Noise-Limiter Circuits

Pulse-type noise can be eliminated to an extent which makes the reception of even the weakest of signals possible. The noise pulses can be clipped or limited in amplitude, at either an RF or AF point in the receiver circuit. Both methods are used by receiver manufacturers; both are effective.

A simple audio noise limiter is shown at Fig. 45. It can be plugged into the headphone jack of the receiver and a pair of headphones connected to the output of the limiter. D1 and D2 are wired to clip both the positive and negative peaks of the audio signal, thus removing the high spikes of pulse noise. The diodes are back-biased by 1.5-volt batteries permitting R1 to serve as a clipping-level control. This circuit also limits the amount of audio reaching the headphones. When tuning across the band,

strong signals will not be ear shattering and will appear to be the same strength as the weaker ones. S1 is open when the circuit is not in use to prevent battery drain. D1 and D2 can be germanium or silicon diodes, but 1N34As or 1N914s are generally used. This circuit is usable with only high-impedance headphones.

The usual practice in communication receivers is to use low-level limiting, Fig. 46. The limiting can be carried out at RF or AF points in the receiver, as shown. Limiting at RF does not cause poor audio quality as is sometimes experienced with series or shunt AF limiters. Limiting at audio affects the normal AF signal peaks as well as the noise pulses, giving an unpleasant audio quality to strong signals.

In a series-limiting circuit, a normally conducting element (or elements) is connected in the circuit in series and operated in such a manner that it becomes nonconductive above a given signal level. In a shunt limiting circuit, a nonconducting element is connected in shunt across the circuit and operated so that it becomes conductive above a given signal level, thus short-circuiting the signal and preventing its being transmitted to the remainder of the amplifier. The usual conducting element will be a forward-biased diode, and the usual nonconducting element will be a back-biased diode. In many applications, the value of bias is set manually by the operator; usually the clipping level will be set at about 1 to 10 volts.

The AF shunt limiter at A and the RF shunt limiter at B operate in the same man-

ner. A pair of self-biased diodes are connected across the AF line at A, and across an RF inductor at B. When a steady CW signal is present the diodes barely conduct, but when a noise pulse rides in on the incoming signal, it is heavily clipped because capacitors C1 and C2 tend to hold the diode bias constant for the duration of the noise pulse. For this reason the diodes conduct heavily in the presence of noise and maintain a fairly constant signal output level. Considerable clipping of CW signal peaks occurs with this type of limiter, but no apparent deterioration of the signal quality results. L1 at B is tuned to the IF of the receiver. An IF transformer with a conventional secondary winding could be used in place of L1, the clipper circuit being connected to the secondary winding; the plate of the 6BA6 would connect to the primary winding in the usual fashion.

### IF Noise Silencer

The IF noise silencer circuit shown in Fig. 47 is designed to be used ahead of the high-selectivity section of the receiver. Noise pulses are amplified and rectified, and the resulting negative-going dc pulses are used to cut off an amplifier stage during the pulse. A manual "threshold" control is set by the operator to a level that only permits rectification of the noise pulses that rise above the peak amplitude of the desired signal. The clamp transistor, Q3, short circuits the positive-going pulse "overshoot." Running the 40673 controlled IF amplifier at zero gate 2 voltage allows the direct application of AGC voltage.

# Radio Transceivers

**T**ransceivers have taken the place of separate transmitter/receiver combinations in nearly every Amateur Radio station. Some of the reasons for this are cost, compactness, portability and ease of operation.

The three previous chapters (10, 11 and 12) covered the fundamentals of frequency generation, transmitting and receiving principles. The transceiver brings these concepts together in an integrated package.

### Circuit Considerations

Every transceiver, whether simple or complex, uses some of the same circuitry for transmitting and receiving. Shared stages frequently include oscillators, mixers, amplifiers, filters and tuned circuits. Usually, sharing is achieved by switching the input and output of a particular stage from the receiver to the transmitter. Shared circuitry may result in more economical and compact equipment.

The designer must determine whether any transmitting and receiving stages are sufficiently alike to permit their replacement by a single circuit. To do this, three conditions must be satisfied.

First, the stages must operate in the same frequency range. Depending on the circuit, that range may be wide or narrow.

Second, input and output power levels must be comparable. Often, the low level of IF signal processing that takes place in SSB transmitters allows one or more of the same IF amplifiers to be used by the receiver. However, there are other stages, such as the receiver RF amplifier and transmitter final power amplifier, that are never replaced by a single circuit. Because linearity, efficiency and heat dissipation are major concerns in SSB power amplifier design, the transistors chosen for these stages have internal geometries that optimize their power-handling capability. Receiver RF amplifiers, however, process much smaller signal levels, so power-handling capability is less important. Instead, great care is taken to ensure that the stage exhibits low distortion and good noise figure.

Finally, impedances must be matched. This is often done by designing each stage

for an input and output impedance of 50  $\Omega$ . Even when sharing is possible, it may not always be desirable. The cost and complexity of the required switching circuitry and the additional effort that may be needed to align the transceiving stage must be taken into account. The designer can weigh these factors against the reduction in size, weight and component count that the transceiving approach makes possible.

### Historical Developments

In the early days of radio, great constructional differences existed between transmitters and receivers. The spark-gap transmitter had little in common with the crystal or electrolytic receiver-detector.

The invention of the vacuum tube and development of continuous-wave (CW) transmission led to transmitters and receivers that used amplification. However, differences in power levels and frequency schemes prohibited circuit sharing. Fig. 1 shows the block diagram of a typical AM transmitter. Each block represents a different stage employing one or more tubes. A stable, low-frequency signal is generated by the crystal oscillator, and is isolated from later stages by a buffer amplifier. This signal is then raised to the desired frequency using a nonlinear multiplying stage. Finally, the multiplier output is filtered and then amplified by an RF amplifier. Audio from

the microphone is amplified and then delivered to the RF power amplifier, where voice information is impressed on the carrier. Audio circuits use linear (Class A, AB, or B) amplifiers to avoid distortion. RF amplifiers and frequency multipliers use nonlinear (Class C) stages.

In contrast, a typical AM receiver appears in Fig. 2. There are several important differences. Instead of nonlinear multiplying, the receiver uses heterodyning methods for frequency conversion. Also, frequencies and power levels are generally different from those used in the AM transmitter. The only stages performing the same function are the audio stages. Depending on transmitter power, a microphone amplifier or even the modulator could be used for audio amplification in the receiver.

The development of circuitry for single-sideband suppressed-carrier communication led to many similarities between transmitters and receivers. The AM receiver of Fig. 3A requires only a BFO to demodulate SSB signals. The block diagram of an SSB transmitter, shown in Fig. 3B, more closely resembles that of a heterodyne receiver than an AM transmitter. In fact, the major difference between block diagrams of an SSB heterodyne transmitter and receiver is the direction of signal flow. Both use similar oscillator frequencies, mixing schemes and power levels to pro-

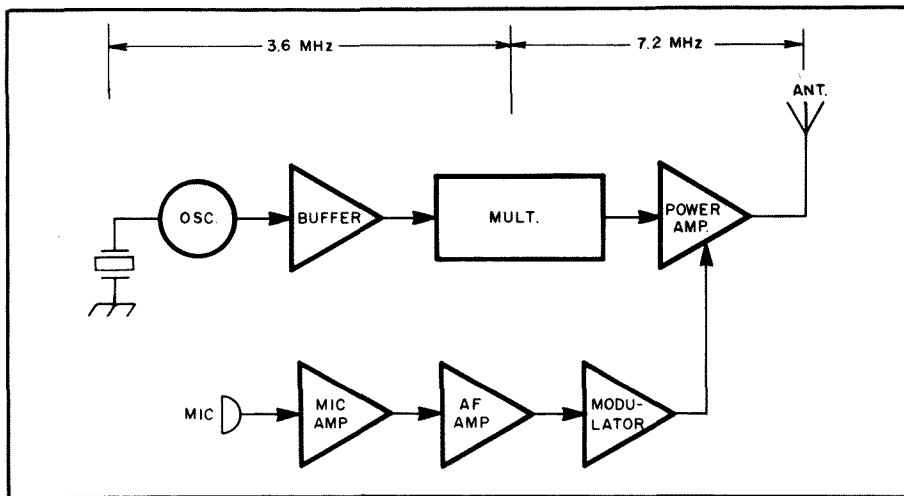

Fig. 1 — Block diagram of a conventional AM transmitter.

cess SSB signals, leading to many opportunities for circuit sharing.

### Block Diagram Basics

Analyzing a transceiver reveals how the concept of block sharing has been realized. By minimizing circuitry, size, cost and energy consumption can be reduced. Fig. 4 shows how compatible signal levels and frequency schemes have been successfully used to eliminate duplicate circuitry in the Heath HW-101. Proceeding from left to right, the first shared circuit is the crystal-controlled carrier oscillator/BFO. This circuit supplies RF to the balanced modulator, for production of a double sideband, suppressed carrier signal, and to the product detector, for converting the receiver second IF signal to audio. The oscillator supplies both signals simultaneously, eliminating switching, impedance-matching and frequency-pulling problems.

The product detector and balanced modulator are mixers. In this transceiver, the transmitter requires a balanced mixer

to null out the unwanted carrier signal, while the receiver uses a simple, active product detector. There is no reason why a singly or doubly balanced product detector might not be employed, instead. Such a circuit could serve a dual role as both product detector and balanced modulator.

The crystal filter, an expensive item, is also shared. On transmit, it is used to pass only one sideband of the double-sideband signal and to provide additional carrier suppression. On receive, the steep-skirted 2.1-kHz passband response of the filter provides sharp selectivity. Output from the crystal filter is applied to an adjustable-gain IF amplifier. Gain in this stage is controlled by either an automatic level control (ALC), or an automatic gain control (AGC) voltage, depending on mode. On transmit, an ALC bias voltage developed from the signal in the final amplifier stage ensures maximum transmitter output without overloading. On receive, an AGC voltage similarly reduces the IF gain to maintain a relatively consistent volume level.

Both transmitter and receiver are simultaneously tuned by a 5.1-MHz VFO. On transmit, the VFO signal and the 3-MHz single-sideband signal are mixed together to produce an 8-MHz IF signal. A band-pass filter attenuates all RF energy falling outside this 500-kHz-wide IF. On receive, a signal entering the second receiver mixer from this same band-pass filter is mixed with the VFO signal. This converts the received signal from the 8-MHz IF down to 3 MHz, where it can be "cleaned up" by the narrow 2.1-kHz crystal filter.

A crystal-controlled heterodyne oscillator is used for mixing in a manner similar to the VFO. But instead of producing a variable frequency, this oscillator establishes a fixed frequency, one per band, to convert that band to the 8-MHz IF. This method allows every block to the left of the heterodyne oscillator to use the same frequencies regardless of the particular band of operation. The receiver IF circuitry passes signals between 8.4 and 8.9 MHz. Depending on the setting of the VFO, only one particular signal in this 500-kHz-wide IF is converted to 3 MHz, then passed by the narrow crystal filter and demodulated into audio. A similar process is used by the transmitter to convert audio into an 8-MHz single-sideband signal.

All circuitry to the right of the heterodyne oscillator operates at RF. As a result, these blocks must employ band-switching to resonate the proper LC combinations for each band of operation. The driver grid and driver plate circuits provide RF selectivity to both the transmitter and the receiver.

### Design Considerations

Circuit sharing in a transceiver helps to streamline a design, but the switching circuitry is sometimes rather extensive. To show just how complicated the switching task may become, let us refer once again

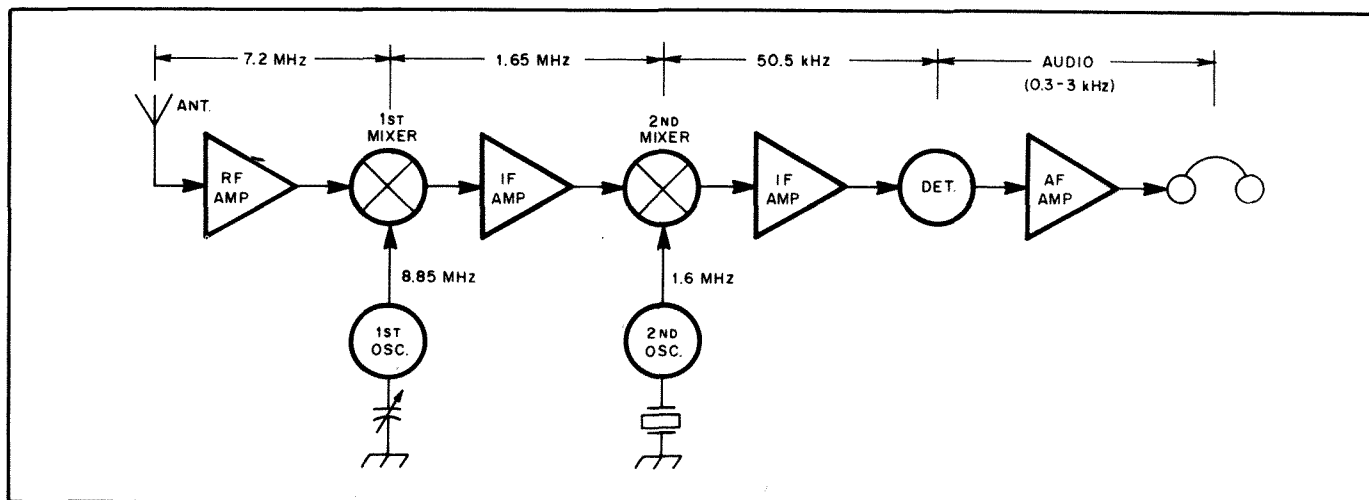

Fig. 2 — A superheterodyne AM receiver.

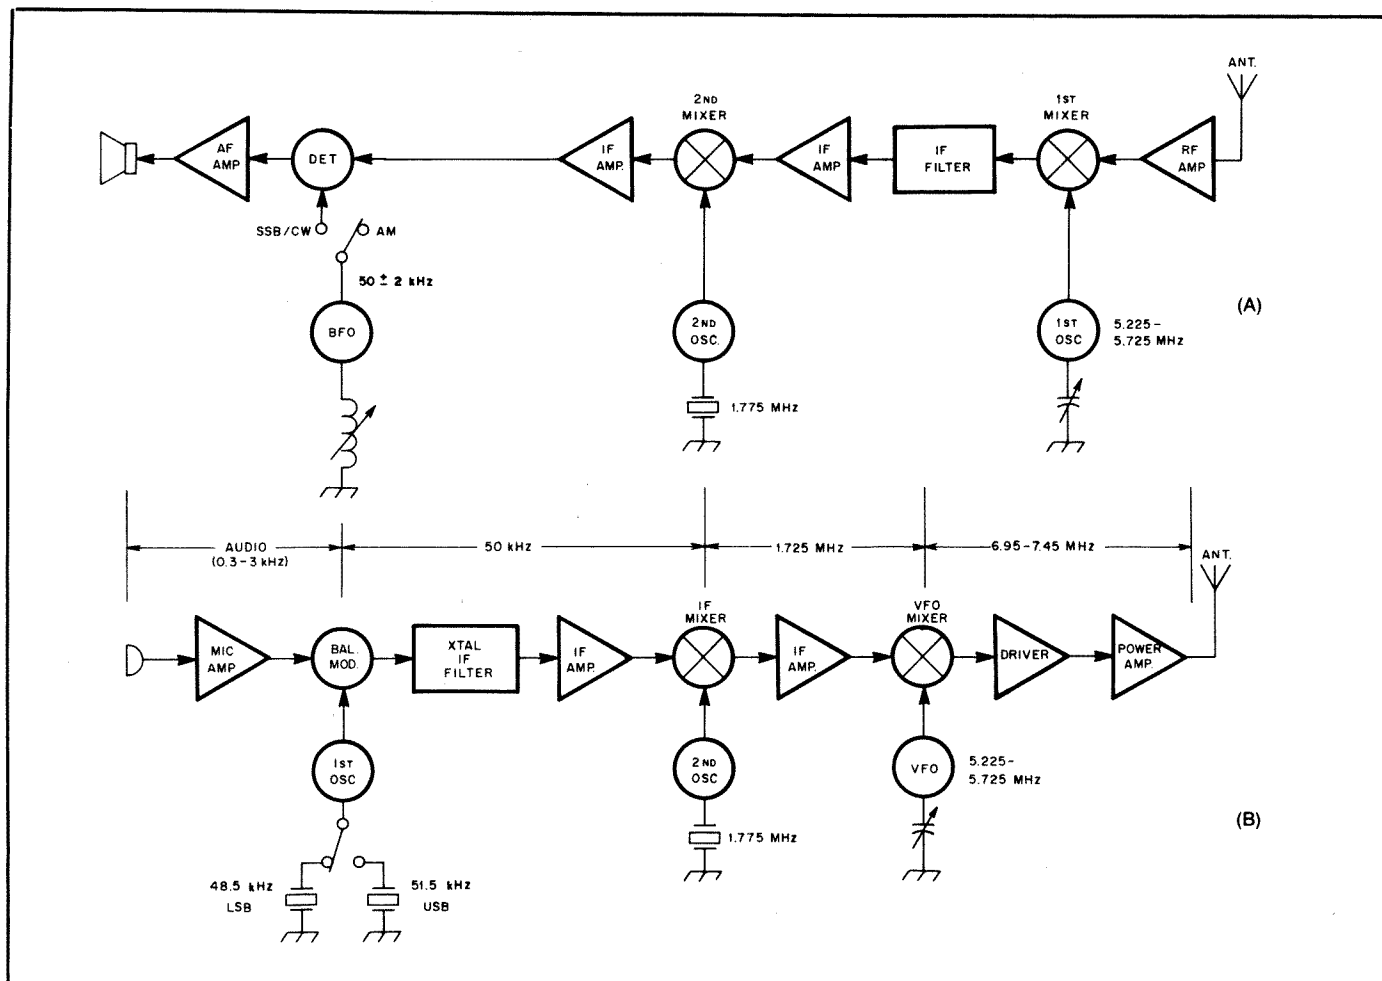

Fig. 3 — Block diagrams show similarities between a superheterodyne AM/SSB receiver (A) and a heterodyne SSB transmitter (B).

to Fig. 4. In this tube/transistor hybrid, voltage is switched from the screens of V2, V7, V8 and V9 in the transmit mode to V4, V10 and V11 in the receive mode. Bias voltage used for cutting off the receiver audio amplifier and second mixer in transmit is grounded to allow reception, while simultaneously, cutoff bias is applied to the transmitter mixers and driver stage. Switching circuitry also protects the sensitive small-signal stages of the receiver. An especially large negative bias applied to the grids of the receiver RF amplifier is necessary to ensure that this stage remains cut off. Otherwise, peaks in the driver RF envelope might turn this tube on, resulting in spikes on the transmitted waveform.

Occasionally, it may be necessary to actually change circuitry within a common stage to achieve proper transceiver operation. In the transceiver of Fig. 4, additional capacitance must be switched into the driver preselector circuit when receiving, to compensate for tube stray capacitance. Otherwise, the driver preselector control setting that produces a peak on receive will not produce a coinciding peak on transmit.

Most transceivers use a combination of relays and switching diodes to perform the required switching. PIN diodes, which can be biased to appear as either open or closed

switches to RF energy, are especially useful. By placing them at the required circuit location, long and potentially troublesome RF interconnections may be avoided.

Most transceiver circuits require some form of sequencing to ensure that the receiver is properly muted before the transmitter is energized. This involves shutting off and turning on various transmitting and receiving stages in a predetermined sequence. Yaesu uses such time-delay sequencing circuitry in their FT-ONE transceiver. Fig. 5 shows a section of this circuitry. During CW operation, key closures are detected by the KEY line and applied to two inverter gates, U14e and U14f. The RC time constant on U14f delays the keying signal before it can pass through buffer U13d to actuate Q20, the transmit bias switch. The TX SIG line, whose logical state changes at the same time as the KEY line, has many functions. It supplies the third input to the transmit bias switch (U14d) and provides a proper voltage to the RC network on the input of Q12. This RC time constant delays operation of the receiver zero-voltage reference switch (RX 0). The TX SIG line supplies inputs to several other sequentially delayed gates. These control the transmit zero-voltage reference switch (Q11), both transmit and

receive 13.5-volt supply switches (Q19 and Q22) and the receiver bias switches (Q15, Q16). The antenna relay, powered by relay drivers Q25 and Q26, is also controlled by the TX SIG line.

## TRANSCIVER FEATURES

The basic transceiver is fine for casual sideband and CW work, but it has limitations in more rigorous operation, such as DX chasing and contesting. Fortunately, most transceivers today offer built-in features to help increase their flexibility.

## RIT and XIT

Receiver incremental tuning (RIT) has become an almost universal transceiver feature that allows adjustment of the receive frequency without changing the transmit frequency. One important use of this feature is correcting for an operator who tunes to a beat note that differs from the transceiver's built-in frequency offset on CW or who prefers to listen to slightly different-sounding voice characteristics on SSB. By using the RIT control instead of the VFO dial, the pitch of the received audio can be changed while leaving the transmit frequency undisturbed. Otherwise, if during a QSO one operator adjusts the VFO to fine tune the receiver, he will also

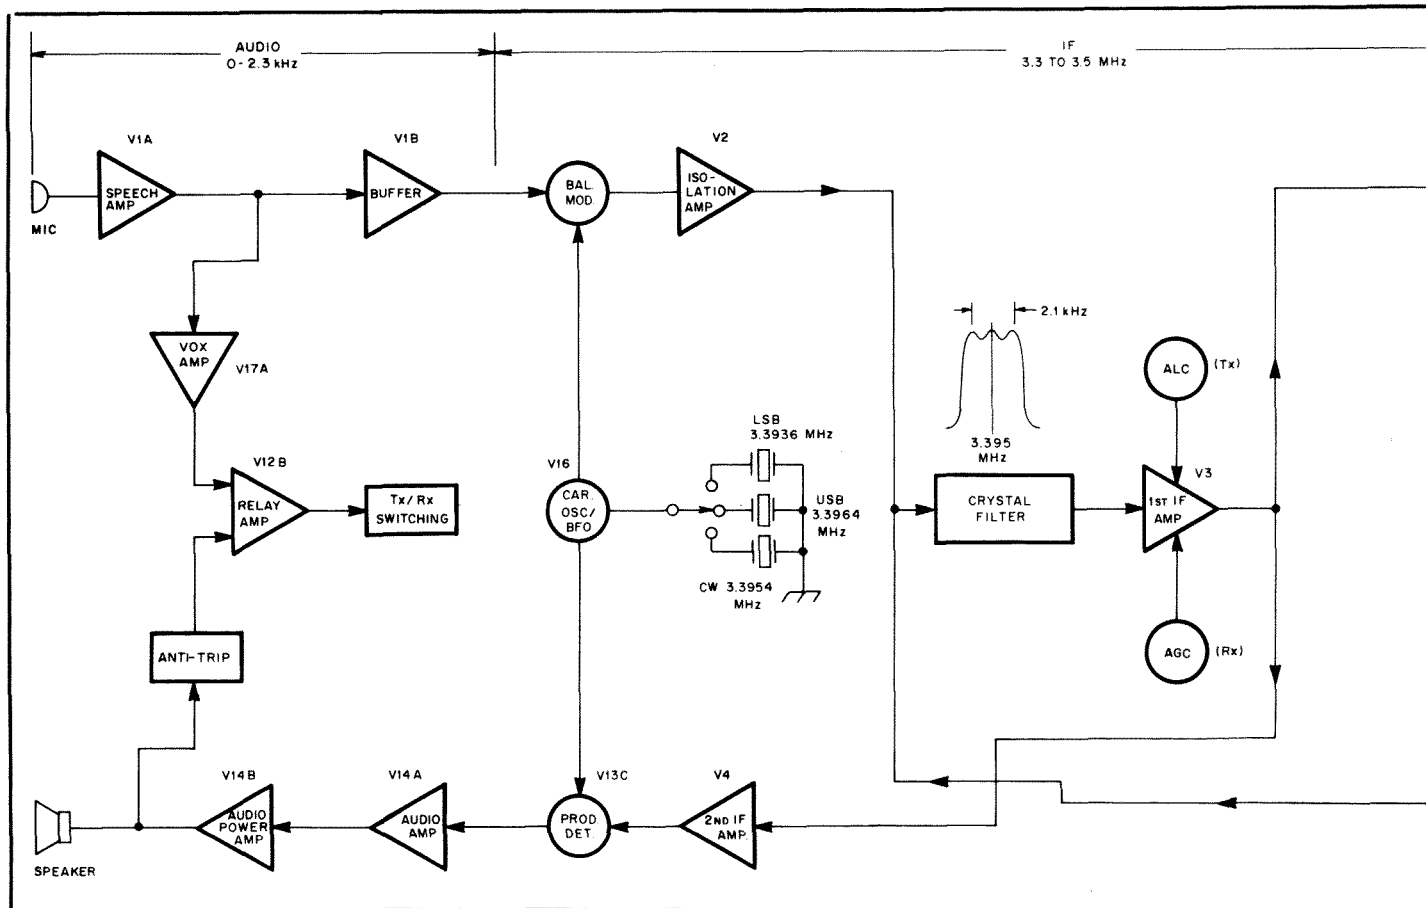

Fig. 4 — Block diagram of the Heath HW-101. Circuitry used exclusively for transmitting is shown at the top. Receiver circuitry is at the bottom. The middle section contains blocks used for both transmitting and receiving.

Ten-Tec's Argosy is a SSB/CW QRP transceiver. This unit allows for operator selection of input power levels of 10 or 100 watts, QSK (break-in) CW operation and frequency coverage of 80-10 meters.

adjust the transmit frequency. The other operator will likely compensate for this frequency shift by similarly adjusting the VFO. Before long, such frequency leap-frogging may move both stations far enough to cause interference with other ongoing communications.

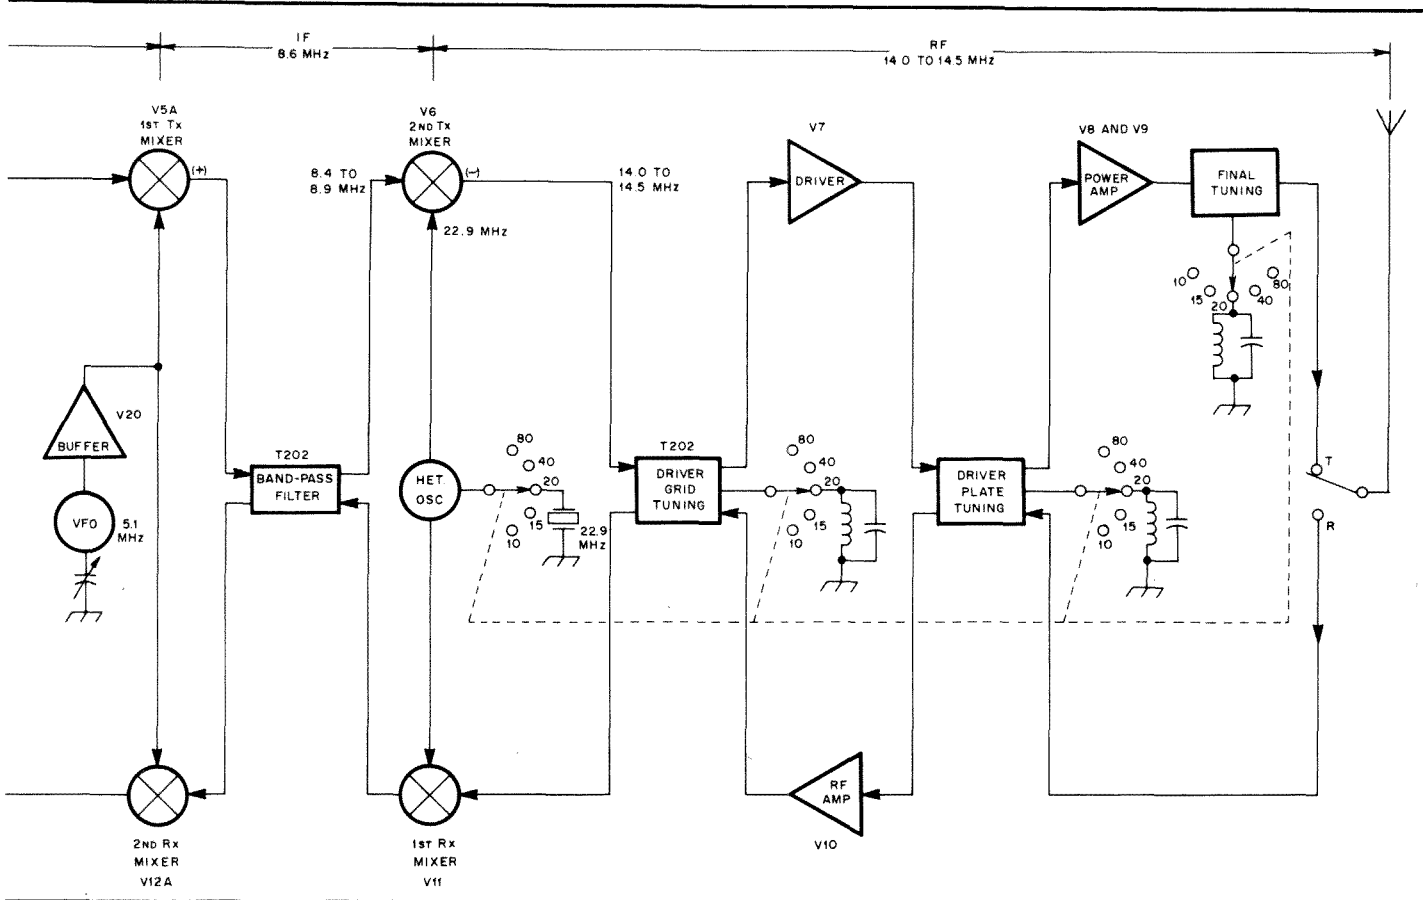

Some RIT controls permit the receive frequency to be shifted as much as 10 kHz. These controls can be used as a second VFO, allowing split-frequency operation.

XIT (Transmitter Incremental Tuning) is closely related to RIT, permitting the transmitter frequency to be shifted a few

kilohertz away from the receive frequency. Many transceivers use the same knob for controlling both the RIT and XIT functions to permit listening on the transmitter offset frequency.

Fig. 6A is a schematic diagram of an RIT similar to that used in the Kenwood TS-520S and TS-820S transceivers. D1 is a varactor diode. Because it forms parts of the VFO tuning circuitry, any change of dc bias on D1 will cause a shift in VFO frequency. Potentiometer R1 is used as the RIT frequency-shift control. It forms part of a voltage divider with R3 and R4 when the RIT is switched on, allowing a variable bias to be applied to D1 (Fig. 6B). When the RIT is off, or when the transceiver is in transmit, however, a fixed bias is applied to D1 (Fig. 6C). When R1 is at the center of its range, the transmit and receive frequencies should coincide. R2, an internal trimmer potentiometer, ensures this by providing limited adjustment of the fixed varactor dc bias, eliminating any frequency difference.

XIT circuits operate in the same manner, except that the potentiometer that applies dc bias to the varactor diode is switched into operation during transmit instead of receive. Generally, RIT and XIT circuits

use relays or solid-state devices for switching.

### IF Shift

This useful receiver feature, sometimes called passband tuning, effectively changes the center frequency of the receiver passband without changing the frequency to which the receiver is tuned. By leaving the pitch of the received signal or signals undisturbed, IF shift permits optimum placement of the available receiver selectivity around an SSB or CW signal.

Although IF shift can be viewed as changing the center frequency of the receiver IF filter, this filter operates on only one fixed frequency. Instead, the IF signal is shifted above and below this passband. Fig. 7 is a block diagram of a simple IF shift system. A tunable oscillator provides an 8.455-MHz signal to the mixers. The first mixer uses this signal to convert the incoming 455-kHz IF to the 8.000-MHz filter frequency. The second mixer then takes this 8.000-MHz signal and converts it back down to 455 kHz. By varying the oscillator frequency, the position of the desired signal within the filter passband can be changed.

When properly tuned, a received signal

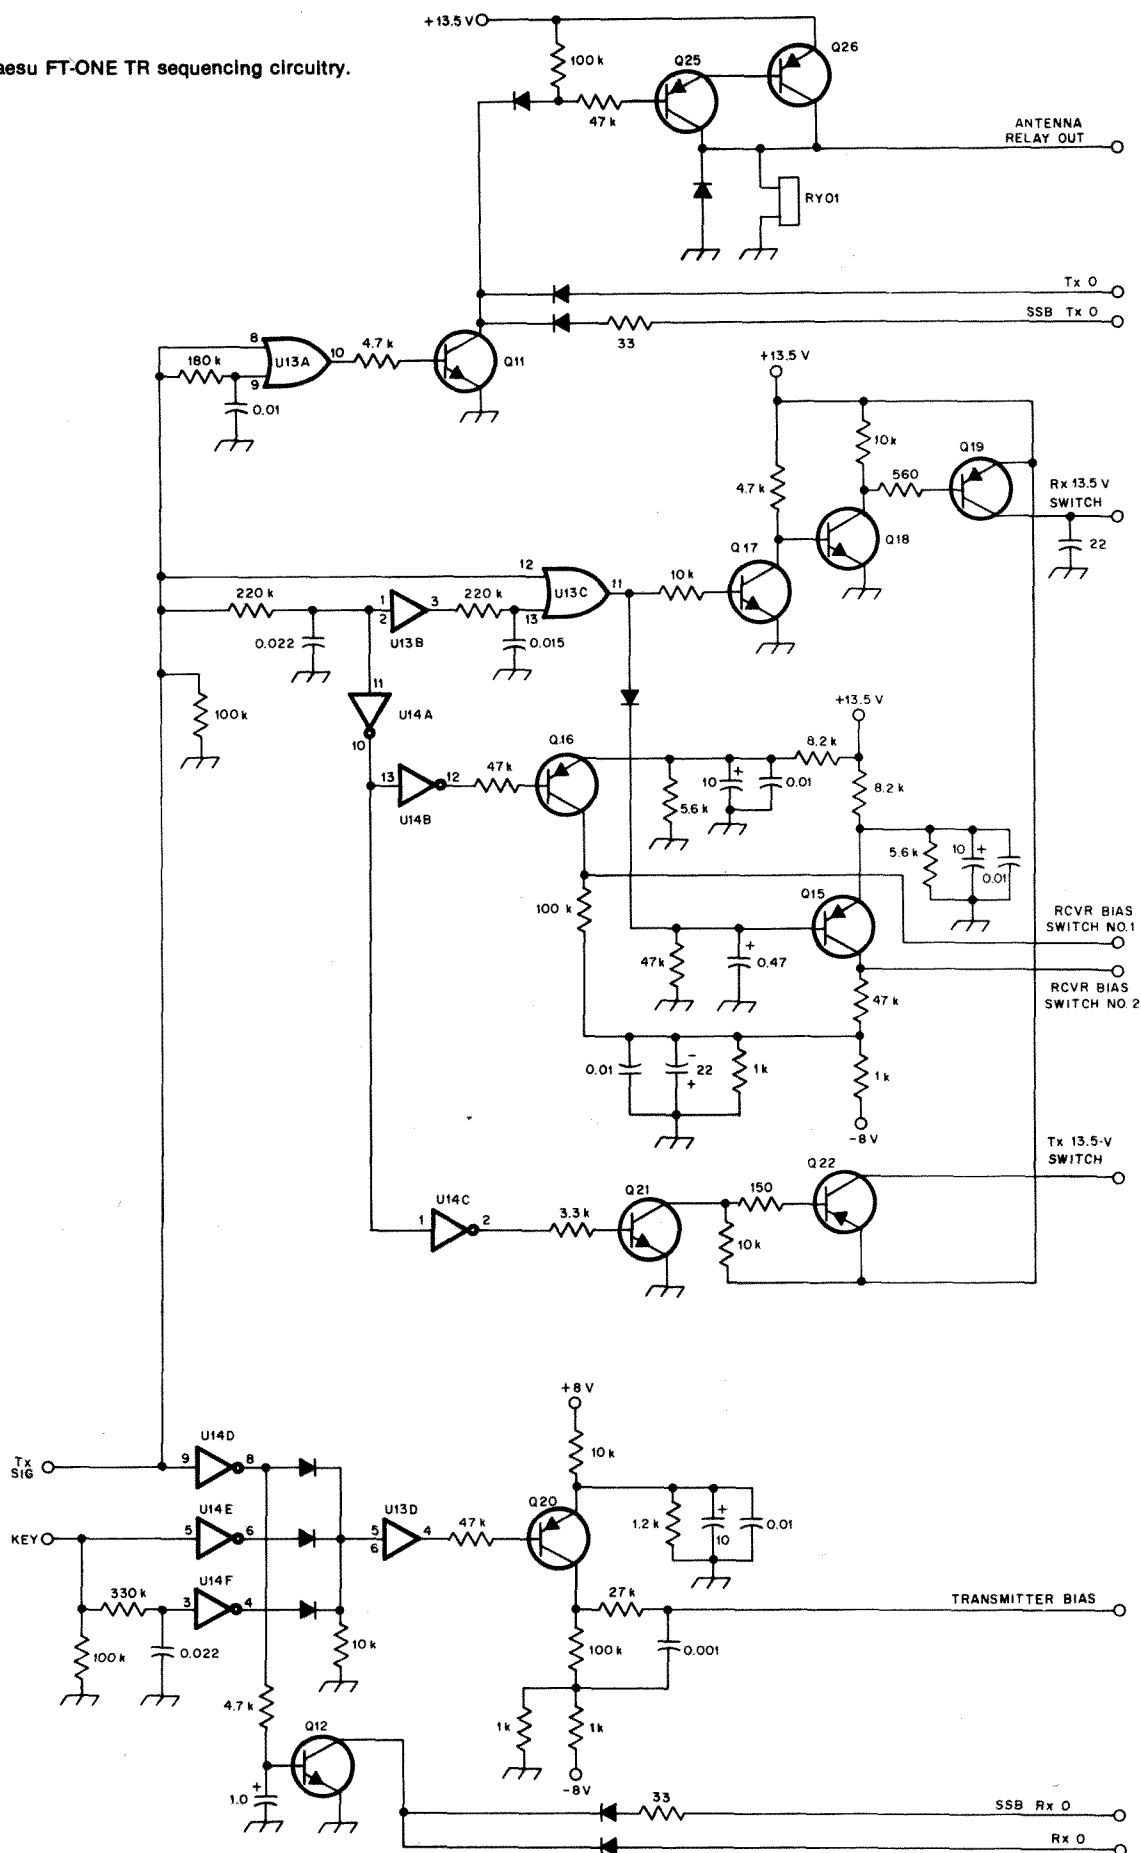

The ICOM IC-735 offers SSB, CW, AM and FM modes, a 100-W transmitter, versatile memory system and general-coverage receiver in a compact package.

will pass through the center of the IF filter. Interference to one side of this desired signal may be removed by several methods. Fig. 8A shows such an interfering signal and its relationship to the passband filter.

If the transceiver is tuned upward 250 Hz (Fig. 8B), the interfering signal will no longer fall within the passband. This is an effective and practical interference cure on CW, requiring only that the operator listen

**Fig. 5 — Yaesu FT-ONE TR sequencing circuitry.**

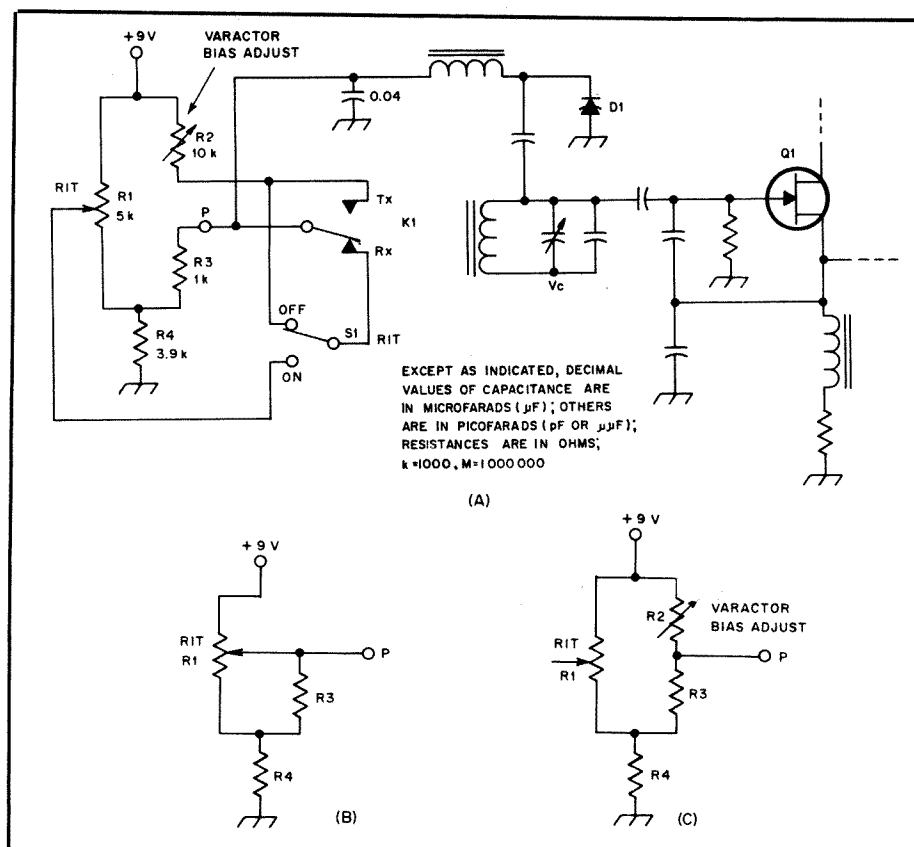

Fig. 6 — RIT circuit similar to that used in the Kenwood TS-520S and TS-820S series transceivers (A). At B is the equivalent circuit formed when the RIT is switched on. At C is the circuit when RIT is off or during transmit.

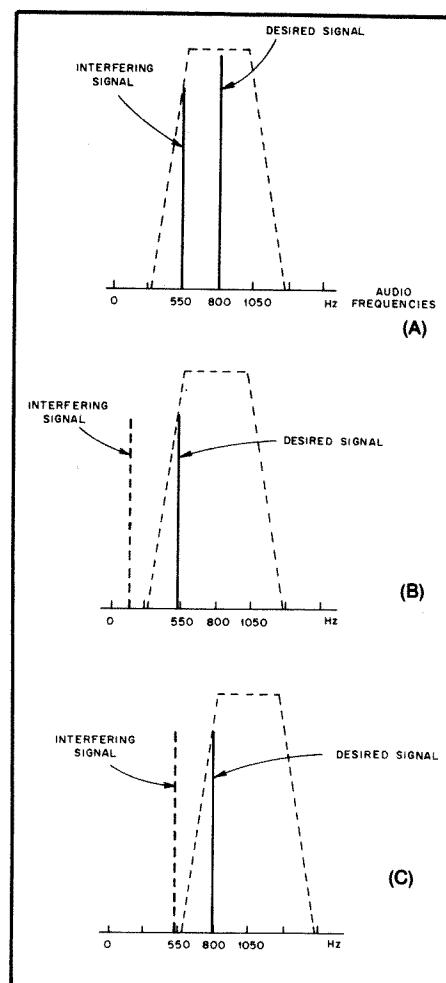

Fig. 8 — At A, receiver tuning places desired signal in center of the 500-Hz-wide CW pass-band filter. Another signal 250 Hz away will also fall within the passband, causing interference. At B, interfering signal has been removed by tuning receiver up 250 Hz. Desired signal will now have a 250-Hz lower pitch, however. At C, IF shift permits the passband to be moved, eliminating the interfering signal without changing the pitch of the desired signal.

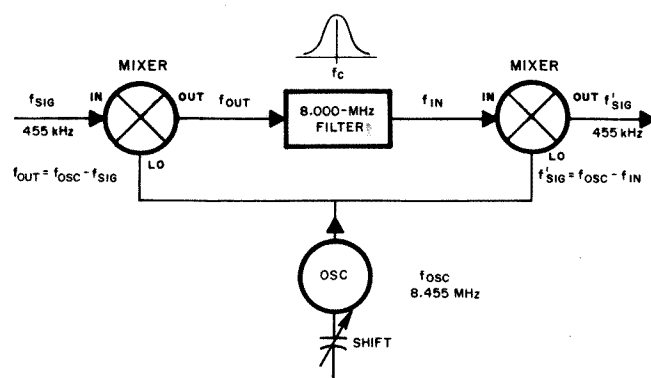

Fig. 7 — Block diagram of a simple IF-shift circuit.

to a CW note 250 Hz lower than normal. On SSB, however, this solution is impractical, because it leaves the voice signal unintelligible. By using the IF shift control, the interfering signal may still be eliminated (Fig. 8C), and signal intelligibility retained.

In practice, an IF shift circuit may not be as simple as the one shown in Fig. 7. The Kenwood TS-820 HF transceiver incorporates an IF shift circuit that is also part of the phase-locked-loop (PLL) frequency synthesizer. In the block diagram (see Fig. 9) operation on 14.250 MHz is shown.

In the synthesizer, the heterodyne

oscillator supplies a fixed 19.5-MHz signal to the heterodyne mixer. This is mixed with a 23.08-MHz signal from the voltage controlled oscillator (VCO) to produce a difference frequency of 3.58 MHz. With the IF shift off, this 3.58-MHz difference frequency mixes with an 8.8315-MHz carrier oscillator signal in the carrier mixer to produce a 5.2515-MHz difference frequency.

The phase detector compares this signal with the 5.2515-MHz signal generated by the VFO. If any phase difference between these two signals is detected, an appropriate dc voltage will be produced by the phase

detector and applied to the voltage-controlled oscillator. The VCO will respond by changing frequency slightly, in a direction that reduces this phase difference. The net effect is that the VCO remains locked to the 5.2515-MHz VFO signal.

The PLL has two outputs. One supplies the 23.08-MHz VCO signal to the RF mixer. This mixes with the desired RF input signal (14.250 MHz) to produce an 8.83-MHz IF signal. The other output is at 8.8315 MHz; it mixes with the filtered 8.83-MHz IF signal in a product detector, producing audio at 1.5 kHz.

As the VFO is moved up in frequency, an error voltage will be produced in the phase detector, causing the VCO frequency to shift down by the same amount. This relationship is a result of the mixing scheme, which uses difference frequencies instead of sum frequencies. The result is a lower frequency being tuned in by the transceiver.

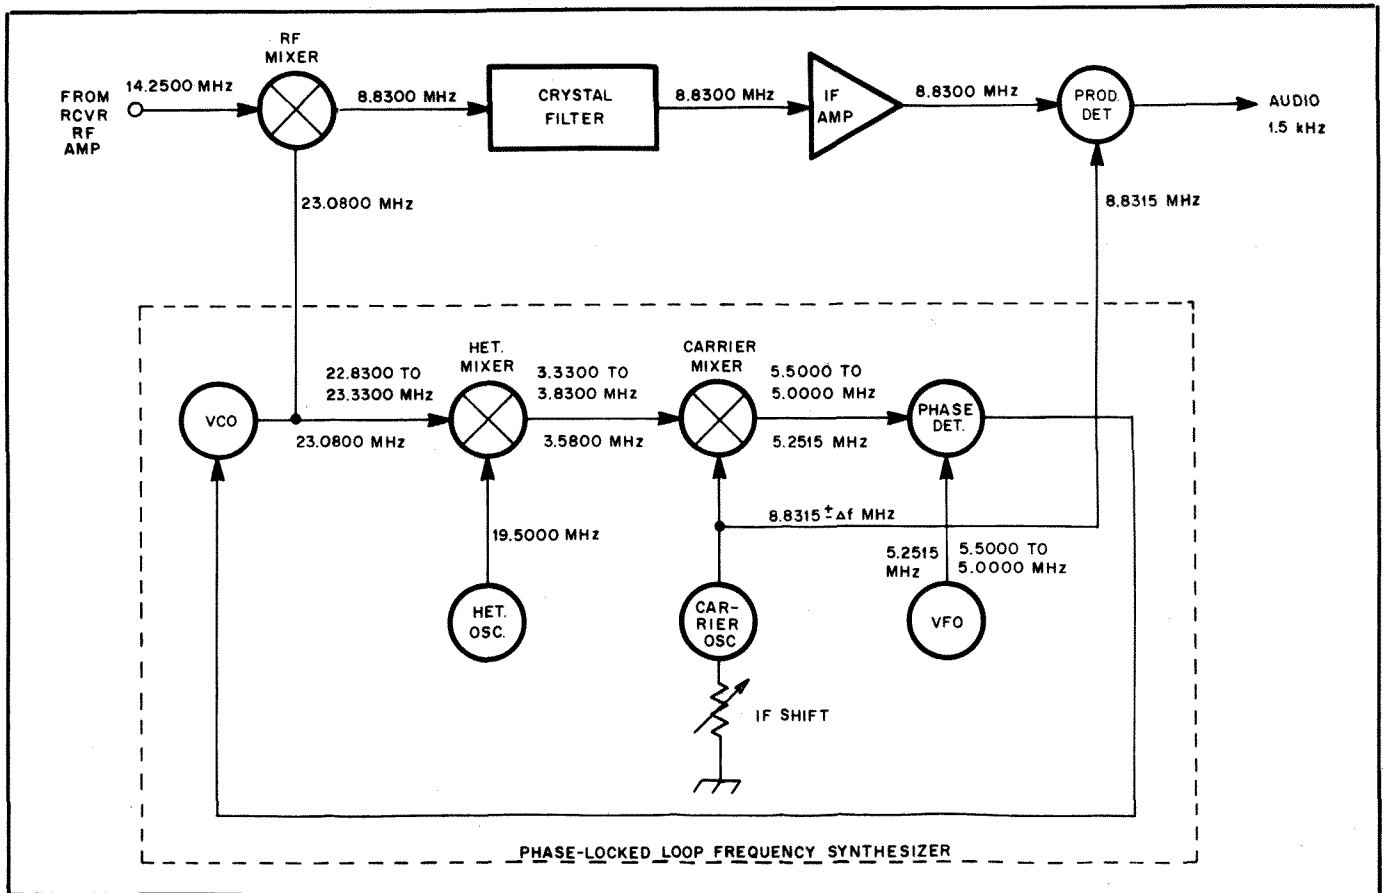

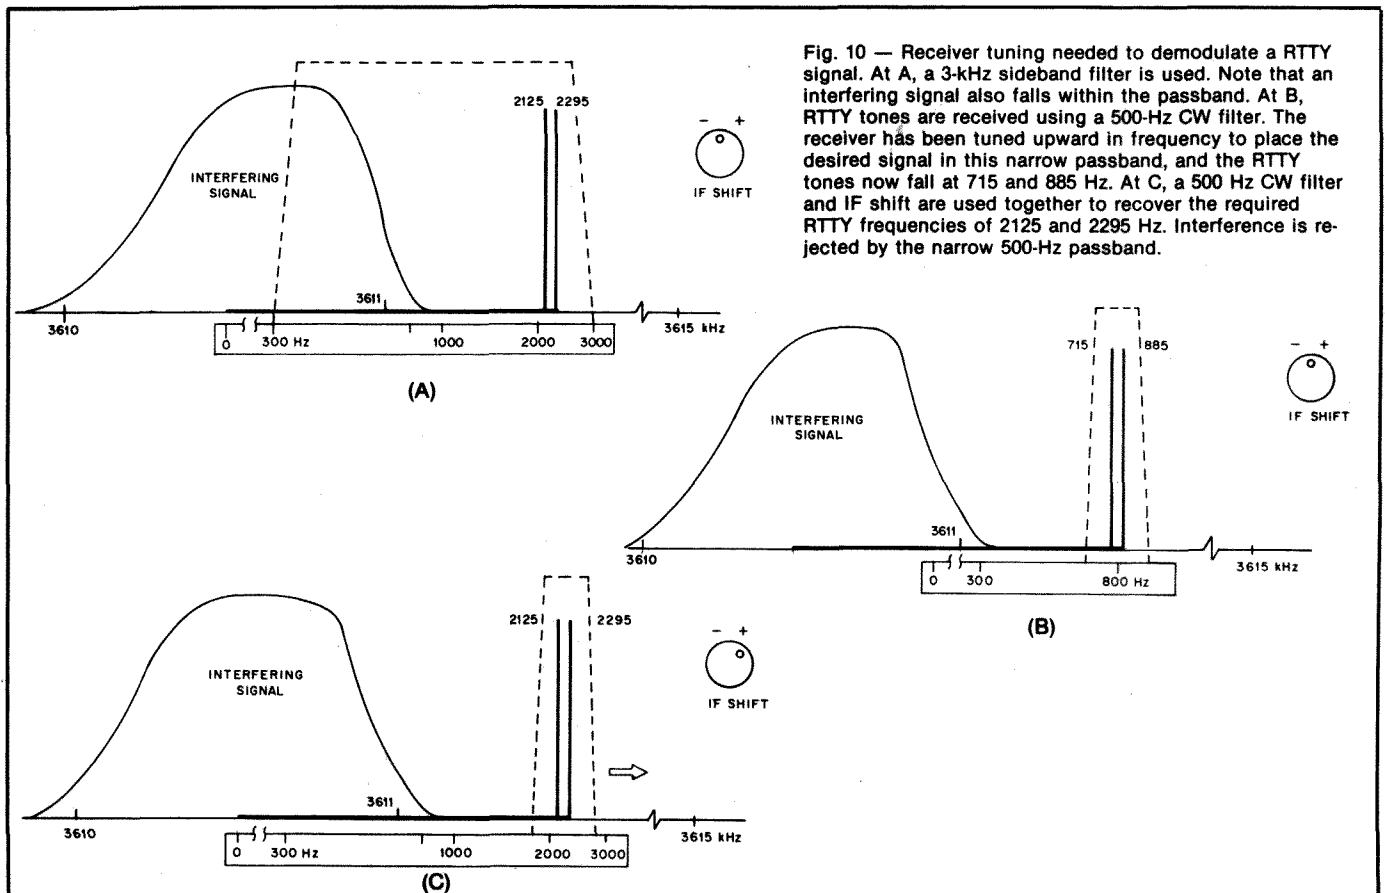

Fig. 9 — TS-820 IF shift block diagram. Frequencies given in the boxes indicate ranges for the parts of the synthesizer. For further discussions see text.

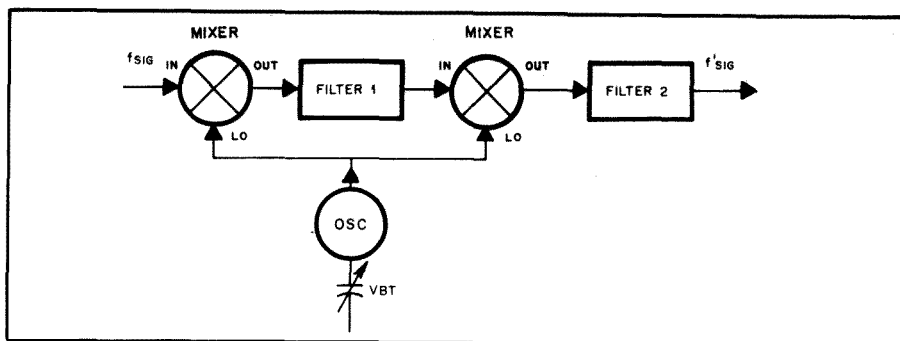

Fig. 11 — Variable-bandwidth tuning can be obtained by placing a second filter at the input or output of the IF shift circuit shown in Fig. 7.

Fig. 12 — Variable-bandwidth tuning requires the use of two passbands. By moving the center frequency of one passband, the overall bandwidth is reduced.

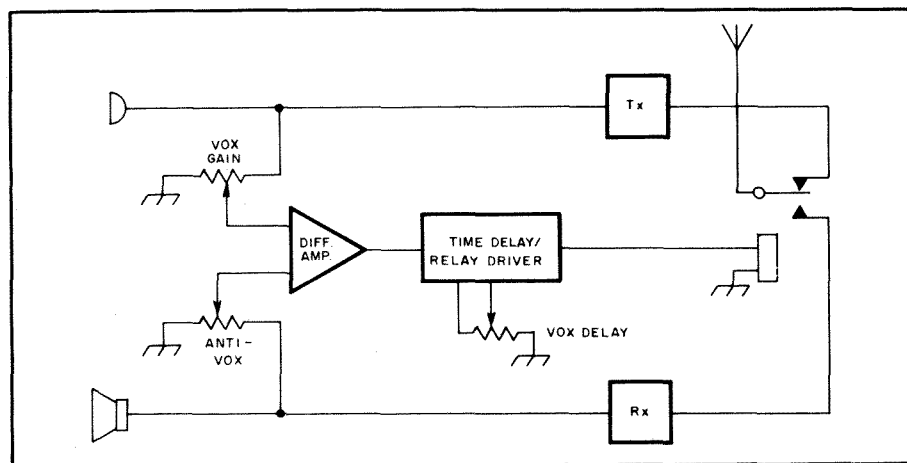

Fig. 13 — A basic VOX system.

Consider the transceiver once again tuned to 14.25 MHz. As the IF shift control is adjusted to raise the carrier oscillator 500 Hz to 8.832 MHz, a higher difference frequency will be produced by the carrier

mixer. The phase detector will in turn detect this frequency difference and force the VCO up 500 Hz, to 23.0805 MHz, to compensate. At this point, the higher VCO frequency injected into the RF mixer will

cause a portion of the 20 meter amateur band 500-Hz higher to pass through the crystal filter, just as a 500-Hz adjustment of the VFO would. (Keep in mind, however, that the VFO frequency has not been changed.)

After filtering, the resultant IF signal is mixed in the product detector with the IF-shifted carrier oscillator signal. This 500 Hz higher carrier-oscillator signal effectively compensates for the 500 Hz higher VCO signal, producing demodulated, IF-shifted audio. If the carrier oscillator had not been shifted up 500 Hz, the net effect would be exactly as if the VFO had been used to shift the receiver frequency up 500 Hz to 14.2505 MHz.

IF shift is also useful for improving reception of radioteletype (RTTY) and other data signals. Ordinarily, a reasonably wide SSB filter is used to recover the standard RTTY modem or terminal unit (TU) audio tones of 2295 and 2125 Hz. Unfortunately, BFO placement relative to the center frequencies of many such SSB filters allows recovery of audio frequencies from 300 to 3000 Hz (Fig. 10A). Only the higher frequencies are important here, so the lower 300 to 2000 Hz response represents unneeded bandwidth that only makes the receiver more susceptible to interference from adjacent signals.

To get around this, a 500-Hz CW filter might be used, but such filters are generally used with BFO placements allowing an 800-Hz beat note with signal at filter center. The two RTTY tones separated by only 170 Hz would still be heard, but their recovered audio frequencies would be centered about 800 Hz (885 and 715 Hz, respectively) — totally unacceptable to the RTTY demodulators (Fig. 10B). The solution, IF shift, allows the recovered-audio pitch at filter center to be varied at will — from 800 to 2210 Hz, for example. This allows reception of audio tones at 2295 and 2125 Hz, and provides a narrow passband response (Fig. 10C).

Frequently, an SSB or a special FSK mode is used by transceivers for RTTY transmission and reception. When poor band conditions make reception difficult with the SSB filter, a narrow CW filter and IF shift can improve copy. However, in most transceiver designs, the CW filter can be used only in the CW mode. This situation requires the operator to switch back and forth between modes when transmitting and receiving RTTY.

### Variable-Bandwidth Tuning

To avoid the expense of equipping a transceiver with several IF filters, variable-bandwidth tuning (VBT) has been developed. This circuit is similar to IF shift. However, instead of shifting the IF passband, VBT permits adjustment of the IF width to optimize reception under various operating conditions. VBT also provides reasonable receiver CW selectivity in transceivers equipped only with SSB filters.

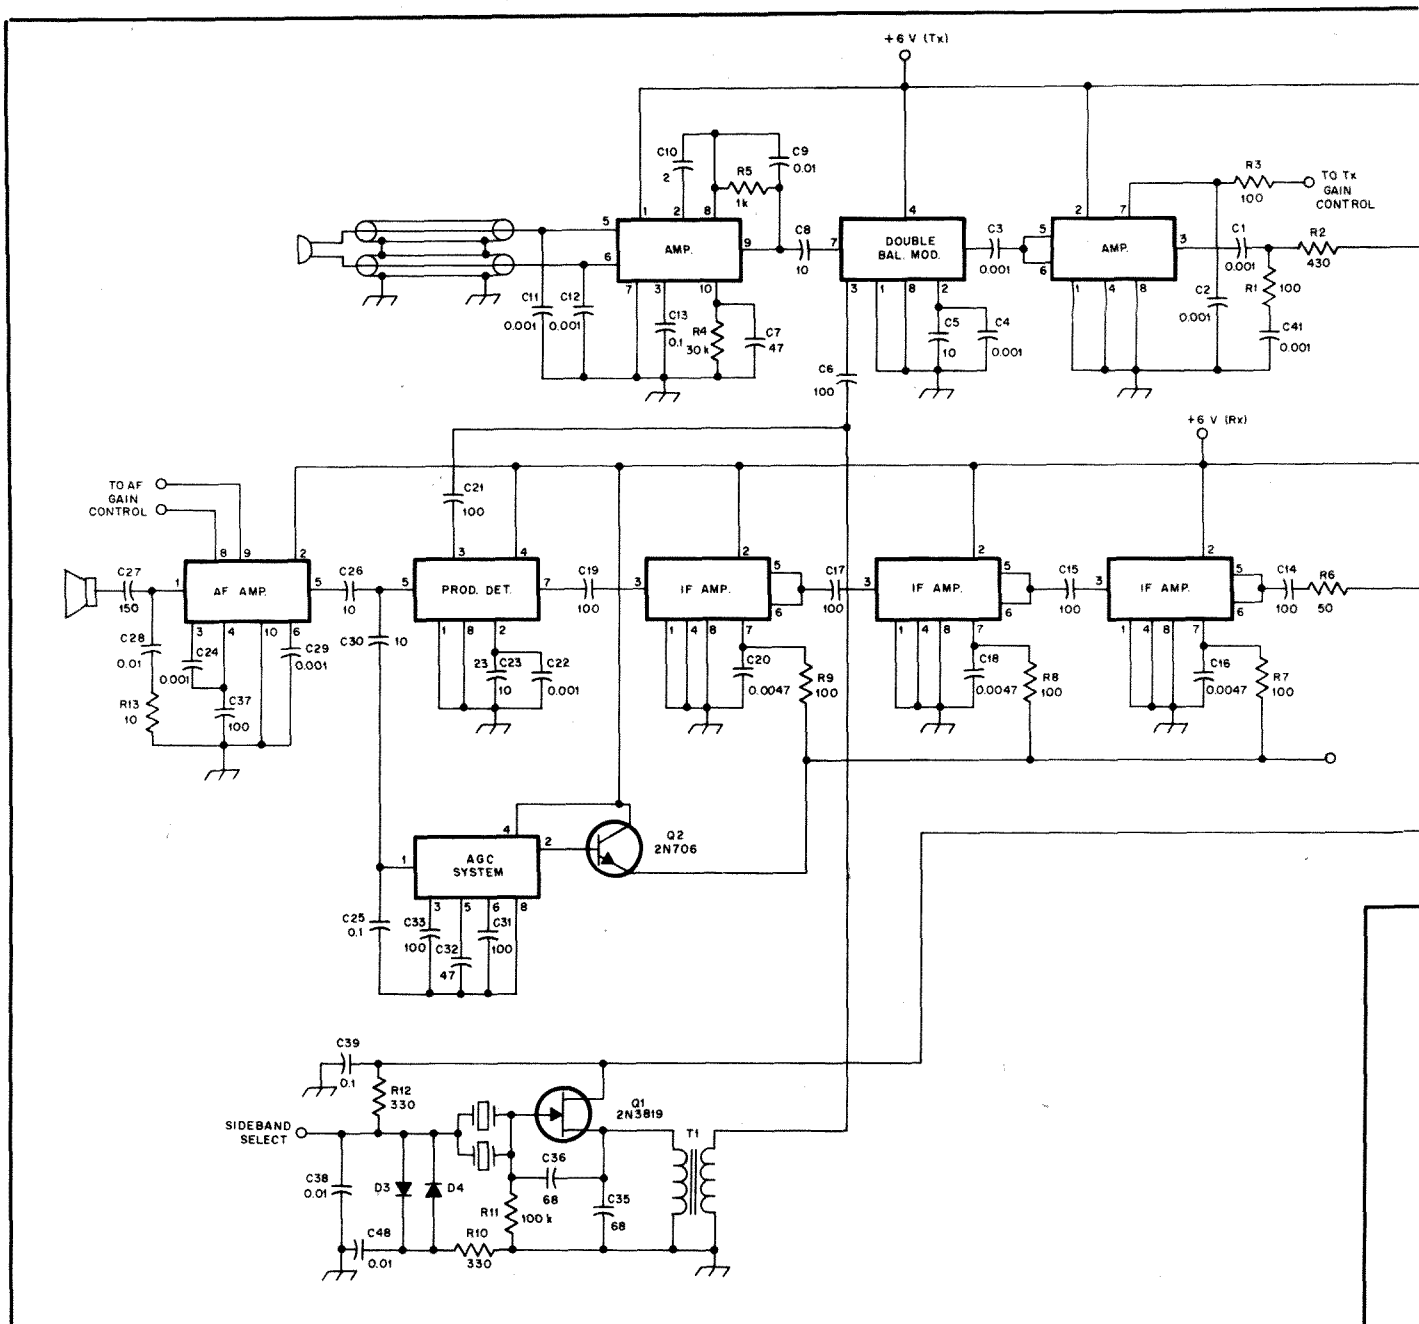

Fig. 14 — Schematic diagram of a transceiver IF module constructed from integrated-circuit building blocks.

One way of implementing VBT is by taking the simple IF-shift system of Fig. 7 and placing a second IF filter at its output. The resulting VBT system is shown in Fig. 11. By shifting the passband of the first filter with respect to the second, the effective system bandwidth may be reduced (Fig. 12A). When two equal-bandwidth filters are exactly aligned, the overall system bandwidth will be at a maximum (Fig. 12B).

#### Notch Filtering

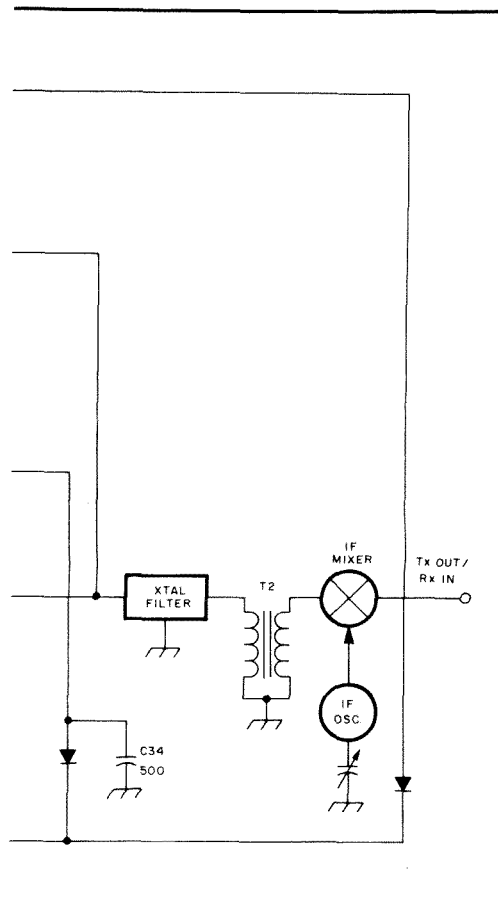

Another way of reducing interference is

to notch, or reject, the offending signal. A notch filter reduces receiver response over a narrow band of frequencies. The notch frequency is adjustable, so it can be tuned to the interfering signal frequency, eliminating unwanted CW or AM carrier tones, while preserving the desired signal's audio response.

Today, two types of notch filters are found in amateur transceivers. One type, the IF notch, operates at the receiver IF. The other type is the audio notch filter. IF notch filters are most often employed at relatively low frequencies, such as 455 or

50 kHz, where the high circuit Q required for a narrow bandwidth notch can be easily obtained. In a single-conversion receiver that uses an IF in the 8- to 10-MHz range, notch filtering is generally provided by means of audio filters.

Both filter types can be effective, although some audio notch filters do not provide the attenuation or notch depth afforded by typical IF notch filters. Typical values of attenuation range from 30 to 60 dB. If a filter has only a 30-dB notch, it will attenuate a 20-dB-over-S9 signal to a level equivalent to about S7. A 60-dB notch

The Rockwell/Collins KWM-380. Extended 160-10 meter frequency coverage is provided. The optional 16-button keypad offers alternative methods of frequency control. A combination ac/dc power supply is self-contained.

can be overcome by disabling the AGC circuitry.

### VOX

A transceiver equipped with VOX (voice operated switch) may be changed from receive to transmit by merely speaking into the microphone. Fig. 13 is a block diagram of a basic VOX system. It consists of a differential amplifier, variable time-delay circuit and transmit-receive (TR) switch. Audio energy from the microphone, controlled by the VOX-gain potentiometer, is applied to one of the two input terminals of a differential amplifier. Audio input level is adjusted so the operator's normal voice intensity will energize the TR switch. The time delay circuit keeps the TR switch

energized during short pauses in speech. Without the time delay, the switch would alternate rapidly between transmit and receive. Proper adjustment of the VOX delay prevents this annoying condition.

A problem may develop when audio from the speaker reaches the microphone. If it is as loud as the operator's voice, it will turn on the transmitter. A solution might be to place the speaker and microphone at opposite ends of the shack, or to wear headphones. Fortunately, a more convenient solution, anti-VOX, makes this unnecessary. With anti-VOX, a portion of the receiver audio is applied to the other input of the differential amplifier. Signal level is determined by the anti-VOX (or anti-trip) potentiometer. When the anti-VOX po-

would reduce the same signal to approximately S2.

### Audio Peak Filters

Another type of filter found in some receivers is the audio peak filter (APF). These filters are narrow-bandwidth band-pass filters. Usually, the bandwidth is a few hundred hertz (or less), and the center frequency is adjustable.

An APF can offer a significant improvement in overall selectivity, even in a receiver equipped with a narrow bandwidth IF filter. There may be some problems, however, if an APF is used instead of an IF crystal filter for CW reception. Because the APF is located in the receiver audio section, a strong signal outside the APF pass-band can still be amplified to a very high level in the receiver IF stages. In fact, the signal level can overload some receiver stages, producing distortion and reducing receiver sensitivity. An IF filter prevents this problem by removing the undesired signal before it reaches the IF amplifiers. Even a receiver that is not overloaded may suffer from an undesired signal activating the AGC circuit and reducing receiver sensitivity to the point where a weak signal will not be heard. Sometimes this problem

Yaesu's innovative FT-726 VHF/UHF all-mode transceiver also covers the 10- and 15-meter bands. Plug-in modules are installed for the bands of interest. Up to three such modules may be installed at any time; the 2-meter module is supplied as standard equipment. The '726 can be thought of as a 10-MHz IF unit with separate transverter modules for the bands covered. The power supply is built in.

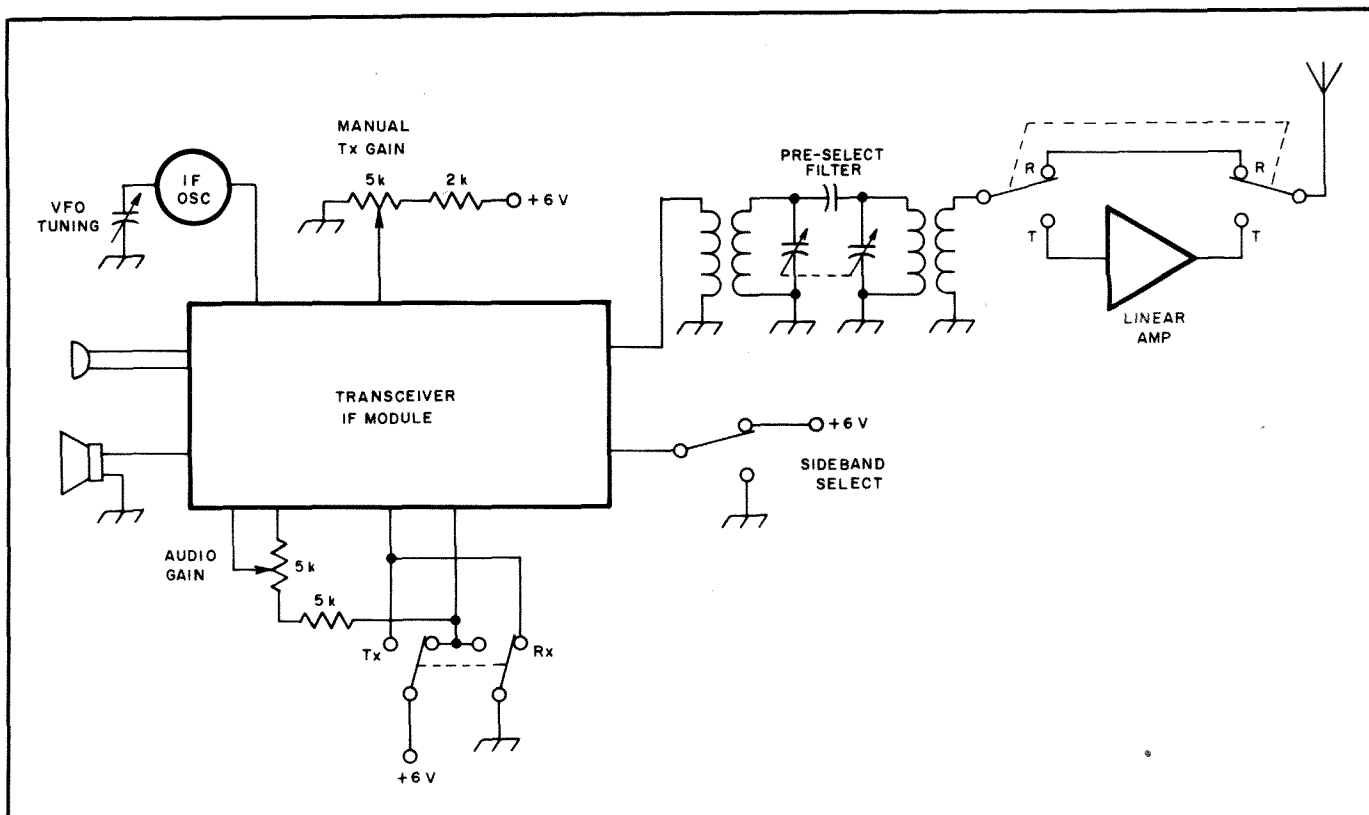

Fig. 15 — A complete transceiver, using the IF module of Fig. 14.

tentiometer is set properly, any speaker audio picked up by the microphone will be cancelled by this anti-VOX signal, preventing the receiver from keying the transmitter.

### FUTURE TRENDS

The latest transceiver designs are strongly influenced by recent developments in RF and computer technology. Complete

receiver subsystems are now available in single IC packages. Improved fabrication techniques promise to increase device reliability while decreasing cost. These changes are sure to have an effect on the Amateur Radio equipment of tomorrow.

### Building Block Basics

It is already possible to assemble a transceiver from IC building blocks, adding

only a few discrete components (individual resistors, capacitors, transistors, etc.). The schematic diagram in Fig. 14 bears strong resemblance to a block diagram, since the circuitry needed for each stage function (mixer, amplifier), is entirely contained within IC modules.

This single-conversion design is described in the RSGB *Radio Communications Handbook*. It can be used as the foundation for either a single- or multi-band HF transceiver. Audio at the transmitter microphone input will produce a 70-mV RMS, 9-MHz SSB output. Similarly, the receiver will accept a 9-MHz SSB input signal and convert it down to audio, providing 65 mW of power to a speaker or external power amplifier. Fig. 15 is a schematic diagram showing how the basic transceiver may be expanded into a fully operational HF communications system.

This circuit design illustrates an important shift away from conventional transceiver design philosophy. There is practically no sharing of circuitry. This approach may well be more economical than trying to use a single chip for both transmitting and receiving, for several reasons. First of all, it is much easier to merely switch supply voltage from the receiver circuitry to the transmitter circuitry than to develop extensive RF switching arrangements for each shared chip. Second, the cost of switching circuitry might easily add up to more than the cost of the chips they were designed to

Trio-Kenwood's TS-940S is a top-notch radio that offers SSB, CW, AM, FM and FSK operation on the 160-10 meter amateur bands, as well as a general-coverage receiver. The power supply is built in. Options include an automatic antenna tuner and several crystal-filter combinations.

Fig. 16 — Computer graphic display from the Yaesu FT-980 transceiver controller program.

eliminate! Additionally, alignment is sure to be quicker and easier when transmitting and receiving circuitry can be isolated from one another.

#### Digital Aspects

Digital electronics plays an extensive role in Amateur Radio today. For the amateur transceiver, digital methods are used both externally, for generating and interpreting various modes of digital communications, and internally, for performing such circuit functions as stabilizing the operating frequency, storing and recalling control set-

tings from memory, and preventing out-of-band operation.

The Yaesu FT-980, for example, has a built-in microprocessor that allows up to 16 frequencies to be stored and instantly recalled from memory. Mode and VFO information for each channel is simultaneously programmed and stored. Other features of the digital frequency controller include push-button frequency tuning and tab setting. This tab function permits an operator to partition an amateur band to avoid accidental transmissions on unauthorized frequencies.

The '980 can be connected to a personal computer through an appropriate interface. This arrangement makes it possible to tune the radio and store and manipulate frequencies from the computer keyboard. Control of such important operating features as RIT, IF shift, mode control, IF width, FSK shift, and even TR switching may be performed by the computer.

Fig. 16 is the graphic display from an FT-980 controller program. This particular program, as supplied by Yaesu, is designed to be run on an Apple II computer. Complete transceiver diagnostics are given, and any listed parameter may be changed at will, making the transceiver front panel unnecessary. In fact, practically every front panel control is disabled when the computer program runs.

A more complex program might not only control the transceiver, but also format and send RTTY text. Or, the computer might serve as a processor for voice signals, permitting fingertip control of compression, frequency response, and so on. The possibilities are limited only by the skill and imagination of the software designer.

Two relatively new forms of digital communications, AMTOR and packet radio, make computer control necessary both for generating and interpreting data and for transmit/receive mode switching. Close synchronization is required among the various hardware and software elements within each system, and among all active systems comprising a network. A transceiver used in an AMTOR system, for example, must exhibit quick recovery time (on the order of 10 ms) when switching from receive to transmit. Care must be taken to ensure that circuit time constants are short enough to permit this type of high-speed operation.

#### Tomorrow's Transceiver

As digital methods improve and digital logic increases in speed, it may only be a matter of time before amateur signals are

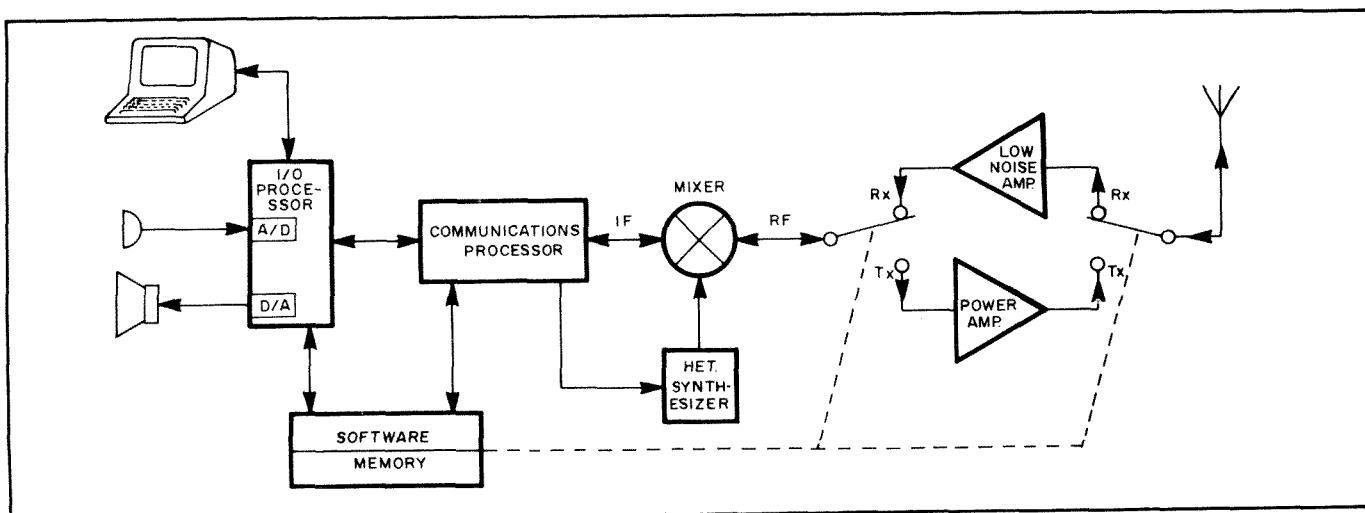

Fig. 17 — A transceiver of the future?

exclusively digitally processed. The transceiver of tomorrow may employ a receiver consisting of an analog-to-digital (A/D) converter at the antenna or IF input and a digital-to-analog (D/A) converter/amplifier or a line driver at the audio/baseband output to accommodate voice or

data signals, respectively (Fig. 17). In between, all information would be processed as digital data. When the transceiver is transmitting, the process would simply be reversed, with audio from a microphone applied to an analog-to-digital converter, digitally processed up to the operating frequency, and transmitted

using conventional RF techniques. With the ever-increasing speeds of microcomputers, the transceiver of today may tomorrow be reduced to little more than packaged software, with the necessary RF A/D and D/A conversion tasks handled by small plug-in interface modules.

# Repeaters

**R**epeaters, particularly FM repeaters, have had a great impact on Amateur Radio. Find a copy of any Amateur Radio magazine from the early 1970s and compare the amount of advertising for FM equipment with the amount of advertising in a current issue. Dramatic isn't it? Advertising from manufacturers and dealers is a good barometer of buyers' interest.

Why the widespread popularity of FM repeater operation? Repeaters are ideal for increasing the range of mobile and hand-held portable radios. Telephone interconnects (autopatches) provide instant access to local police, fire and medical assistance during emergencies. The repeater provides a local "party line" for club members. These are some of the reasons why repeaters have become so popular.

A repeater is a well situated automatic retransmission station used to extend the range of other stations. Repeaters often serve hand-held, portable and mobile stations in a local area. The repeater station consists of a receiver, control circuitry, interconnect circuitry, a transmitter, power supply(ies), at least one antenna and various other associated items (Fig 1).

Repeaters are as much a product of FCC rules, regulations and definitions as they are of radio technology. Unlike other less-regulated aspects of Amateur Radio, the repeater operator must calculate the effective radiated power (ERP; definition follows) instead of simply measuring the output power. Furthermore, FCC rules require the repeater operator to calculate the height above average terrain (HAAT; definition follows).

The FCC has valid reasons for treating repeaters more strictly than other amateur stations. It is usually difficult, if not impossible, for two repeaters to share the same service area and frequency(ies). In most stations, the operator (person controlling the equipment) is also the most frequent user of the station; not so for repeaters. In a typical repeater group, one or two individuals may be the operators, but tens (hundreds) of other stations will use the facilities of the repeater.

This chapter is meant to provide the reader with an overview of the dual nature

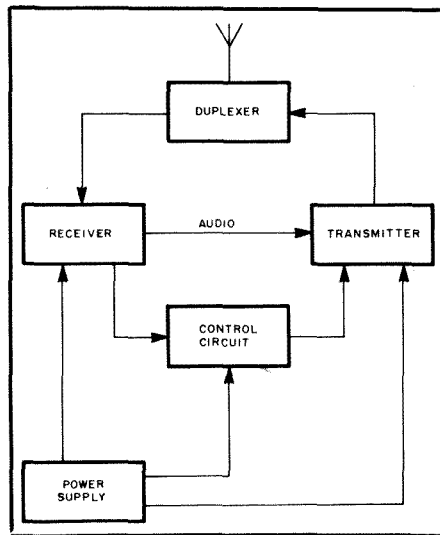

Fig 1—Block diagram of simple dual-frequency repeater.

Fig 2—Pictorial diagram of frequency usage in a dual-frequency repeater system. A transmits on frequency X, which is the repeater receive frequency. The repeater retransmits A's signal on frequency Y, which is B's receive frequency. When it is B's turn to transmit, the paths are reversed, with B transmitting on X and A receiving on Y.

of repeaters—the technology and the rules. Most of the circuits serve to illustrate the concept as simply as possible and, therefore, may not be the best design for those looking for a construction project. For those in the process of building a repeater station, we suggest you consult recent issues of *QST*, *Ham Radio* or *73* for the latest in practical circuits, and ARRL's *FCC Rule Book* for the latest in repeater regulations.

In the amateur service at VHF and UHF, there are basically two approaches to producing a station that functions as a repeater. The first repeater format receives the signal on one frequency, demodulates it, processes it, applies it to the input of the repeater transmitter and retransmits it (usually on a second frequency in the same band), as depicted in Fig 2. Most repeater stations in the US are designed to operate with FM in the 2-meter band. But FM voice repeaters can be found on the 28, 50, 220, 450-MHz and higher bands as well. Some repeaters are designed for other modes besides voice, such as RTTY, slow-scan TV, fast-scan TV and packet radio.

Packet repeaters usually use the second fundamental format for repeater operation (Fig 3). Here, only one frequency is used: The repeater station receives and transmits on the same frequency. *It does not, however, transmit and receive at the same time.* With digital data there is no problem storing the received information and retransmitting it. Thus, one frequency can be used, and many of the problems associated with dual-frequency systems are not present. Obviously, voice conversations do not lend themselves to this store-and-forward technique. Single-frequency repeaters are fundamentally different from dual-frequency repeaters and have radically different problems associated with them. The balance of this chapter is devoted primarily to dual-frequency systems.

In some instances, a voice repeater may also be used for another mode, such as RTTY. If this is accomplished with audible tones, its operation is not different than that of normal voice repeaters. Some groups have successfully integrated auxiliary modes with the primary voice mode using techniques that make the secondary communications transparent to the voice users. Such techniques are beyond the scope of this chapter.

## Isolation

The primary consideration in dual-frequency repeaters is isolation. Everything else is secondary. Isolation means keeping the output of the repeater transmitter and other unwanted transmitters from affecting the input of the repeater receiver. No

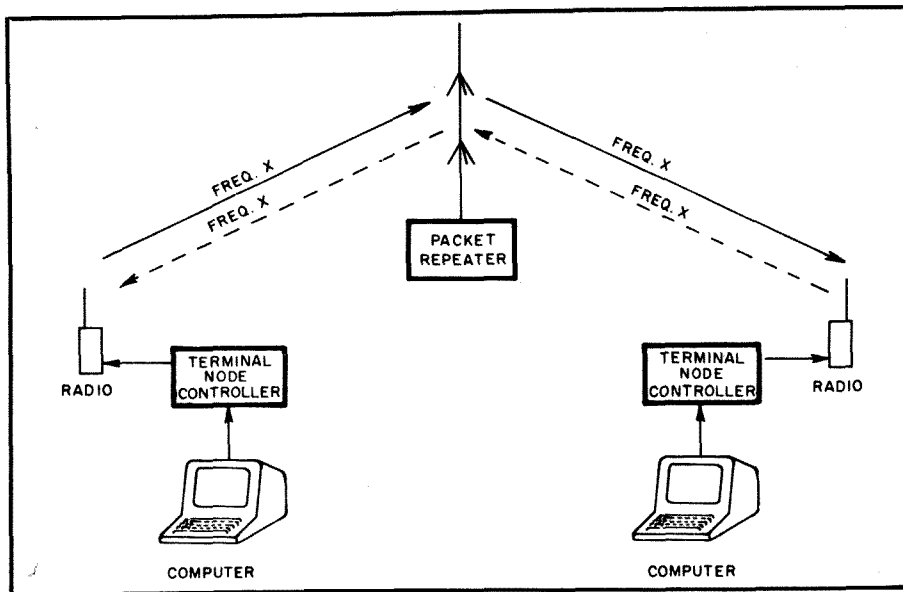

Fig 3—Packet repeaters use only one frequency for transmitting and receiving, but they do not transmit and receive at the same time.

matter what options are added to a repeater, the performance will be unsatisfactory if the transmitter “desenses” the receiver.

Desensitization is the reduction in receiver sensitivity caused by noise or RF overload of the receiver front end. Although desensitization from the repeater transmitter may be the most common form of this malady, it can be caused by any strong signal or noise reaching the receiver front end.

The least expensive—and usually the least effective—method of providing the needed isolation is to use separate antennas for the transmitter and receiver. To be effective, the antennas must have low angles of radiation with virtually no lobes of power high in the vertical plane (Fig 4). Usually in such installations, the receiver antenna is mounted directly above the transmitter antenna. The greater the vertical separation, the better the isolation, but the greater the separation, the greater the difference in the patterns of the two antennas. If the receive and transmit antenna patterns do not match closely, the system will seem to perform erratically for stations in certain locations (Fig 5). For instance, a weak hand-held might be able to access the repeater, but a directional gain antenna and preamplifier might be required to receive it. Thus, one is forced to compromise between isolation and consistent performance.

One way of minimizing the effect of the transmitter on the receiver in such installations is to keep the transmitter power to a minimum. Such a system might be marginally useful when the transmitter operates at a power of 1- or 2-watts output, and totally useless when the transmitter output power increases to 25 or 30 watts. Receiver desense can often be identified in a repeater

Fig 4—Pictorial diagram of a typical two-antenna repeater installation. The vertical separation should be at least four wavelengths.

Fig 5—Use of two antennas can cause disparity in the coverage areas of the receiver and transmitter. The solid line represents the boundaries of the receiver coverage area, while the broken line represents the coverage area of the transmitter.

Fig 6—At A, the coaxial sleeve, or “bazooka,” balun for isolating the feed line from the antenna. At B, a typical 2-meter FM antenna with two sets of radials spaced  $1/4$ -wavelength apart.

Fig 7—Cutaway view of a section of coaxial Hardline cable. At VHF and UHF, virtually all currents flow at the surface of the conductor; therefore, the signal path is along the outer surface of the inner conductor and the inner surface of the shield. Current flowing on the outer surface of the shield can create fields that combine with the antenna fields causing a change in the radiation pattern of the antenna.

Fig 8—At A, pictorial diagram of main lobes of radiation for receiving and transmitting antennas. At B, representation of a distorted radiation pattern, which would cause problems if it were to replace the transmitter pattern in A.

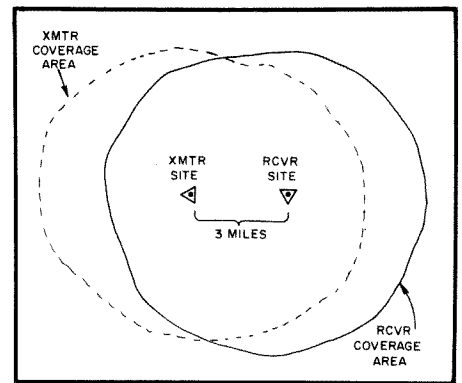

Fig 9—Disparity in coverage area caused by using two sites.

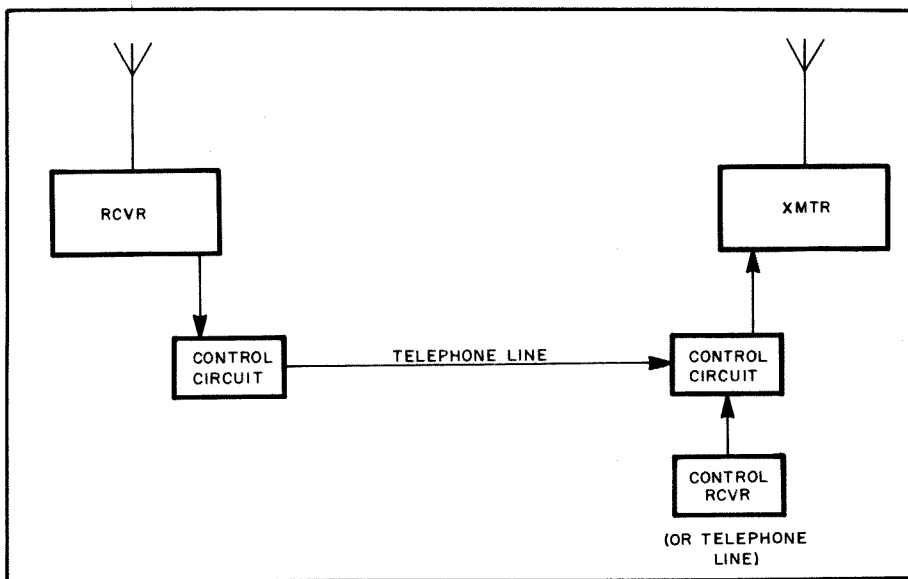

Fig 10—Block diagram of two-site system using telephone line to send audio and control functions from the receiver to the transmitter.

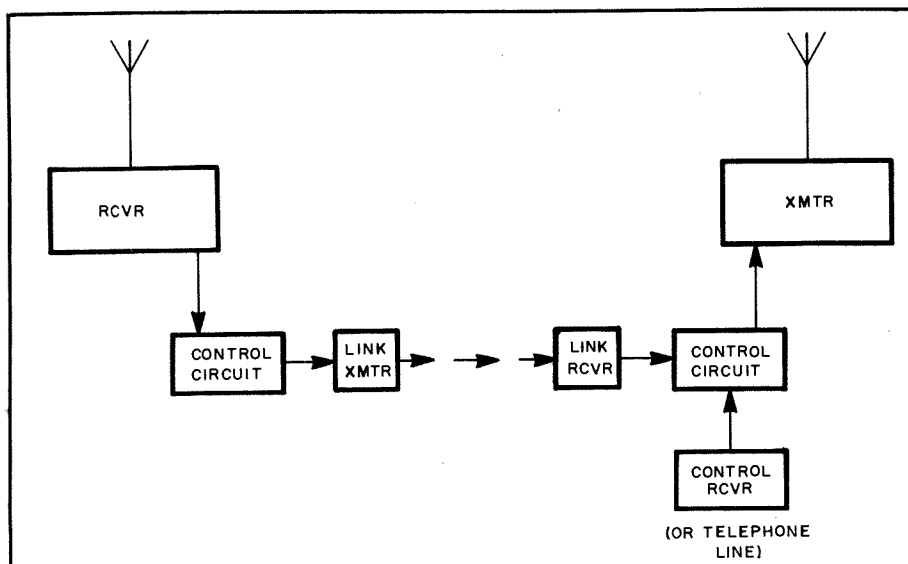

Fig 11—Block diagram of two-site system using RF link between receiver and transmitter sites.

system using this principle, whether the system is using vertically separated antennas or some other isolation procedure. If a weak station is able to break the receiver squelch, but disappears when the repeater transmitter is turned on, desense is indicated. To confirm this condition, reduce the output power of the repeater or simply disable the transmitter; the weak signal should now be able to capture and hold the repeater receiver.

Antennas that are well decoupled from the transmission line and the use of Hard-line coaxial cable are two means of improving the performance of the two-antenna system. Decoupling the feed line from the antenna means preventing the antenna field from inducing current flow on the outside of the coaxial cable shield. Current flowing on the outer surface of the shield will create fields that combine with and distort those of the antenna, which may produce lobes in undesired directions.

Various devices can be used to accomplish decoupling; they create a very high impedance point somewhere along the surface of the outer conductor that effectively blocks the current, and they provide another very low impedance path that effectively short circuits the current and prevents it from flowing farther along the transmission line. Fig 6 shows antennas with a "bazooka" at A and two sets of quarter-wave radials at B. The "bazooka" is  $\frac{1}{4}$ -wavelength-long conductive sleeve attached to the shield at the bottom and insulated at the top. Because it is  $\frac{1}{4}$ -wavelength long, it has a very low impedance at the point that it is attached, but a very high impedance at the top where it is insulated from the shield. Since the "bazooka" and the corresponding portion of the outer surface of the shield form a section of transmission line, the shield also has a very high impedance at this point and blocks the RF current. The  $\frac{1}{4}$ -wavelength radials in B provide a low-impedance path for the current. Two sets of radials spaced  $\frac{1}{4}$ -wavelength apart are substantially more effective than one set.

Since at VHF and higher most of the RF current tends to flow on the surface of a

Fig 12—Details of a 146-MHz cavity to be used as part of a duplexer. To minimize loss, the conducting surfaces should be silver plated.

conductor, a coaxial cable can be considered to have three conductors: the outer surface of the inner conductor, the inner surface of the shield and the outer surface of the shield. In a perfect system the signal travels on the outer surface of the inner conductor and the inner surface of the shield (Fig 7). If the outer shield has holes in it (for example, gaps in braid), fields on the outside of the coaxial cable can influence the field existing on the inside of the conductor. Because Hardline coaxial cable has a shield made of a conductive tubing (usually copper or aluminum), the holes are entirely eliminated. The only possibility of an outside field invading the internal field is at the junction points (connectors). If braided-shield type coaxial cable is to be used, the double-shielded variety is preferable.

A little reflection on Fig 8 will give the reader some insight into the significance of Hardline and decoupling. Since the receiver antenna is mounted above the transmitter antenna, it is obvious that the receiver transmission line must run through the major lobes of the transmitter antenna field. The limitations of the vertically

separated, two-antenna configuration often outweigh the benefits of cost-savings.

### Two Sites

A second means for providing isolation between the repeater receiver and transmitter is to place the two at different sites and provide some means for linking the output of the repeater receiver to the input of the repeater transmitter. Where we talk of vertical separation in terms of a few feet or a few wavelengths, we talk of horizontal separation in terms of miles.

The pitfalls of a two-site system are many. To the system users, the most significant may be the disparity in coverage between the receiver and transmitter (Fig 9). Where this is a minor consideration for vertically separated antenna systems, it becomes a major concern for the two-site system. Two sites require two separate installations and the expenses that go with them. Amateur Radio groups are often required to pay rent for the space on a mountaintop, tower or tall building. Both the receiver and the transmitter require some means of providing electrical power. All this spells added expense for the group.

For the repeater operator, controlling two sites and interconnections are the big problems. Somehow the audio output of the receiver must be linked to the input of the transmitter. This can be accomplished in different ways. Probably the easiest, and in the long run the most expensive, is to rent a dedicated line from the local telephone company (Fig 10). A second method is to use an RF link consisting of a transmitter located at the receiver site and a receiver located at the transmitter site (Fig 11).

The equipment of the link is frequently chosen to operate on a band other than the one the repeater operates on. Although the initial expense may be greater, equipment can be selected with a life expectancy of several years. If the equipment is amortized over its expected life, the cost will often be found to be lower than that of renting a telephone line for a comparable period of time.

In addition to getting the audio from the receiver to the transmitter, the transmitter must be told to turn on when a signal is present at the output of the receiver. Typically, some form of encoding will be used to accomplish this task. For instance, a tone or current (dc) may be used on the telephone line to signal the transmitter to turn on.

A further complicating factor comes when service is required. It may not be obvious to the operator whether a problem exists at the receiver, over the link, or at the transmitter. Unless a technician is available for both sites, several trips back and forth may be required to bring the system back to optimum.

### Duplexers

A duplexer is a device that allows the repeater transmitter and receiver to be connected to the same antenna. If properly constructed and installed, a duplexer will allow the signal from the antenna to reach the receiver while blocking energy from the transmitter. We live in a world governed by the axiom, "There's no such thing as a free lunch." The price of including a duplexer in a repeater system is insertion loss. Properly constructed, a duplexer will provide adequate isolation with an insertion loss of less than 1 dB.

What is a duplexer? How does it work? A duplexer is a device that provides a high Q passband for both the receiver and the transmitter. On the one hand, the passband circuit connected to the receiver passes energy at the receive frequency with a minimum of attenuation, while providing a high degree of attenuation (a notch) for energy at the transmitter frequency. On the other hand, the passband circuit connected to the transmitter passes energy at the transmit frequency, while rejecting or notching energy at the receive frequency.

Some FM transmitters lacking in good design produce a broad spectrum of energy as well as energy at the desired output

Fig 13—Typical frequency response of a single cavity of the type used for duplexers. The dashed line represents one cavity alone, while the solid line is for a cavity with a shunt capacitor connected between input and output. An inductance connected in the same manner will cause the rejection notch to be above the frequency that the cavity is tuned to.

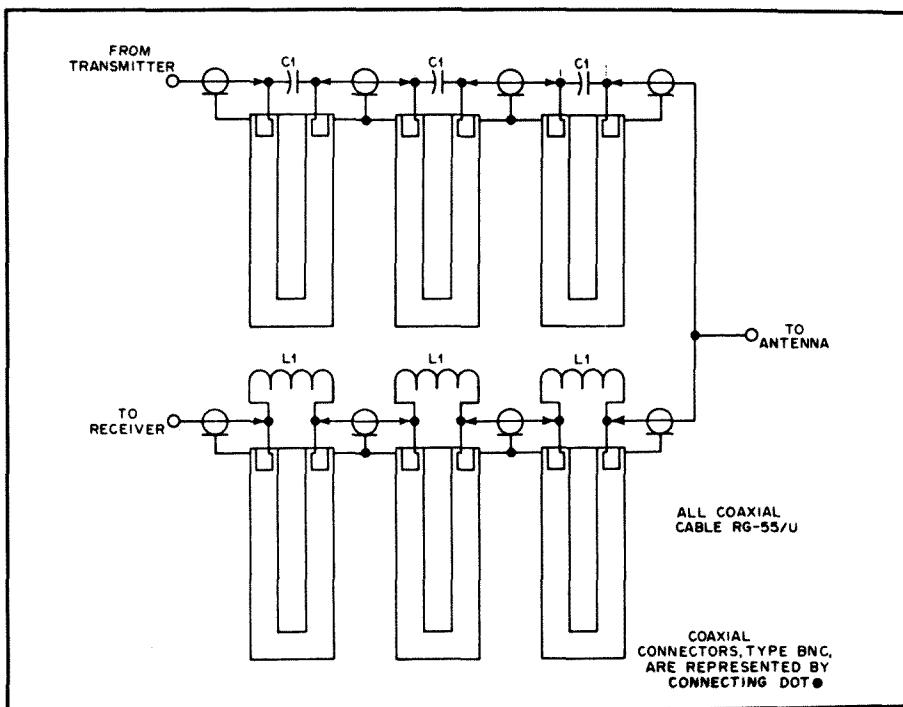

Fig 14—Diagram of a six-cavity duplexer.

frequency. This broad spectrum of energy is often referred to as white noise. Practically any transmitter will produce some white noise, but in good designs that noise will be at least 80 dB lower than the carrier. Although this may seem like an insignificant amount of power, it is more than enough to cause desense when the white noise appears on the frequency the receiver is tuned to. In poorly designed transmitters, the white noise is not likely to be down as much as 80 dB. A duplexer has the added advantage of preventing white noise energy

on the receive frequency from passing from the transmitter to the receiver.

In most VHF/UHF applications, resonant coaxial cavities are used to form the high-Q circuits needed for the duplexer (Fig 12). The cavity functions as a series-resonant circuit. When a capacitor or inductor is connected across a series-resonant circuit, an antiresonant notch is produced, and the resonant frequency is shifted. If a capacitor is added, the notch appears below the resonant frequency. Adding an inductance will make the notch

appear above the resonant frequency. The value of either component will determine the spacing between the notch and the resonant frequency.

Fig 13 shows the band-pass characteristics of the cavity with and without shunt elements. This example shows a cavity tuned to 146.94 MHz. Note that without the shunt capacitor, the cavity would provide only about 10 dB of attenuation 600 kHz below the primary frequency, which is the standard offset for the 2-meter band in the US. With the shunt element, the attenuation is approximately 35 dB—an increase of nearly 25 dB. The insertion loss in both cases is less than 1/2 dB, which is an acceptable level.

Typically, a duplexer in the Amateur Radio Service will consist of three cavities in the receive leg and three cavities in the transmitter leg (Fig 14). Using cavities similar to those described, we see that the receive leg will provide 100 dB of rejection of the transmitter signal, while having no more than 1.5 dB of insertion loss. Both of these figures are acceptable and attainable. Commercially available six-cavity duplexers may have less than 1 dB of insertion loss per leg, while providing over 100 dB of isolation. Measurements in the ARRL lab have found insertion losses as high as 5 dB per leg in homemade duplexers manufactured from circuit-board material. Although far from ideal, these duplexers are probably still preferable to using separate antennas.

A second type of duplexer uses the hybrid ring circuit of Fig 15. The isolation provided by a hybrid ring depends on the arrival of two signals of equal magnitude but 180 degrees out of phase, at the output terminal. The signal is split into two parts at the input. One signal path is made one-half wavelength longer than the other to achieve the required 180-degree phase shift.

For duplex operation, the hybrid ring must be made to pass the desired frequency while attenuating the unwanted signal. A high-Q cavity is placed in the ring to act as a switch to take one of the signal paths out of the circuit. The cavity is resonant at the pass frequency of the hybrid ring, and thus will act as a short circuit at this frequency. Quarter-wavelength lines isolate the cavity from the signal so the desired energy is not attenuated.

At the frequency to be canceled, the cavity is not resonant and, therefore, it acts as a high impedance in parallel with one branch of the hybrid ring. Because the cavity does contribute some phase shift, a stub tuner is included in the opposite leg as a means to adjust the ring for maximum attenuation of the unwanted signal.

#### Common Practices

Even with a good-quality duplexer installed, there is no guarantee that the repeater receiver will be isolated from the transmitter. It is common practice to locate the transmitter and receiver in the same

Fig 15—At A, a hybrid ring with a tuned cavity attached. At B, two hybrid-ring and cavity assemblies may be combined to serve as a duplexer. For additional isolation between the receiver and transmitter, another ring and cavity assembly may be inserted at points X and Y.

cabinet. This is not mandatory, but given the cramped space at most repeater sites, it is quite common and often necessary. Care must be taken to properly shield the receiver from the transmitter. Most commercially available repeaters designed for the amateur service house the transmitter and receivers in RF-tight metal boxes. Equipment for the commercial services, which is usually more costly, often has even more elaborate shielding. Power, audio and control leads are fed into the transmitter and receiver by way of feed-through capacitors and other decoupling devices. It simply does not make good sense to spend hundreds of dollars for a duplexer, and then turn around and defeat its purpose with sloppy construction practices.

Another potential problem point is the coaxial cables that connect the duplexer to the transmitter and receiver. If RF leaks out of or into these cables, the duplexer will likely be compromised. Simply keeping the cables as far away from each other as possible will help. These jumper cables should be made of high-quality double-shielded coaxial cable as a minimum. Hard-line would be preferable from this point of view, but it sometimes is not practical because a fair amount of flexibility is required.

If double-shielded cable is not conveniently available, it can be fabricated

Rear view of Maggiore Hi Pro Mk II 220-MHz repeater. The transmitter and receiver strips are housed inside the cast aluminum boxes mounted to the chassis. Feedthrough capacitors are used for all leads going to the transmitter and receiver strips. The control circuitry is located beneath the chassis. Audio signals are at line level, minimizing the possibility of RF interference. These measures represent an acceptable level of isolation between the receiver and transmitter.

Fig 16—Map used to define coverage area and to estimate "center" area where search for repeater site is to be conducted.

from ordinary single-shielded cable and braid removed from another section of cable. The coaxial cable is inserted into and pushed through the center of the braid—it will probably be necessary to do this before

attaching the connectors. The braid is then secured to the connectors with ordinary hose clamps. Although not pretty, this procedure is functional. Some hams have even used soft-drawn copper tubing as an

Fig 17—Location of K1CE repeater halfway up the mountain gives desired coverage of Pleasant Valley, while reducing co-channel interference from signals originating in Nearby Valley.

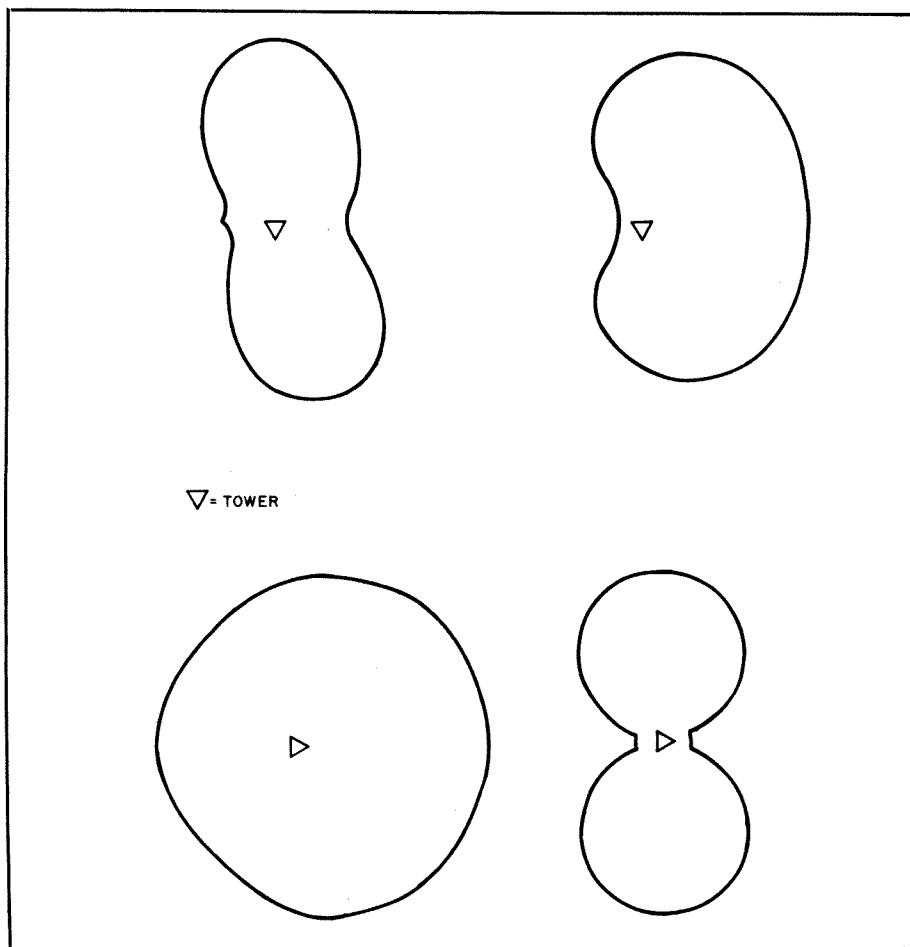

Fig 18—Special radiation patterns obtained by varying installation of "omnidirectional" Stationmaster antenna, as suggested in Phelps Dodge sales literature.

outer shield when flexibility was not of prime importance.

#### Repeater Sites

Usually hams are interested in finding a repeater site that will provide good coverage of the community. This roughly translates into the the highest building, hill or mountain in the area. The site must be accessible, and some means for providing electrical power must exist. For control purposes and possibly autopatch, it is

desirable to have access to telephone lines also.

In the early days of Amateur Radio repeaters, the commonly accepted definition of the best site was simply the highest point on the highest hill or building. Those were the days when repeaters were few and far between. In most urban areas, particularly along the East and West coasts of the US, the 2-meter band is approaching complete occupancy—and in some areas this is even true of the 220- and 450-MHz

bands. Thus, it is not uncommon to have mobile stations accessing more than one repeater with the slightest band opening.

It is time to reexamine our definition of "best site." A 2-meter repeater located in Lewistown, Montana would probably be expected to have a much wider service area than one located in Hartford, Connecticut. Although it may be advantageous for the Lewistown repeater to cover an area with a radius of 100 miles, it would be irresponsible for a repeater in Hartford to do the same. Such a service area for the Lewistown repeater would not even include any of the major cities of Montana, whereas a similar sized service area centered in Hartford would take in both Boston and New York City.

To find the ideal site, the first thing that should be considered is the service area—specifically, what area should the repeater cover. For crowded urban areas, this probably should be no greater than a 60-mile diameter. Using topographical maps and taking the geographical idiosyncrasies into consideration, locate the center of the service area (Fig 16) and begin the search for a suitable site in that vicinity. A moderately high hill may provide better coverage of the service area than the highest hill—simply because the system will receive less co-channel interference.

Sometimes geographical peculiarities dictate the selection of a site at one extreme of the service area, or at least somewhat removed from the center of the service area. If the service area is to be a valley, it may be wise to locate the repeater on one of the mountains bordering the valley (Fig 17). Rather than choosing the peak of the mountain, the repeater operator should locate the station somewhat below the crest to minimize coverage to the other side of the mountain.

Directional antennas can also be used to shape the pattern of coverage also. For more information on this topic, consult *The ARRL Antenna Book* and literature available from various VHF/UHF antenna manufacturers. For instance, the Phelps Dodge Stationmaster series of antennas are fiberglass-enclosed collinear arrays exhibiting (usually) an omnidirectional horizontal pattern. Fig 18 displays a variety of horizontal radiation patterns that can be achieved by varying the installation of a Stationmaster. Exposed multiple-dipole arrays (Fig 19) and beam antennas offer even more possibilities.

Businesses are often willing to pay rent for the right to install their radio equipment at these sites. Some landlords are willing to rent space at a reduced rate or even donate it to an Amateur Radio group. When you discuss financial matters with the landlord, it may be good strategy to emphasize emergency communications and other forms of public service—if you are prepared to make good on any promises. Good negotiating and salesmanship skills on the part of the site committee may mean

Fig 19—Typical dipole array for repeater use. Various patterns can be obtained by varying the alignment of each element.

the difference between a good site (high altitude, low rent) and a poor one. Increased cost may be the least of the problems caused by the proximity to other radio stations, though.

### Living With Your New Neighbors

With the proliferation of radio transmitters in service, even a mediocre site is likely to have several transmitters. The repeater receiver, in this case, not only contends with the RF from the repeater transmitter, it must also face the onslaught of all the other RF at the site. Two problems are likely to develop. The RF fields in and around the site may be so strong that they simply overload the front end of the receiver. A more insidious problem exists when fundamental and harmonic signals from the various transmitting devices mix (heterodyne) somewhere outside the repeater producing a resultant signal on the frequency the receiver is tuned to. This problem is called intermodulation distortion, or simply intermod.

With simple front-end overload, cavities often can be used to eliminate the problem. Instead of placing the cavity in series with the transmission line, it is placed in parallel. Since it is a series resonant device, it now acts as a very sharp notch filter. Thus, a cavity across the transmission line can sharply attenuate an interfering signal (Fig 20).

The front end of an FM receiver can be further fortified with the addition of helical resonators, if they are not already installed. Helical resonators can be built exhibiting  $Q$ s of 1000 or more at VHF and UHF. Because the  $Q$  is so high, it is possible to design front-end tuned circuits using helical resonators that provide a high degree of selectivity with low insertion loss. Various coupling designs may be used. The walls

of the cavity should be seamless, if possible. Receivers for the commercial services often come with six or more resonators constructed in a cast-aluminum housing. Such design and construction practices provide for "bulletproof" front ends, but they are expensive to produce. Some of the equipment manufactured for the Amateur Service uses less expensive—and less effective—designs.

If the intermod signal is being generated somewhere other than the front end of the repeater receiver, cavities and bulletproof front ends will be of no use in combating it (Fig 21). The first step is to determine the frequency of various transmitters operating at or near the site. Remember, broadcast radio and TV signals, which may be very powerful at your site, can beat with other signals to produce the intermod. Once the likely culprits have been identified it will be necessary to work with the technicians who service the equipment causing the problem. (See May 1983 *QST*, pp 17-18, for a primer on intermod.)

At this stage of the game, human relations skills may be more essential than engineering skills in resolving the problem. Some form of filtering applied to one or more of the offending pieces of equipment will be necessary to clean up the problem. Although technically and legally it may be the responsibility of the owners of this equipment to pay for the filters and their installation, it may be difficult or impossible to force them to take action. In such cases, the expedient solution is to provide the filtering for them.

### Antennas, Gain, ERP and HAAT

The most commonly used type antenna for repeater service is the vertically polarized omnidirectional gain antenna. (*The ARRL Antenna Book* contains a discussion of polarization and patterns.) In short, an antenna does not create or amplify power or energy, but it does concentrate it in some directions at the expense of others. The ideal repeater antenna will have most of its energy in the vertical plane concentrated near the horizon. If you conceive of the antenna as being represented by a pencil standing on its end on a table top, and of the radiation from the antenna as being a doughnut surrounding the pencil, increasing the gain toward the horizon is accomplished by flattening out the doughnut (Fig 22). The doughnut has not been "created" or "amplified;" it merely has been rearranged or concentrated.

Sales literature for antennas from reputable manufacturers usually express gain figures as compared to either an isotropic radiator or to a half-wavelength dipole. The isotropic radiator is imaginary, and thus the gain figures can only be calculated instead of measured. An isotropic radiator is a single point in space and radiates energy in a pattern that can be visualized as a sphere. The dipole, of

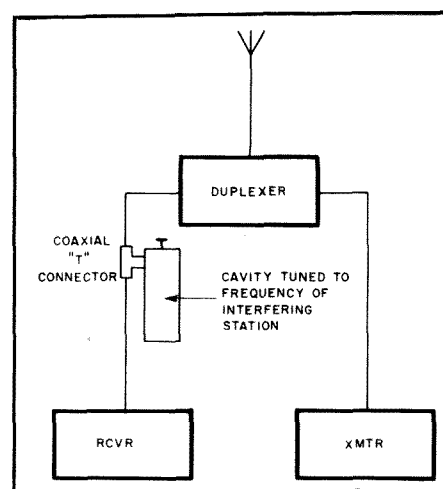

Fig 20—Single cavity used to notch out interfering signal.

Fig 21—Pictorial diagram representing creation of intermod signal on repeater input frequency, when energy from the channel 8 visual carrier combines with output signal of the Rocky Road Fuel Oil Co. transmitter in the output stage of the transmitter ( $181.25 \text{ MHz} - 36.4 \text{ MHz} = 144.85 \text{ MHz}$ ). Some form of filtering must be applied to the Rocky Road transmitter to eliminate the intermod.

Fig 22—At A, radiation nearly equal in all directions from the  $\frac{1}{4}$ -wavelength vertical antenna. At B, the gain antenna has concentrated the signal toward the horizon at the expense of high angle radiation.

course, is a real antenna producing the familiar doughnut pattern.

In practice, measurements on the antenna being tested usually are compared with measurements made on a half-wavelength dipole. The latter should be at the same height and have the same polarization as the antenna under test, and the reference field—that from the half-wavelength dipole comparison antenna—should be measured in the most favored direction of the dipole. The data can be obtained either by measuring the field strengths produced at the same distance from both antennas when the same power is supplied to each, or by measuring the power required in each antenna to produce the same field strength at the same distance.

A half-wavelength dipole has a theoretical gain of 2.14 dB over an isotropic radiator. Thus the gain of an actual antenna over the dipole can be referenced to the isotropic by adding 2.14 dB to the measured gain. If the gain is expressed over an isotropic antenna, it can be referenced to a half-wavelength dipole by subtracting 2.14 dB. With respect to FCC rules, antenna gain is based on a reference half-wavelength dipole. If an antenna is rated at 9-dB gain over as isotropic radiator, the gain of the antenna by FCC standards is  $9 - 2.14$ , or 6.86 dB.

Repeater output power is usually specified in terms of effective radiated power (ERP), which is a term not widely used in most other Amateur Radio activities. Commercial services used ERP for many years before it came to be used in the Amateur Service.

It is not difficult to determine ERP for a given installation. First you need to know the exact power output from the transmitter—usually measured with a calibrated wattmeter. Next, deduct from this figure any losses caused by the duplexer. If this figure is not known, it is acceptable to measure the power coming out of the duplexer. Subtract the power lost in the feed line. This figure can be obtained from a table of coaxial cable characteristics, such as those found in Chapter 16. This gives the power reaching the feed point of the antenna. Combine this figure with the gain of the antenna; the result is the effective radiated power. In short, ERP is a measure of the power aimed in a direction that should be useful to the system.

For instance, assume the power output of a repeater transmitter is 200 watts. The duplexer has a loss of 3 dB. This means that 100 watts of power is reaching the feed line input. The feed line also has a loss of 3 dB, resulting in 50 watts reaching the antenna input. The antenna has a gain of 13 dB, which means the ERP of the repeater station is 1000 watts. (Note: These figures were chosen to simplify computation.)

Another important repeater specification is the *height above average terrain* (HAAT). HAAT is a geomathematical construct that means what it sounds like.

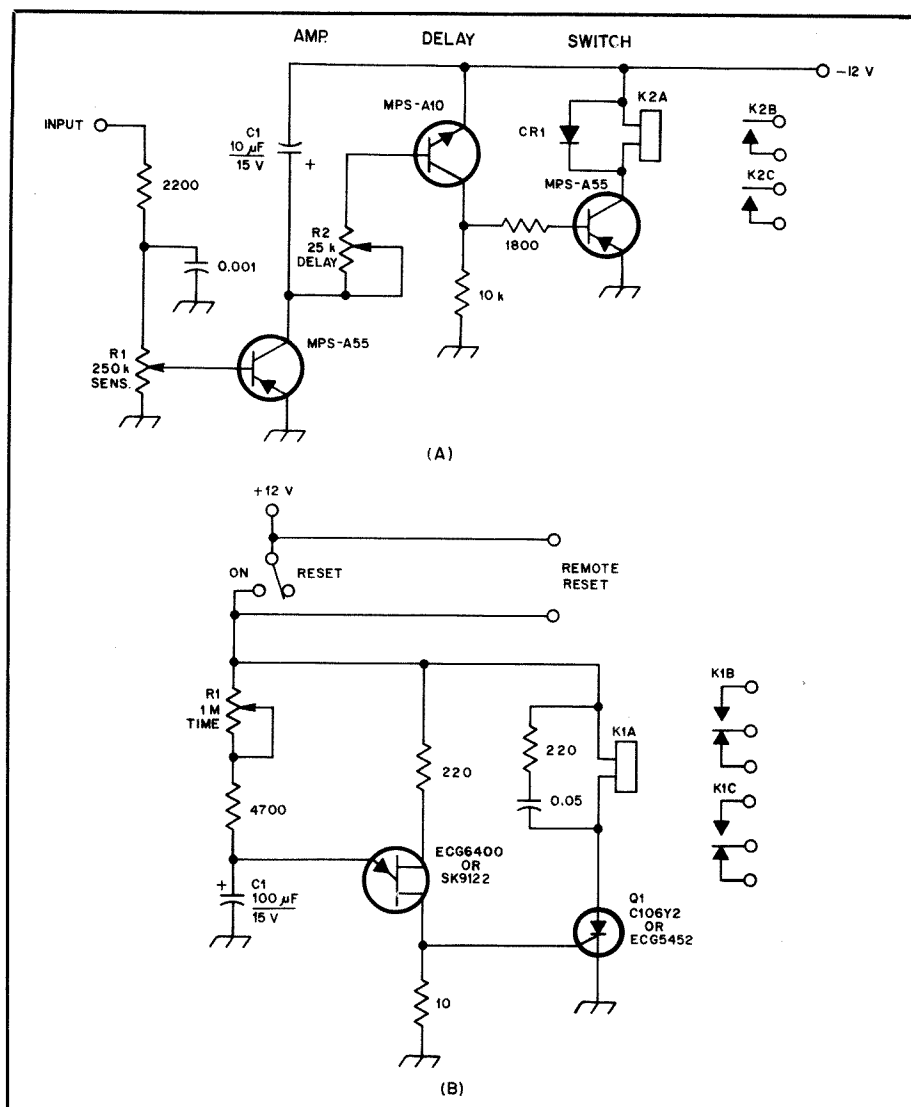

Fig 23—Elementary COR circuits.

To determine HAAT, follow this procedure: On a US Geological Survey map having a scale of 1:250,000, lay out eight evenly spaced radials (0, 45, 90, 135, 180, 225, 270 and 315 degrees) extending from the transmitting site to a distance of 10 miles. By reference to the map contour lines, establish the ground elevation above mean sea level (AMSL) at 2, 4, 6, 8 and 10 miles from the antenna structure along each radial. If no elevation figure or contour line exists for any particular point, use the nearest contour line elevation available. Now, compute the height of average terrain by adding the individual elevations at each of the 40 points and dividing that sum by 40. Thus the HAAT is the height AMSL of the transmitting antenna's center of radiation minus the height of average terrain.

#### Basic Repeater Controls

For a repeater to operate automatically, some circuit must determine when to turn the transmitter on and off—it's against FCC rules (and common sense) to simply let the transmitter stay on the air con-

tinuously without a signal to be retransmitted. The circuit that handles this function is usually called a carrier-operated relay or COR (Fig 23). Other names such as squelch relay, squelch-operated relay, squelch gate or signal-operated relay may be used. The name is not important, but the function is. In fact, in modern solid-state equipment, the COR function is often accomplished without benefit of a relay in the circuit, but the name persists.

An early COR used a portion of the limiter grid voltage in the receiver to drive a dc amplifier. The dc amplifier, sometimes called a relay driver, activated the relay, thereby controlling the transmitter. Such a simple system has some flaws, a major one being that anything causing limiter grid current to flow will activate the COR. Atmospheric noise, white noise, off-channel signals, a change in temperature or a change in voltage may cause such a simple system to turn the transmitter on.

A more reliable COR is one that is derived from the high-frequency noise component in the discriminator passband. This is the hissing sound you hear when an

Fig 24—The function of hysteresis in a COR circuit. The upper line represents variations in the signal strength, while the lower line represents the squelch action. Notice that it takes a stronger signal to open the squelch than it does to keep it open.

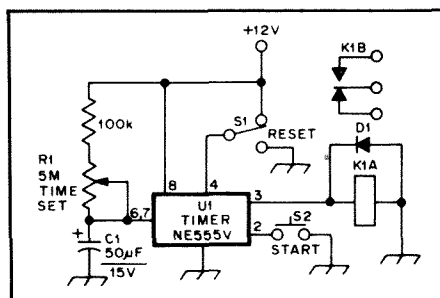

Fig 25—Elementary timer circuit using 555 IC. S1 and S2 should be parallel with the corresponding elements of the COR to provide start and reset functions.

FM receiver squelch is open but no carrier is present. A carrier “quiets” the receiver, causing the noise to disappear. Depending on the receiver design, this noise band may extend well beyond the range of human hearing. Any such ultrasonic component will also be quieted by a carrier. Sophisticated squelch circuits detect and act on the quieting of this ultrasonic component. Such squelch circuits are more reliable than those based on grid (or collector) current.

A second feature that improves the COR is hysteresis in the squelch circuit. Hysteresis is the property wherein it takes a stronger signal to open the squelch than it takes to keep it open (Fig 24). This is advantageous when a mobile station is on the fringe of the service area. Without this feature, the squelch will open and close rapidly as the signal level fluctuates. The result is audio that clips in and out, which is usually rather frustrating to operators attempting to listen.

Another improvement to the basic COR is to add a circuit that produces a “hang-time.” Hangtime is simply the amount of time that the COR holds the transmitter on after the signal has disappeared from the receiver input. Such a feature prevents wear and tear on the equipment, particularly relays, if any are involved. It is also desirable during periods when the received signal is fading or “picket fencing.”

A VOX circuit, similar to those commonly used in HF SSB equipment, can be connected to the COR control. To activate the transmitter, a voice or audio tone, as well as a carrier, must be received. This prevents the transmitter from being held on for a long time by an unmodulated carrier.

FCC rules require that some means be incorporated for disabling the transmitter if a carrier holds the repeater receiver squelch open for more than three minutes. The circuit that performs this function is often referred to as the time-out timer. In the early days, time-out timers were based on the electromechanical devices or simple RC circuits. Such procedures are archaic by today's standards.

One inexpensive modern approach is to use a 555 timer IC (Fig 25). The 555 contains two voltage comparators, a flip-flop and an output stage. The chief drawback is that large-value capacitors are required for durations in excess of a few seconds. The leakage of such capacitors often degrades the precision and accuracy of such circuits. Also, as the components age, some adjustments to the circuit will likely be necessary.

A second inexpensive solution is to use digital clock and counter circuitry. The common problems with the 555-type circuits are overcome at the cost of increased component count and design complexity. A simple digital timer circuit is shown in Fig 26. An MM5369 counter-timer IC is used to provide a stable 60-Hz reference signal. The 60-Hz signal is divided by 3600 by U1-U4, providing a 1-minute clock (1/60 Hz) at the input of U5. The last divide-by-ten counter (U5) can provide outputs at one-minute intervals from one minute to ten minutes. The selected output is wrapped around to the ENABLE input of the counter; this holds the count when the selected output is reached. As long as the RESET input of U5 is open, the counter is disabled. This input must be LOW to allow the timer to run. This circuit can be used either as a three-minute time-out timer or as part of a Morse or voice identifier circuit (See Fig 27).

More important than the particular circuit is the functioning of the timer. Rules require the timer to time out no longer than three minutes after the signal appears and remains on frequency. Some means must be provided for the timer to reset automatically during the course of a QSO. For the convenience of the users, most operators design the time-out timer to reset on the disappearance of a received carrier at the repeater receiver. One problem with this approach is that intermittent noise at the repeater input can cause the time-out timer to reset before the transmitter carrier drops. The result is that the transmitter can stay on indefinitely. This problem can be solved by resetting the time-out timer only after the transmitter carrier drops, but this method is often annoying to users.

Courtesy tones are frequently added to

the timer circuit. These short “beeps” notify the user that the timer has been reset and that it is okay to begin transmitting. Sometimes a tone with a slightly different pitch is used to inform listeners that the transmitting station has ceased transmitting. Although such devices have the beneficial effect of encouraging courtesy in a Pavlovian sort of way, an operator who neglects careful analysis of tone and timing when he installs them on his repeater runs the risk of having his repeater sound like a “Pong” game.

## Identification

Another function required by FCC rules is that the repeater be identified every ten minutes during use. Some of the first “IDer” circuits used electromechanical devices to key Morse code into the repeater transmitter. These archaic mechanical monsters required frequent adjustment. Few repeater operators lamented their passing.

A simple solid-state identifier circuit is shown in Fig 27. An RS flip-flop (U1A and U1B) latches the input COR signal. The flip-flop gates a divide-by-ten counter (U2) which counts one-minute (1/60 Hz) input signals from a divider circuit like the one shown in Fig 26. When the selected time is reached by the counter, the output goes high, resetting the RS flip-flop and a binary counter (U4). When the binary counter is reset, its clock (U3A) is allowed to run. The binary counter clocks the address lines of a memory chip (U5), and the data programmed into the EPROM appears at pin 9. This data is used to gate the tone oscillator (U3B) to produce the Morse code ID. When U4 reaches binary 10000000, its Q8 output is high, and this stops the U3A clock until the counter is again reset by U2.

Only the least-significant bit of each data word in the EPROM is used in this application. The ID is programmed into the EPROM by burning a one for tone on and a zero for tone off. Three ones in a row makes a dash, and three zeros makes a character space. Six or seven zeros in a row can be used as a word space. Programming for “de AA2Z” is shown in Fig 28. The remaining seven bits in the data word are ignored.

The beauty of this approach is its flexibility. Other IDs or messages could be programmed into the EPROM, using the seven unused data bits. A simple logic circuit could then be used to select which bit of the data word is used to gate the tone oscillator. Other circuit modifications will probably be obvious to more advanced builders.

Ideally, an identifier circuit should incorporate means for the operator to vary the speed, pitch and amplitude of the Morse code being sent. FCC rules require that the code be sent at a speed no greater than 20 WPM and that it have sufficient deviation to be understandable when a voice is simultaneously being transmitted.

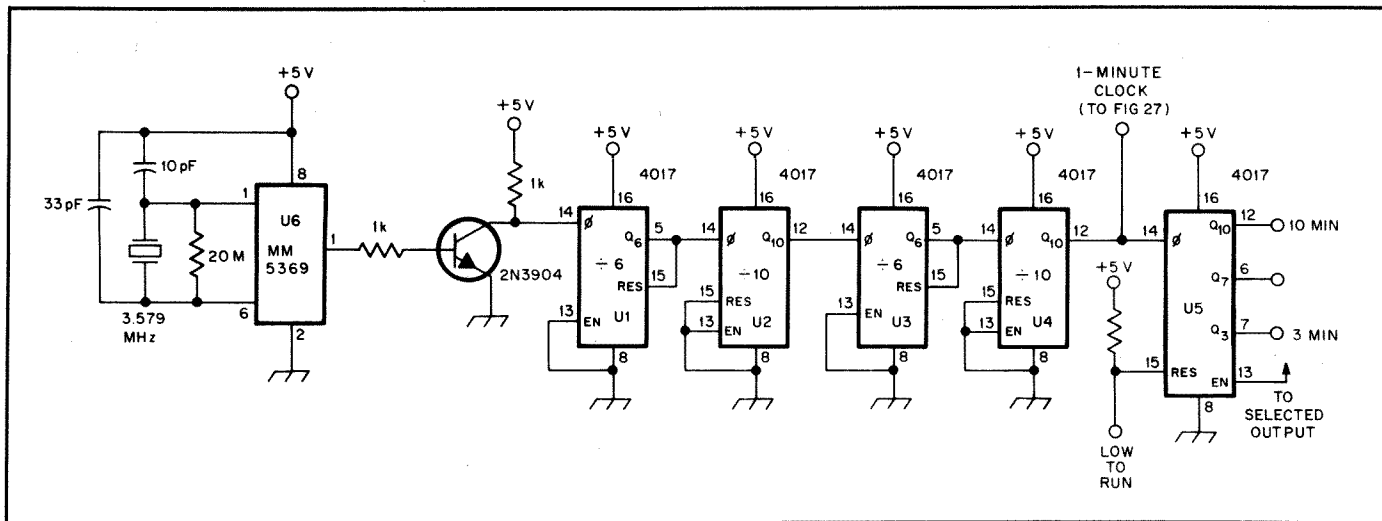

Fig 26—A simple digital timer circuit. Ten output lines are provided by the last 4017 IC; this allows the user to select an output at one-minute intervals from one to ten minutes. The three-minute output is useful for time-out timers, while the seven-, nine- or ten-minute outputs could be used to time an identifier circuit.

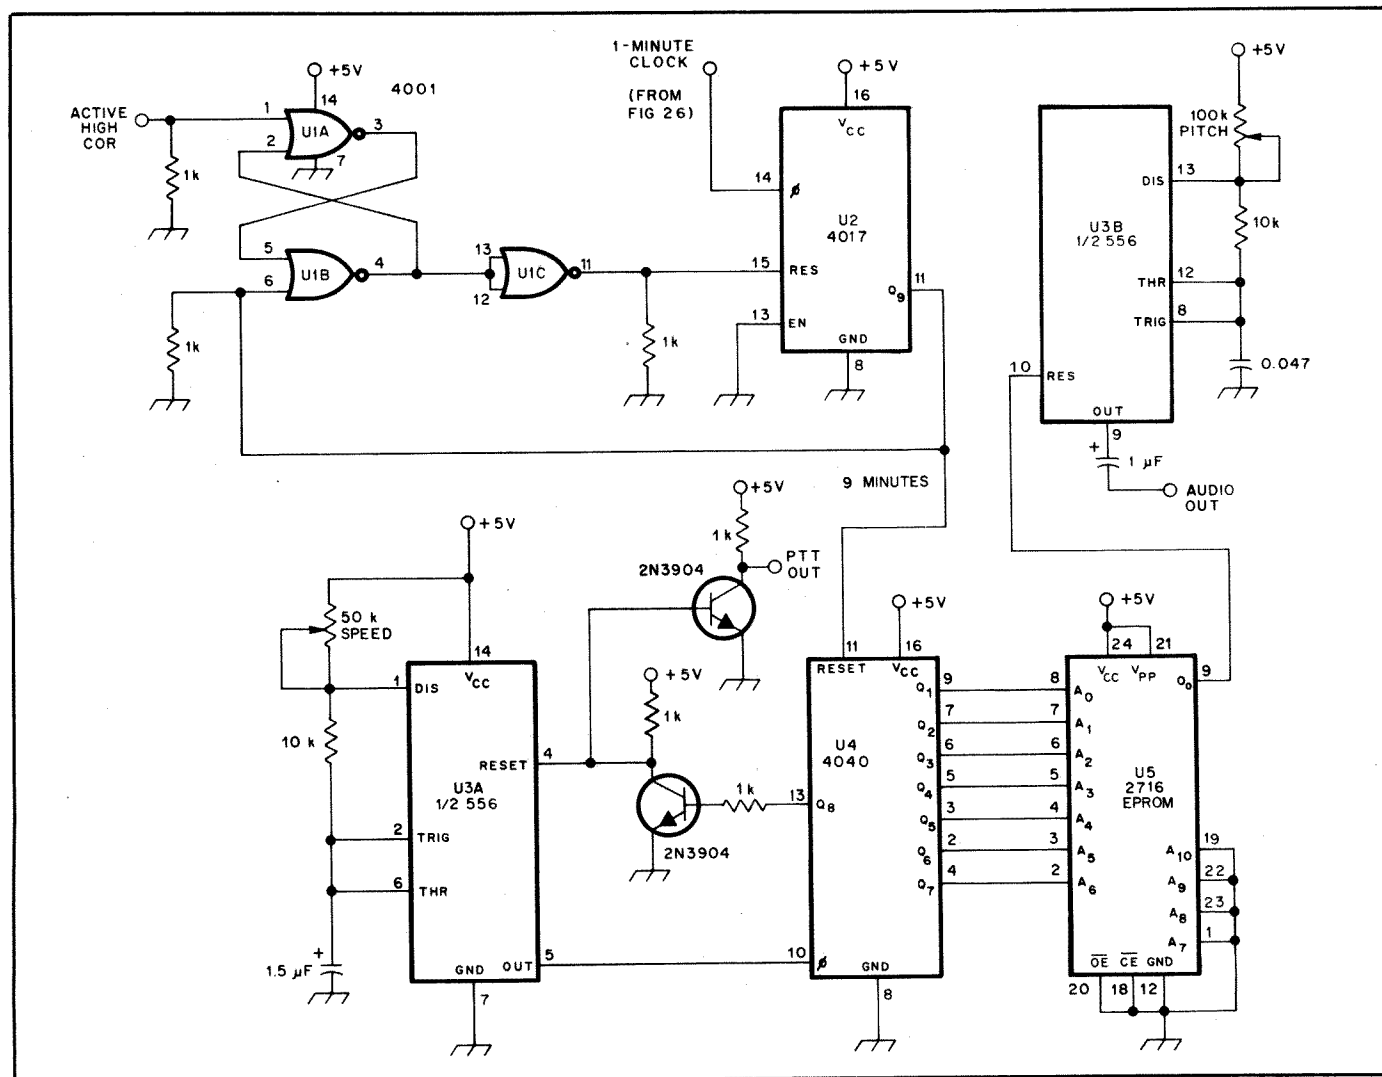

Fig 27—A simple Morse code identifier circuit. See text for details.

**Table 1**  
**Touch-Tone Audio Frequencies**

Low Tone (Hz)	High Tone			
	1209 Hz	1336 Hz	1477 Hz	1633 Hz

852	7	8	9	I
941	*	0	#	P

possible numbers and symbols.

When originally developed by Bell Labs, DTMF encoders and decoders were constructed using precision inductors and capacitors. For audio frequencies, such components are rather bulky, but they are capable of close tolerances and good stability over long periods of time.

In the last few years, advances in solid-state technology have produced single-IC encoders that derive the audio tones digitally from crystal controlled oscillators. These encoders are much smaller than their inductor-capacitor counterparts, which makes them ideal for use with miniaturized equipment, such as hand-held transceivers. Several companies manufacture complete pads that require only mounting and connecting three wires. As an alternative, the amateur can obtain the IC and custom design his own encoder. One minor drawback is that these encoders are slightly more susceptible to RF interference than the inductor-capacitor types.

Surplus telephone company DTMF decoders have never been widely available, probably because the telephone system requires far fewer of them than it does of the encoders. But they are available for those who wish to invest the time and effort involved in locating them. As with the encoders, these inductor-capacitor decoders are durable and provide reliable service.

When the 567 tone-decoder IC was introduced it received widespread attention in the Amateur Radio community and quickly became the nucleus of a number of DTMF decoders. As with many other popular ICs from that period, mass production and mass marketing has brought the consumer price down to under \$1 per IC from many surplus dealers. The 567 was readily available, easy to work with and required no special components or techniques.

Most repeater operators soon learned that there is another side to decoders built with 567s. Resistors used to set the decoder operating frequency often change value as they age or as temperature or humidity change. The result is that the operator must frequently "fine tune" the decoder. These decoders have a tendency to "false"—indicate the presence of a signal that really is not there.

DTMF tone-decoder ICs have improved dramatically in the last few years. Where eight 567 ICs are required to decode all 16 digits, new devices require only one IC to accomplish this task. The Silicon System

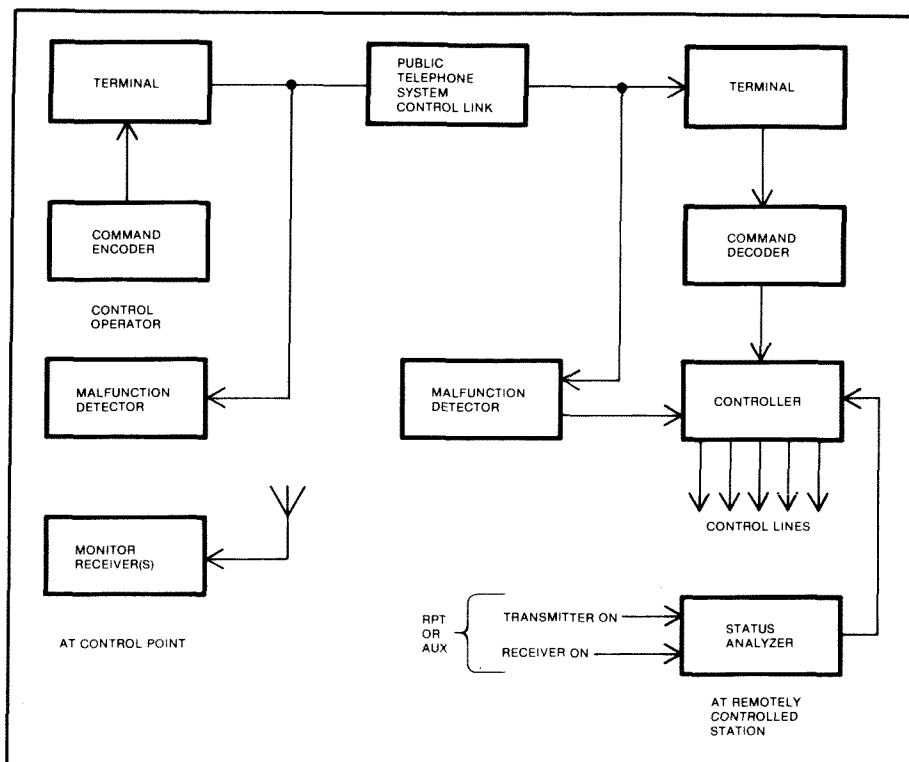

Fig 30—Block diagram of a public telephone system control link.

SSI204 14-pin single-chip DTMF decoder is typical of these new devices. A complete one-of-sixteen DTMF decoder can be built with the addition of only a few external components. One circuit using this device is shown in Chapter 34. Any repeater operator considering a DTMF decoder would be well advised to opt for one of the modern single-IC decoders over the 567 types.

Once the DTMF decoder is functioning, the repeater operator may install a number of options for his convenience in controlling the repeater and for that of the users. Remote sensors to provide information about the state and condition of various circuits can be included. Tape recorders may be connected to provide various forms of bulletins and general-interest information. The repeater may be linked to transmitters and receivers on other bands (crossband links). One thing that may not be done legally is to connect a receiver tuned to another radio service frequency—such as a NOAA weather station—to the repeater transmitter. The automatic retransmission of signals from other radio services by an Amateur Radio station is illegal. The one exception to this rule is that the FCC has granted a permanent waiver for amateurs to retransmit NASA space shuttle signals during shuttle missions.

#### Controlling the Repeater

As with any amateur station, a station in repeater operation must be under the control of a licensed amateur called the

control operator. He and the station licensee are both responsible for the transmissions of the repeater. There are three kinds of control according to FCC thinking—local, remote and automatic.

Local control means that the control operator is on duty at a control point, which is the same location as the transmitter. The control point is defined in the rules as the operating position of an Amateur Radio station where the control operator function is performed.

Remote control means that the control operator is on duty at a control point located at a place other than the transmitter site. Remote control takes place over a control link, such as telephone line or radio link. A phone line (Fig 30) can be used in the normal manner, with the operator dialing an unlisted number that rings at the repeater site. Some device at the repeater site must answer the ring. He then sends a signal which either activates or deactivates the repeater functions. Another kind of control involves a dedicated line, which is constantly connected to the repeater. Again some signal must pass from the control operator enabling or disabling a function.

Remote control over a radio link (Fig 31) is possible by transmitting command signals to a special receiver interfaced with the repeater to accomplish the control function. (DTMF encoders and decoders are most often used for these signaling functions.) The repeater cannot be legally controlled on the repeater receive (input) frequency. A signal to control any Amateur Radio station—including repeater stations

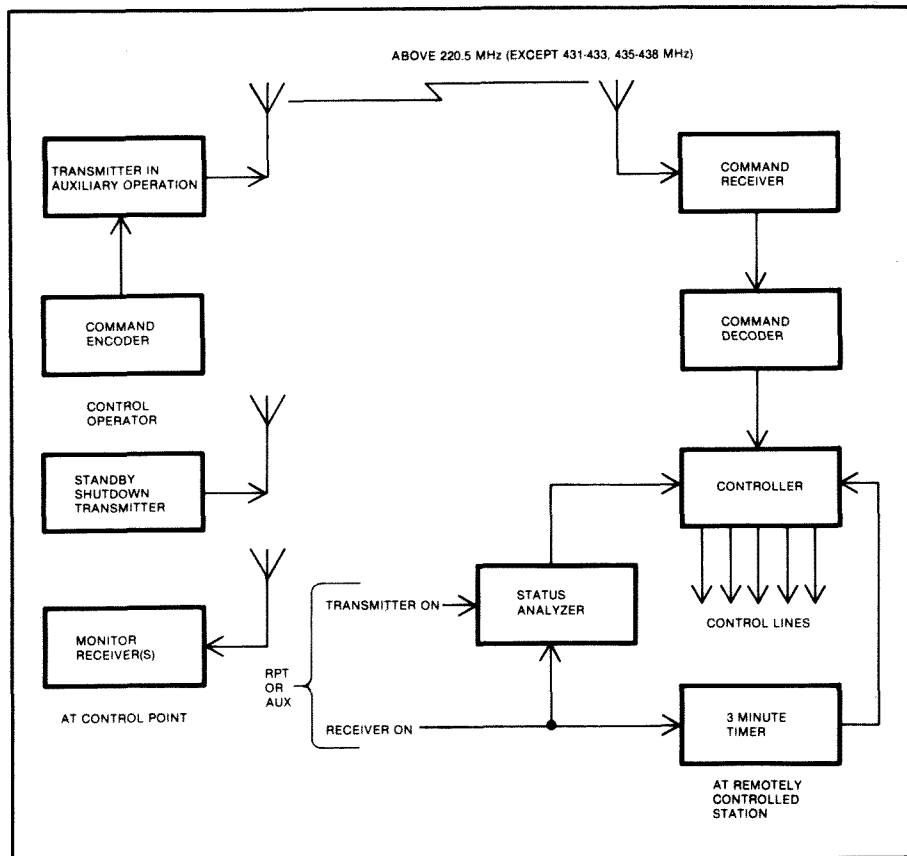

Fig 31—Block diagram of an RF control link.

—must be transmitted on a frequency where auxiliary operation (radiocommunication for the purpose of remotely controlling another Amateur Radio station) is permitted: 220.5 MHz and above, except 431 to 433 and 435 to 438 MHz.

Automatic control means that the repeater is controlling itself, without a control operator being at a control point, local or remote. Under such operating conditions third-party traffic is prohibited, and control features must be built in to ensure that the repeater transmitter will be taken off the air if the repeater malfunctions. If such safeguards are built in, locally or remotely controlled repeaters may be placed in automatic control for short periods of time when it is not convenient to have a control operator on duty—such as the wee hours of the morning. Once the control operator is back on duty, the repeater is no longer considered under automatic control, and functions that permit third-party traffic are again legal.

#### Autopatch

Autopatch is a function that allows the repeater to be connected to the commercial telephone lines, thus permitting phone calls to be placed by repeater users. This is the most common form of third-party traffic found in repeater usage. Most repeaters use DTMF signaling to accomplish this function. Usually the user transmits an access

code, which enables the patch. He then stops transmitting and waits to hear the dial tone. Once he hears the tone, he transmits again and dials the number using his DTMF encoder. Audio from the repeater receiver is passed on to the phone line, and the telephone switching office detects the tones originated in the user's encoder as it would tones coming from a standard telephone.

Noise from the radio link may interfere with the switching office's ability to decode the tones. Distortion in the radio link and the interface may force the tones outside the tolerances in the switching equipment. In such simple autopatch designs, we often find cases where A's encoder always "works," and B's doesn't. The solution is to provide circuitry at the repeater that decodes and stores the number being encoded by the user (Fig 32). The repeater then uses an onboard encoder to dial the number into the telephone system. In areas having only pulse dialing available, it will be necessary to use a tone-to-pulse converter.

Care should be taken not to design an autopatch that will encourage abuse. Calls should be limited to short durations. The patch should be disabled when a control operator is not on duty. Calls that might be construed as business in nature should be avoided. Devices can be added that automatically lock out long-distance dialing. Autodialer features can be added, that

automatically dial prestored emergency numbers when the user dials a short command (for example, \*0 to connect to the State Police Department).

#### Microprocessors As Controllers

Properly interfaced, microprocessors make marvelous repeater controllers, because the programming can be tailored to suit the needs and desires of the operator. Functions that might have required a vast array of logic ICs can be easily handled by the microprocessor (and a few support ICs). Success or failure depends largely on the software.

If the operator wants to change a repeater function, he has but to change the programming. Where discrete logic controllers encourage a set-it-and-forget-it attitude with respect to repeater control parameters, the microprocessor encourages the "fine tuning" instinct.

The programming must be stored in some kind of memory device. If the programming is stored in ROM or PROM, then changing the software is a relatively involved procedure. A new IC must be "burned" each time changes are to be made. If the programming is to be stored in RAM, it is much easier to make changes. In fact, it is quite possible to reprogram the controller remotely in such a system. The drawback here is that a nearby lightning strike or a power-line glitch may reprogram the controller, also.

Advanced Computer Controls, which manufactures the ACC RC-850 computer controller, has gotten around these problems by using three different forms of memory in their controller. The basic operating system of the microprocessor is stored in EPROMs. This programming is permanent; ACC does from time to time update and add features by exchanging new EPROMs for old. When power is removed from the controller, this basic operating programming is there to "reboot" the microprocessor when power is restored.

A second form of memory found in the RC-850 is RAM "scratchpad," which permits the operators to make minor changes to optimize the repeater functions for the particular application. Any or all of dozens of various parameters can be changed locally or remotely by means of DTMF commands. Any programming stored in this scratchpad will be lost if power is removed from the system. This might be annoying if it happened often.

ACC gets around this potential pitfall by adding a third type of memory, Electrically Erasable Programmable Read Only Memories (EEPROMs). Like PROMs and EPROMs, EEPROMs retain memory when removed from a power source. Identifier messages, "permanent" changes in operating parameters, and such are programmed into the EEPROMs by means of the onboard EEPROM programmer. Thus, if the repeater system loses power, the operator

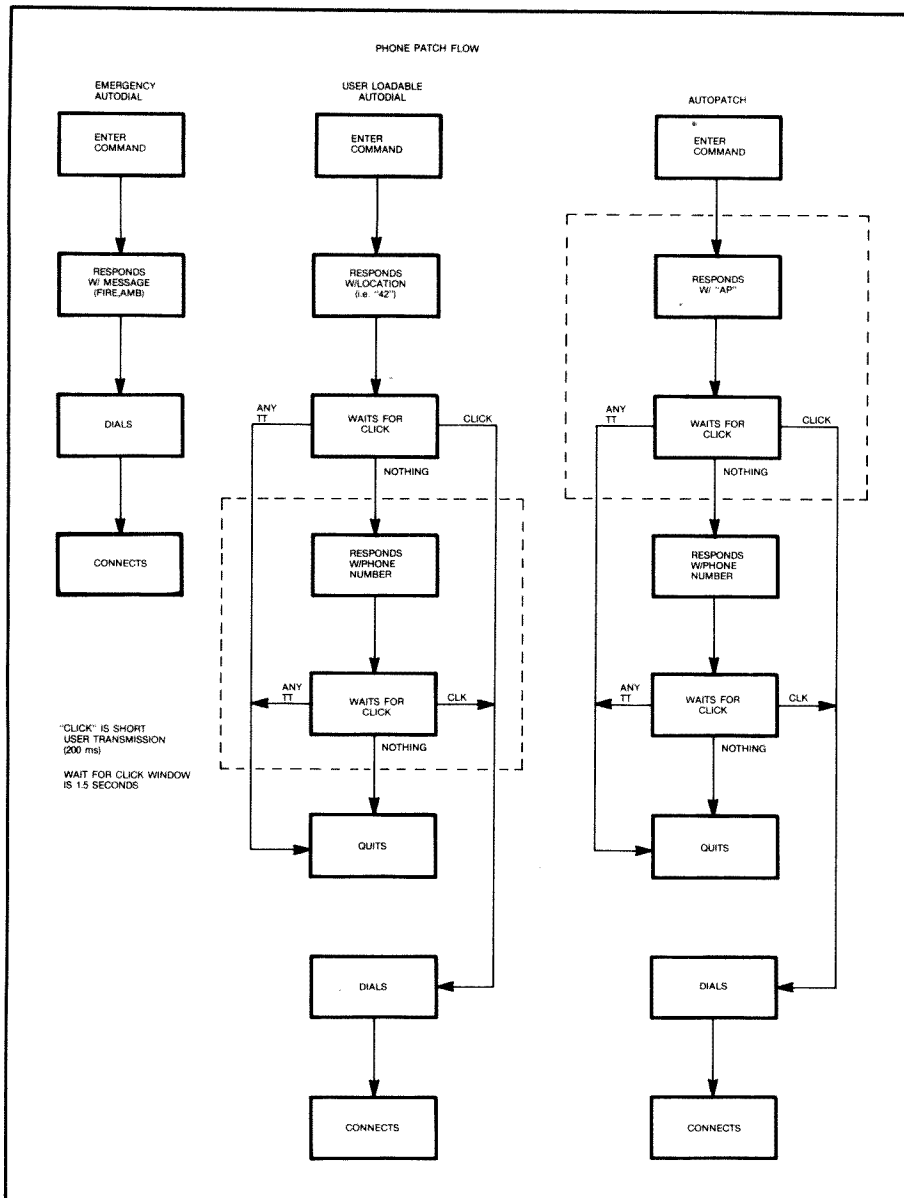

Fig 32—Flow sequence for ACC's RC-850 autopatch. It is actually three separate patches in one. The emergency autodialer rapidly dials stored emergency numbers when accessed. Both the user loadable autodialer and the standard autopatch provide the user with a great deal of control. All tones are regenerated by the RC-850.

can rest assured that the repeater will function "normally" when it returns to the air. Such an elaborate system provides the repeater operator with tremendous versatility without the risk of frequent major reprogramming efforts. The drawbacks to such a system are primarily ones of cost and increased complexity.

Home computers offer repeater operators another avenue for developing flexible computerized controllers. The same problems with memory storage exist for these devices as for the custom-designed microprocessor controllers. One way around this is to add a disc drive to the system. Of course, the functioning of the controller will largely depend on the creativity and programming skill of the designer/operator.

## CTCSS

Continuous Tone Coded Squelch System (CTCSS) is probably one of the most controversial features to be found in modern FM and repeater equipment. Often referred to by Motorola's trademark, "PL," CTCSS, like many other features and procedures found in Amateur Radio FM and repeater communications, was adapted to the Amateur Radio Service after being developed for the commercial services. Its earliest use in the Amateur Radio Service was to keep uninvited stations from using private closed repeaters. In the commercial services, it is primarily used to minimize co-channel interference. As the Amateur Radio bands have become more crowded, CTCSS has

Table 2

## EIA Standard Subaudible Tone Frequencies

Code†	Freq. (Hz)	Code†	Freq. (Hz)
XZ	67.0	4Z	136.5
WZ	69.3	4A	141.3
XA	71.9	4B	146.2

3A	127.3	M7	250.3
3B	131.8	OZ	254.1

†Motorola designator

gained popularity as a means of minimizing co-channel interference, also. Nonetheless, many amateurs reject it without giving consideration to its merits.

A CTCSS tone is any one of the standard tones (Table 2) established by the EIA that range from 67.0 to 254.1 Hz. This group is generally referred to as the subaudible tone group—subaudible because the tones are set at a very low deviation (usually around 500 Hz in a 5-kHz system) and because the corresponding receiver generally has a high-pass filter installed in the audio chain to prevent the tone from reaching the speaker.

At the transmitter end, the tone is activated when the transmitter begins transmitting and stays on for the duration of the transmission. The receiver is equipped with a decoder that is set to recognize the presence of that particular tone. The presence or absence of the tone operates the squelch (COR) function instead of the standard squelch. In a typical commercial installation, the operators at the receiver and transmitter have switches that allow them to choose either CTCSS or standard squelch operation.

Some amateur groups have shown more creativity in the use of CTCSS in their repeater systems. For instance, one group has both squelch systems wired in parallel on their repeater receiver, but the standard squelch is set to require a signal strength 20 dB greater than that of the CTCSS to operate. Thus, no one is excluded from the repeater if he has a strong signal. Weak signals must have the right tone, though. Frequent users with low-powered equipment or those who operate from the fringes have installed CTCSS encoders. Transient mobile stations can access the repeater. Basically, the only signals excluded are those coming from great distances away during marginal band openings.

In the early days, CTCSS encoders and decoders used special circuits that required an expensive “reed”—an electromechanical vibrator much like a tuning fork—for each individual tone. Besides being expensive, these devices are bulky by today’s standards. Several manufacturers make miniature encoders and decoders that use digital techniques and IC technology to reduce the size to a point that they will fit in a small hand-held transceiver. The user programs the desired tone by setting switches or soldering jumpers. The basic encoder units cost approximately \$30. These encoders can hardly be considered a financial burden for most hams.

Several other systems can be employed to minimize co-channel interference. In digital CTCSS, the sine-wave tone is replaced by a 21-bit digital character string. Tone-burst requires a short (approximately 200 millisecond) audible tone to be sent at

the beginning of each transmission or each series of transmissions. A DTMF code can be required to set a timer that will automatically turn the repeater transmitter off at the end of a specified time. Hams often call this “Touch Tone Up.” Like CTCSS, these systems serve to limit the on-channel signals that will turn on the transmitter.

### Coordination, Standards and Cooperation

Early efforts to coordinate repeaters were confined to limited geographical areas around major metropolitan areas. The coordinating bodies that grew out of these efforts evolved differently from one place to another. No national group was involved, and as a result, little communication or standardization existed from one group to the next.

But the popularity of repeaters mushroomed, and the need for national standards became obvious. At this point the ARRL Board of Directors stepped in

and began consulting with representative groups and individuals around the country. The band plans found in the current edition of *The ARRL Repeater Directory* are the result of this ongoing effort. Some regional variation will be found for all except the 220-MHz band plan, which is followed uniformly around the country.

The FCC has begun to recognize these band plans and the local coordinating bodies in administrative decisions. Although not specifically endorsed in Part 97, these band plans and coordinating decisions carry the weight of law. Anyone desiring to place a repeater station on the air must get prior authorization from the local coordinator and follow the band plans, or run the risk of incurring the wrath of the FCC if interference to coordinated activity occurs. Consult the latest edition of *The ARRL Repeater Directory* for the coordinator in your area.

## Linear Translators and Transponders

A linear translator is similar to a repeater in many ways. Each is a combination of a receiver and a transmitter that is used to extend the range of mobile, portable and fixed stations. A typical FM voice repeater receives on a single frequency or channel and retransmits what it receives on another channel. By contrast, a typical translator receiver passband is wide enough to include many channels. Received signals are amplified, shifted to a new frequency range and retransmitted by the translator. Fig 33 shows block diagrams for a simple voice repeater and a simple translator.

By comparing block diagrams, you can see that the major hardware difference between a repeater and a translator is signal detection. In a repeater, the signal is reduced to baseband (audio) before it is retransmitted. In a translator, signals in the passband are moved to an IF for amplification and retransmission.

### A Multi-Mode Machine

Operationally, the contrast is much greater. An FM voice repeater is a one signal, one mode input and one signal, one mode output device. A translator can receive several signals at once and convert (or translate) them to a new range. Further, a linear translator can be thought of as a multi-mode repeater. It is said of computers, “garbage in—garbage out.” In a similar manner, whatever goes into a linear translator is what comes out. A linear translator can be used for AM, SSB, ACSB, FM, SSTV and CW—either single or mixed modes and in any combination.

### Translator Applications

For a variety of reasons, linear trans-

lators have not been used very often in commercial applications. For that reason, there is not much surplus equipment and practical knowledge to be found. This is one area where the amateur community has taken the lead, especially in satellite communications.

Some work has been done with linear translators for terrestrial Amateur Radio communication, particularly on the West Coast of the USA. For most of us, however, the more familiar application is in the amateur communication satellites

(OSCARs and RS).

### Transponders

By convention, any linear translator that is installed in a satellite is called a transponder. Because of the universal availability of satellite communications to amateurs, the remainder of this chapter will refer to linear translators as transponders. For more information on communicating through satellites, see Chapter 23.

A transponder aboard a Phase II satellite may have 130-dB gain and an output power

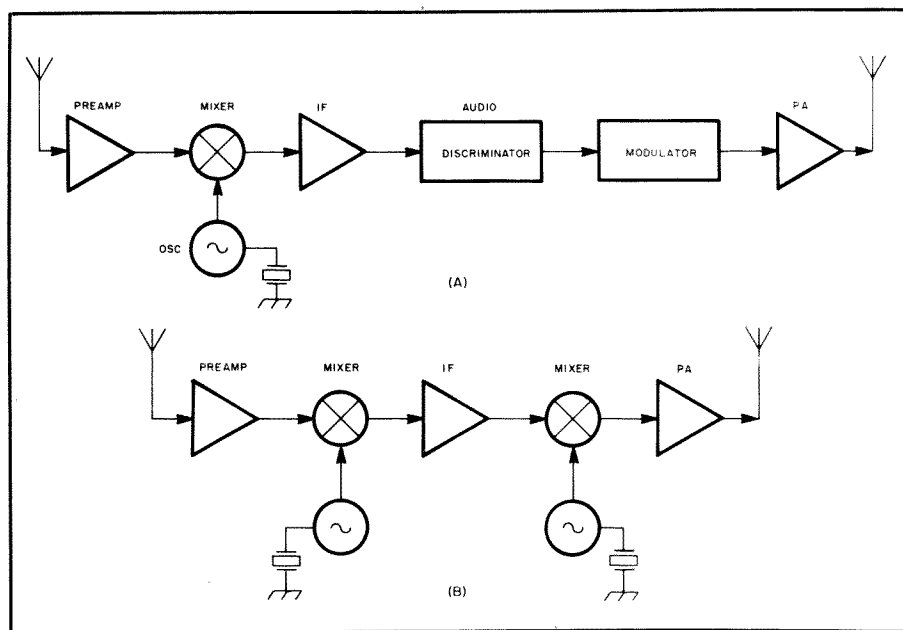

Fig 33—Block diagram of an FM voice repeater at A; of a linear translator at B.

of 1 watt. In that regard, it is much like a communications receiver. The main difference is that the receiver has an audio output and the transponder an RF output.

All stations using a transponder must share the limited power available. For that reason, high-duty-cycle modes such as RTTY and SSTV are limited to specific calling frequencies.

Repeaters are often referred to by their operating frequencies. For example, a .34/.94 machine receives on 146.34 MHz and transmits on 146.94 MHz. A different convention applies to transponders: The input band is given, followed by the corresponding output band. For example, a 2-m/10-m transponder would have an input passband centered near 146 MHz and an output passband centered near 29 MHz. Mostly, transponders are identified by mode—not mode of transmission such as SSB or CW. Mode has an entirely different meaning in this case. The various frequency band combinations used for uplink and downlink are referred to as modes. See Table 3. For example, OSCAR 10 has Mode B and Mode L transponders.

A block diagram of a simple transponder is shown in Fig 34. For several reasons, transponders used aboard satellites are more complex than the one shown. Just as a receiver design provides band-pass filtering, image rejection, AGC and overall gain, a transponder design must meet similar considerations. For that reason, transponder designers use multiple-frequency conversions. A block diagram of the basic Mode-A transponder used on OSCAR 8 is shown in Fig 35.

**Inverting and Noninverting Transponders**

In any conversion stage, the LO may be above or below the incoming frequency. The LO frequencies in a single- or multi-conversion transponder may be chosen so that entering signals are inverted. That type design changes upper-sideband signals into lower-sideband (and vice versa), transposes relative mark-space placement in RTTY, and so on. When this scheme is used, the result is called an inverting transponder.

**Table 3**  
**Bands Used for Satellite Communications**

Mode	Uplink	Downlink
A	2 m	10 m
B	70 cm	2 m
J	2 m	70 cm
K	15 m	10 m
L	23 cm	70 cm
S	70 cm	13 cm
T	15 cm	2 cm

The major benefit of an inverting transponder is that Doppler shifts on the uplink and downlink are in opposite directions and will, to a limited extent, cancel. With the 146/29-MHz Mode A link combination, Doppler is not serious; transponders using this frequency combination are typically noninverting. Transponders using higher frequency combinations are usually inverting.

**Power and Bandwidth**

The power output, bandwidth and operating frequencies of a transponder must be compatible. When a transponder is fully loaded with equal-strength signals, each signal should provide an adequate signal-to-noise ratio at the ground.

Low-altitude (800-1500 km) satellites perform well with from 1 to 4 watts of PEP

at frequencies between 29 and 435 MHz, using a 100-kHz-wide transponder. More sophisticated, high-altitude (35,000 km) provide acceptable performance with 35 watts PEP using a 500-kHz-wide transponder downlink at 146 or 435 MHz. A gain budget for Phase III, Mode B can be found in Chapter 23.

**Dynamic Range**

Dynamic-range requirements for a transponder may appear to be less severe than for an HF receiver. An HF receiver will handle signals differing in level by as much as 100 dB. A low-altitude satellite will encounter signals in its passband differing by perhaps 40 dB. That, however, is only part of the story. The HF receiver filters out all but the desired signal before introducing most of the gain. All transponder users must be accommodated simultaneously—quite a different situation. In one sense, all stations share a single channel. Transponder gain can, therefore, be limited by the strongest signal in the passband.

When a strong station is driving the satellite transponder to full power output, stations more than 22 dB lower than that level will not be heard on the downlink. That is true even if the weaker stations are perfectly readable when the strong signal is not present! User stations must cooperate by using only the minimum power necessary for communication through the satellites.

# RF Power Amplifiers

**R**F power amplifiers present significant design challenges to the radio amateur. A power amplifier in an amateur station may be called upon to develop as much as 1500 watts of RF output power, the legal maximum in the United States. The voltages and currents needed to perform this feat are much higher than those found in other amateur equipment; the voltage and current levels are potentially lethal, in fact. Every component in an RF power amplifier must be carefully selected to endure these high electrical power levels without failing. Large quantities of heat are produced in the amplifier and have to be dissipated safely. Spurious signal generation must be minimized, not only for legal reasons, but also for sound neighbor relations. Every one of these challenges has to be overcome to produce a loud, clear signal from a safe and reliable amplifier.

### TYPES OF POWER AMPLIFIERS

Power amplifiers are categorized by their power level, intended frequencies of operation, device type, class of operation and circuit configuration. Within each of these categories there usually is a wide range of circuit options. Choosing from almost all the possibilities to arrive at a suitable combination is the entire concept of design.

#### Solid State versus Vacuum Tubes

Today, most items of commercially manufactured amateur equipment use solid-state devices exclusively. A few manufacturers still offer HF transceivers with tubes in the final transmitter output stage, but their popularity is dwindling. Using transistors exclusively offers the manufacturers several advantages:

1) Compact design — Even with their heat sinks, transistors are smaller than tubes, allowing smaller packages.

2) Power-supply simplification — Tube amplifiers need a multitude of voltages to function. The filament requires a low

voltage, high current supply; the plate circuit, several hundred volts. To meet these needs requires additional power supply components, beyond what the rest of the transceiver needs.

3) “No-tune-up” operation — By their nature transistors lend themselves to low impedance, broadband operation. Harmonic energy suppression can be performed by fixed-tuned, low-pass filters; these can be switched when changing bands. Tube amplifiers must be retuned on each band, and even for significant frequency movement within a band.

4) Long life — Nothing in a transistor wears out. Unless the device is defective, or damage is inflicted on it because its ratings are exceeded, transistors can last virtually forever. Vacuum tubes wear out as their filaments deteriorate from continued operation.

5) Manufacturing ease — Transistors are ideally suited for printed-circuit-board fabrication. The low voltages and low impedances encountered with transistor circuitry work very well on printed circuits (some circuits use the circuit board traces themselves as circuit elements); the high impedances found with vacuum tubes do not. The transistor’s physical size and shape also works well with printed circuits; the device can be soldered right to the board, an impossible task with a vacuum tube. These advantages in fabrication mean reduced manufacturing costs.

Based on all this reasoning, it seems there would be no place for vacuum tubes in a transistorized world. Transistors do have significant limitations, however, especially in a practical sense. Individual transistors available today cannot develop more than approximately 150-W output. Pairs of transistors or even pairs of pairs are usually employed in practical designs, even at the 100-W level. Present-day transistors just cannot withstand the high currents needed for high power levels, so the current must be divided among several devices. Beyond

the 300-W output level, somewhat exotic (at least for radio amateurs) techniques of power combination from multiple amplifiers must be used. Although this has been successfully done, it is an expensive proposition.<sup>1</sup> Even if one ignores the challenge of the RF portions of a high power transistor amplifier, there is the dc power supply to consider. A solid-state amplifier capable of delivering 1 kilowatt of RF output might require regulated 50 volts at more than 40 amperes. Developing that much current is a formidable and expensive task. These limitations considered, solid-state amplifiers are practical up to a couple of hundred watts output. Beyond that point, the vacuum tube still reigns.

### CLASSES OF OPERATION

The class of operation of an amplifier stage is defined by its output current conditions. This, in turn, determines the amplifier’s efficiency, linearity and operating impedances.

• Class A: The RF drive level and dc bias are set so there is device output current all the time. The conduction angle is 360° (see Fig. 1A). (The conduction angle of an amplifier is defined as the angular portion of a drive cycle over which there is output current. Conduction angle is measured in degrees; a full sine-wave cycle is 360°.) The active device in a Class A amplifier acts as a variable resistor. Output voltage is generated by the varying current flowing through the load resistance. Maximum linearity is achieved in a Class A amplifier, but the efficiency of the stage is low. In theory, maximum efficiency is 50%, but in practice it usually runs about 25 to 30%.

• Class AB: Drive level and dc bias are adjusted so output current flows appreciably more than half the drive cycle, but less than the whole drive cycle. The

<sup>1</sup>Granberg, “One KW — Solid-State Style,” *QST*, April 1976, p. 11; May 1976, p. 28.

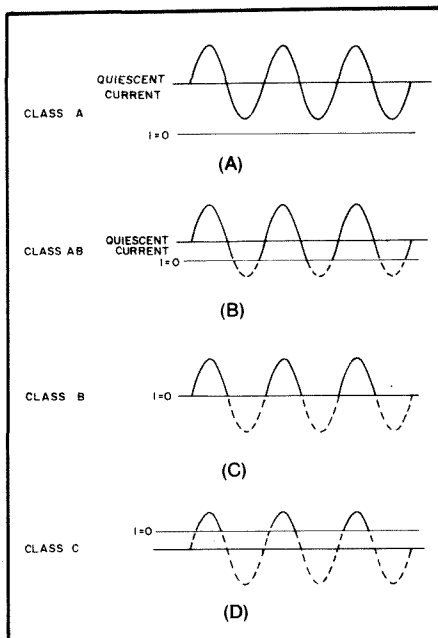

Fig. 1 — Amplifying device output current for various classes of operation. All assume a sinusoidal drive signal.

operating angle is much greater than  $180^\circ$  but less than  $360^\circ$  (see Fig. 1B). Efficiency is much better than Class A, averaging over 50%. Class AB linearity is not as good as that found in Class A, but is very acceptable for even the most rigorous SSB applications.

- Class B: Bias and RF drive are at a level where the device is just cut off (see Fig. 1C) and output current flows during one half of the drive cycle (conduction angle =  $180^\circ$ ). Improved efficiency is attained, up to 65%, and acceptable linearity is still maintained.

- Class C: The dc bias is adjusted so that the device is cut off. Output current flows only during peaks in the drive cycle (see Fig. 1D). The output current consists of pulses at the drive frequency; the conduction angle is considerably less than  $180^\circ$ . Since the output device is cut off for more than half the operating cycle, efficiency is relatively high, up to 80%. Linearity is extremely poor, though.

There are other amplifier classes not usually found in amateur service. Most amplifiers that use Class D through H operate at audio frequencies. Their prime virtue is high efficiency. Manufacturers of audio equipment use these amplifier classes to reduce power supply requirements and the associated high costs in high-power stereo amplifiers. Sophisticated techniques would be required to implement these operating classes in radio-frequency amplifiers, particularly at high power levels. The additional complexity and cost is difficult to justify for amateur RF service.

The class of operation is independent of device type and circuit configuration. The active amplifying device and the circuit

Fig. 2 — The fundamental circuit for a generator and a load includes the internal power source resistance ( $R_1$ ), the load resistance ( $R_2$ ), and associated reactances ( $X_1$  and  $X_2$ ). A network is used to "match" the impedances.

Fig. 3 — Efficiency is dependent on the ratio of the load resistance to the source resistance.

itself must be uniquely applied for each operating class, but amplifier linearity and efficiency are limited by the class of operation. Clever amplifier design cannot improve on these fundamental limits. Poor design and implementation, though, can certainly prevent an amplifier from approaching its potential in efficiency and linearity.

## IMPEDANCE MATCHING

All power sources, such as the tube or transistor in a power amplifier, have an internal impedance. The impedance usually consists of a resistance in combination with some reactance. Current flowing through this internal resistance in the process of generating power is converted to heat. The electrical power consumed by the internal resistance is unavailable to the load, and only goes to heating up the power source. It can be proven algebraically that the maximum power available from a power source is transferred to the load resistance when the load resistance is equal to the source resistance. If the source has reactance associated with it, then the load impedance must be equal to the complex conjugate of the source impedance.

Usually, neither the source impedance nor the load impedance can be changed. In order to achieve maximum power transfer, a matching network is used between the source and the load to transform the load impedance to the source impedance (and vice versa). This is illustrated in Fig. 2.

The total power generated by the source is

$$P_{IN} = P_{OUT} + P_D$$

where

$P_{IN}$  = the source power input

$P_{OUT}$  = the power delivered to the load

$P_D$  = the power dissipated in the source resistance.

The efficiency (the ratio of output power to total power generated) is

$$\text{Eff.} = \frac{P_{OUT}}{P_{IN}} \text{ or } \frac{P_{OUT}}{P_{OUT} + P_D}$$

Efficiency is usually expressed as a percentage.

When the source impedance is matched to the load impedance, each impedance consumes the same amount of power (simple Ohm's Law:  $P = I^2R$ , the current being the same through both series impedances). It then follows that half the power generated is transferred to the load, and half is dissipated by the source. Efficiency is 50% when the source resistance is equal to the load resistance.

One of the main objectives in power amplifier design is to transfer as much fundamental frequency power to the load as possible, without exceeding the amplifier's active device ratings. In other words, maximum efficiency is needed. As illustrated in Fig. 3, efficiency improves as the load resistance to source resistance ratio increases. The usual practice in RF power amplifier design is to select an optimum load resistance that will provide the highest power output, while staying within the amplifying device's power rating.

The optimum load resistance is determined by the amplifying device's current transfer characteristics, and in the case of vacuum tubes, by the amplifier's class of operation. For a transistor amplifier, the optimum load resistance is

$$R_L = \frac{V_{cc}^2}{2P_O}$$

Where  $R_L$  (the load resistance) is equal to the dc collector voltage ( $V_{cc}$ ) squared, divided by two times  $P_O$  (the amplifier power output in watts). Vacuum tubes have more complex current transfer characteristics and each class of operation produces different RMS values of RF current through the load impedance. The optimum load resistance for vacuum tube amplifiers can be approximated by the ratio of the dc plate voltage to the dc plate current, divided by a constant, appropriate to each class of

operation (and this in turn determines the maximum efficiency each class of operation can provide). The optimum tube load resistance is

$$R_L = \frac{V_P}{KI_P}$$

where

$R_L$  = the appropriate load resistance

$V_P$  = the dc plate potential in volts

$I_P$  = the dc plate current in amperes

$K$  = a constant that approximates the RMS current to dc current ratio appropriate for each class. For the different classes of operation

Class A,  $K \approx 1.3$

Class AB,  $K \approx 1.5$

Class B,  $K \approx 1.57$

Class C,  $K \approx 2$

The load resistance for an RF power amplifier usually is a transmission line connected to an antenna, or the input of another amplifier. It isn't practical, or usually even possible, to modify either of these load resistances to the optimum value needed for high-efficiency operation. A matching network is normally used to transform the true load resistance to the optimum load resistance for the amplifying device. The matching network is also used to cancel any reactance in the two impedances (source and load). Two types of matching networks are found in RF power amplifiers: tank circuits and transformers.

## TANK CIRCUITS

Parallel resonant circuits and their equivalents have the ability to store energy. Capacitors store electrical energy in the electric field between their plates; inductors store energy in the magnetic field induced by the coil winding. These circuits are referred to as tank circuits, since they act as storage "tanks" for RF energy.

The energy stored in the individual tank circuit components varies with time. At some point the capacitor in a tank circuit is fully charged, and the current through the capacitor is zero. All the energy in the tank is stored in the capacitor's electric field. Since the inductor is connected directly across the capacitor, the capacitor then starts to discharge through the inductor (since the inductor has no energy stored in it, there is no magnetic field and the voltage potential across the inductor is zero).

The current flowing into the inductor creates a magnetic field; energy now is being stored in the inductor's magnetic field. Assuming there is no resistance in the tank circuit, the increase in energy stored in the inductor's magnetic field is balanced by the decrease in the energy stored in the capacitor's electric field. The total energy stored in the tank circuit stays constant; some is stored in the inductor, some in the capacitor. As the energy level rises in the inductor, the voltage potential across the

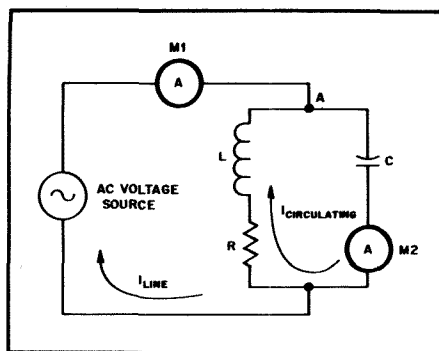

Fig. 4 — There are two currents in a tank circuit: the line current ( $I_{LINE}$ ) and the circulating current ( $I_{CIRCULATING}$ ). The circulating current is dependent on tank Q.

inductor will climb from its original zero voltage condition. According to Lenz's law, the voltage produced is in opposition to the increasing current flowing into the inductor. Eventually, the induced voltage is large enough to totally oppose the current created by the transfer of energy from the capacitor to the inductor. The capacitor's electric field is depleted at this point, and all the tank circuit's energy is stored in the magnetic field of the inductor.

The voltage potential across the inductor, which is in parallel with the capacitor, then starts to recharge the capacitor (the polarity is now reversed from the original condition). Eventually, the capacitor charges fully, and all the energy is then stored in the capacitor's electric field instead of in the inductor's magnetic field. Again, the capacitor discharges into the inductor, where a voltage in opposition to the current develops across the inductor. Once the potential is high enough, the capacitor again recharges. The flow of energy into the inductor from the capacitor and back again is an alternating current. It can be mathematically shown that this alternating current is sinusoidal, and has a frequency of

$$F = \frac{1}{2\pi \sqrt{LC}}$$

which of course is the resonant frequency of the tank circuit. In the absence of a load or any losses to dissipate tank energy, the tank circuit current would oscillate forever.

A typical tank circuit is shown in Fig. 4. The values for L and C are chosen so that the reactance at L ( $X_L$ ) is equal to the reactance of C ( $X_C$ ) at the frequency of the signal generated by the ac voltage source. Since  $X_L$  is equal to  $X_C$ , the line current,  $I_{LINE}$ , as measured by meter M1 is close to zero; only the leakage through C is measurable. However, the current,  $I_{CIRCULATING}$ , in the loop defined by L, R and C is definitely not zero. Examine what would happen if the circuit were suddenly broken at points A and B. The circuit is now comprised of L, C, R and M2, all in

Fig. 5 — The rotation of a point on a flywheel defines a sine wave.

series.  $X_L$  is equal to  $X_C$ , so they are series resonant. The current in the circuit (if some voltage were applied between points A and B), the circulating current, is only limited by the resistance R. If R is equal to zero, the circulating current would be infinite!

## The Flywheel Effect

A tank circuit can be likened to a flywheel — a mechanical device for storing energy. The energy in a flywheel is stored in the angular momentum of the wheel. Most flywheels are very heavy, and concentrate their mass as close to their outer rim as possible to maximize angular momentum. A perfect, unloaded flywheel is unaffected by friction or air resistance. It would spin forever once given an initial shot of energy to start it turning. No energy is expended heating up bearings or moving air; all the energy is stored in the flywheel's rotation.

But, as soon as a load of some sort is attached, the wheel starts to slow or even stop. Some of the energy stored in the spinning flywheel is now being transferred to the load. In order to keep the flywheel turning at a constant speed, the energy drained by the load has to be replenished. Energy has to be added to the flywheel from some external source. If sufficient energy is added to the flywheel, it maintains its constant rotation.

In the real world, of course, flywheels suffer from the same fate as tank circuits; there are system losses that dissipate some of the stored energy without performing any useful work. Air resistance and friction in the bearings slow the flywheel. In a tank circuit, resistive losses drain energy.

The comparison between a flywheel and a tank circuit is more accurate than first appearances might suggest. Fig. 5A shows the side view of a flywheel. This particular flywheel has no load attached, and happens to be in an environment where there is no friction or air resistance (perhaps in outer space). It is already spinning. Since there are no losses and no load draining energy from it, the wheel rotates at a constant speed and probably has been doing so for a long time.

At some particular time, point A is exactly at the three o'clock position. The time it takes for the wheel to make one complete revolution so that point A is again at ex-

Fig. 6 — Equivalent amounts of energy can be coupled into a flywheel over varying operating angles.

actly three o'clock is called the period of rotation. The frequency of rotation is the reciprocal of this; instead of the number of time units it takes for the flywheel to rotate once, the motion is expressed as the number of rotation units the wheel makes in one time unit. In order to measure this properly, some reference points are required. A set of axes, passing through the shaft of the flywheel, is convenient. One is labeled X, one is Y. When point A is exactly at three o'clock, it lies exactly on the X axis. At that instant, point A has a Y coordinate of zero, because it is at the same point along the Y axis as the origin of the flywheel shaft. One quarter revolution later, point A now is exactly on the Y axis. The flywheel happens to have a radius of 1 unit, so the Y coordinate of A at one quarter revolution ( $90^\circ$  of rotation) is 1.

One quarter later, point A is again on the X axis, but opposite from where it started. It has rotated one half turn or  $180^\circ$ . The Y coordinate is again zero. Another quarter turn of rotation later, point A has again rotated  $90^\circ$ , for a total of  $270^\circ$ . It's again on the Y axis, but directly opposite its position one half turn ago. The Y coordinate is now  $-1$ , to indicate that point A's position is below the flywheel shaft rather than above it. Another one-quarter rotation, for a total of  $360^\circ$  since first measured, and point A is back to its position along the X axis. The Y coordinate is again zero, since point A is again vertically level with the flywheel shaft. All further rotations of the wheel follow precisely the same pattern.

By careful measurement, the Y coordinate of point A could be plotted for the

entire rotation of the flywheel, rather than just every quarter turn. The plot would be of a sine wave, just like the circulating current in a tank circuit. This is no mere coincidence; the circulating current in the tank circuit is exactly analogous to the rotation of the flywheel. The circulating current in the tank circuit is the result of the rotation of an electromagnetic field vector as energy is transferred back and forth between the tank circuit's inductor and capacitor.

Fig. 6 illustrates a variety of techniques that can be used to replace the energy transferred to a load from a flywheel. A drive wheel, powered by an electric motor of some type, is coupled to the flywheel. The coupling can be through gear teeth, friction drive or any number of other ways. In this case, the flywheel and drive wheel are coupled together by a 100% efficient friction drive. The drive wheel is shown in Fig. 6A. With no load attached to the flywheel, the energy in the (perfect) flywheel remains constant, demanding no additional energy from the drive wheel and the drive motor. The drive motor uses no electrical current.

As soon as a load is attached, energy flows from the flywheel into the load. In order to maintain the flywheel's energy and thus its rotation, this energy must be replaced. The only source of energy available to the flywheel is the drive wheel, so energy flows from the drive wheel into the flywheel. The drive wheel derives its energy from its drive motor, which in turn takes externally generated electricity and converts it to mechanical energy. A loss in available energy anywhere along this chain causes a similar loss for the remainder of the

linkage. In scientific terms, energy must be conserved.

Conversely, if additional energy becomes available anywhere along the chain, perhaps caused by an increase in electrical power at the drive motor, the additional energy is transferred down the line to the load. This implies that controlling the energy supplied to the drive motor affects the energy levels throughout the linkage, and the energy ultimately supplied to the load. The energy available to the load can then be varied, or modulated, by varying the energy supplied to the drive motor.

Another drive system that requires less energy from the drive motor is shown in Fig. 6B. Part of the drive wheel has been cut away so that the drive wheel engages the flywheel for only a part of the drive wheel's rotation. When the drive wheel contacts the flywheel, it supplies energy to the flywheel. The drive motor draws electrical current since it has to provide the energy for the drive wheel. During the portion of the rotation when the cutout on the drive wheel faces the flywheel (that portion of the rotation when the drive wheel would still contact the flywheel if there were no cutout), the drive motor can coast. The motor draws no current. No energy is being transferred from the drive wheel to the flywheel, and the drive motor coasts until the cutout is passed. When the wheels again engage, the drive wheel transfers energy to the flywheel and the drive motor again draws current.

Since the drive motor draws current only during a portion of the flywheel rotation (because of the cutout), the average current consumption per flywheel rotation is reduced. System efficiency improves, but with one drawback — the drive wheel has no control over the flywheel while the cutout faces the flywheel. However, since the uncontrolled portion of the flywheel rotation is short compared to the overall flywheel rotational period, any corrections can be made during the much longer time frame when the two wheels are in contact.

Fig. 6C represents a drive wheel-flywheel system in which the drive wheel contacts and drives the flywheel for only half of the flywheel rotation. During the other half, the drive wheel coasts and drive motor current goes to zero. The low drive-motor duty cycle makes this scheme the most efficient so far. The bad part is that control of the flywheel is lost for half the rotation period.

A limiting case of this efficiency concept is shown in Fig. 6D. Here the drive wheel only "kicks" the flywheel for a short portion of the flywheel rotation period. The duty cycle is low, but there is almost no control of the flywheel except during the short contact period.

The flywheel drive systems just described are analogous to the different classes under which an amplifier can be run. Fig. 6A is just like Class A operation. During the entire flywheel rotation period, the drive wheel provides energy to the flywheel, just

as the output device in a Class A amplifier transfers current into its tank circuit. The efficiency is not very good, but the control over the flywheel, or tank circuit circulating current, is as tight as it can be. For an amplifier, this translates to faithful reproduction of the drive signal with low distortion. Classes AB, B, and C are represented by Figs. 6B, 6C and 6D, respectively.

Progressively with each class, the drive wheel actually drives the flywheel for shorter segments of the flywheel rotation period. In Fig. 6C the contact is for one half the rotation; the conduction angle is 180°. So it is also in an amplifier. In a Class B amplifier, device output current flows for half the drive cycle or 180°. What is important in both the flywheel system and the RF power amplifier is that the drive system supplies enough energy to keep the flywheel turning or the tank current circulating. It is also important to note that as the conducting angle decreases, control of the flywheel or tank circuit is given up. The amount of energy transferred from the flywheel or tank circuit into the load is decreasingly controlled by the drive system. Reproduction of changes in the drive energy level at the load (also referred to as modulation), deteriorates as the conduction angle decreases. In an RF power amplifier this is called distortion.

### Tank Circuit Q

In order to quantify the ability of a tank circuit or even a flywheel to store energy, a quality factor, Q, is defined. Q is the ratio of energy stored in a system to energy lost.

$$Q = 2\pi \frac{W_S}{W_L}$$

where

$W_S$  = is the energy stored by the flywheel or tank circuit

$W_L$  = the energy lost to heat and the load.

By algebraic substitution and appropriate integration, the Q for a tank circuit can be expressed as

$$Q = \frac{X}{R}$$

where

X = the reactance of either the inductor or the capacitor

R = the series resistance.

Since both circulating current and Q are proportional to  $1/R$ , circulating current is therefore proportional to Q. The tank circulating current is equal to the line current multiplied by Q. If the line current is 100 mA, and the tank Q is 10, then the circulating current through the tank is 1 ampere. (This also implies, according to Ohm's Law, that the voltage potentials across the components in a tank circuit are also proportional to Q.)

When there is no load connected to the tank, the only resistances contributing to

R are the losses in the tank circuit. The unloaded  $Q_U$  in that case is

$$Q = \frac{X}{R_{Loss}}$$

where

X = the reactance of either the inductor or capacitor

$R_{Loss}$  = the loss resistance in the circuit.

To the tank circuit, a load acts exactly the same as circuit losses. Both consume energy. It just happens that energy consumed by the circuit losses becomes heat. The only difference is the use the energy is put to. When energy is coupled out of the tank circuit into a load resistor, the unloaded tank circuit Q ( $Q_L$ ) is

$$Q_L = \frac{X}{R_{Loss} + R_{Load}}$$

where  $R_{Load}$  is the load resistance. Energy dissipated in  $R_{Loss}$  is wasted as heat; ideally, all the tank circuit energy should be dissipated in  $R_{Load}$ . This implies that  $R_{Loss}$  should be as small as possible; the unloaded Q will rise accordingly.

### Tank Circuit Efficiency

The efficiency of a tank circuit is the ratio of power dissipated in the load resistance,  $R_{Load}$  (the useful power) to the total power dissipated in the tank circuit (by  $R_{Load}$  and  $R_{Loss}$ ). Within the tank circuit,  $R_{Load}$  and  $R_{Loss}$  are in series, and the circulating current flows through both. The power dissipated by each is therefore proportional to their resistance. The loaded tank efficiency can therefore be defined as

$$\text{Tank efficiency} = \frac{R_{Load}}{R_{Load} + R_{Loss}} \times 100$$

where efficiency is measured as a percentage. By algebraic substitution, the loaded tank efficiency can also be expressed as

$$\text{Tank Efficiency} = \left(1 - \frac{Q_L}{Q_U}\right) \times 100$$

where

$Q_L$  = the tank circuit loaded Q

$Q_U$  = the unloaded Q of the tank circuit.

It follows then that tank efficiency can be maximized by keeping  $Q_L$  low, which keeps the circulating current low and the  $I^2R$  losses down. The unloaded Q should be maximized for best efficiency; this means keeping the circuit losses low.

The selectivity provided by a tank circuit helps suppress harmonic currents generated by the amplifier. The amount of harmonic suppression is dependent upon circuit Q, so a conflict exists for the amplifier designer. A low  $Q_L$  is desirable for best tank efficiency, but low  $Q_L$  yields poor harmonic suppression. High  $Q_L$  keeps amplifier harmonic levels low, but tank ef-

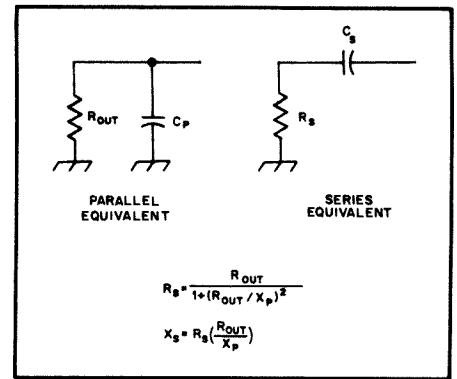

Fig. 7 — Parallel and series equivalent circuits and the formulas used for conversion.

iciency suffers. At HF,  $Q_L$  can usually be chosen as a compromise value where tank efficiency remains high and harmonic suppression is also reasonable. At the higher frequencies the tank  $Q_L$  is not as controllable. However, unloaded Q can always be optimized, regardless of frequency, by keeping circuit losses low.

### Matching Circuits

Tank circuit type matching networks need not take the form of a capacitor directly connected in parallel with an inductor. A number of equivalent circuits can be used to match the impedances normally encountered in a power amplifier. Most are operationally more flexible than a parallel resonant tank. Each has its virtues and failings, but the final choice usually is based on the actual component values needed to implement a particular network. Different networks may require unreasonably high or low inductance or capacitance values. In that case, a change to another type of network or to a different value of  $Q_L$  may be required. Several different networks may have to be investigated before the final design is reached.

Normally, the impedances of active amplifying devices are given as a resistance in parallel with the reactance. The equivalence between parallel impedance and series impedance is the basis for all matching network design. The equivalent circuits and the equations for conversion are given in Fig. 7. In order to use most design equations for computing matching networks, the parallel impedance must first be converted to its equivalent series form.

The  $Q_L$  of a parallel impedance can be converted from the series form as well. Substitution of the usual formula for calculating Q into the equations from Fig. 7 gives

$$Q_L = \frac{R_P}{X_P}$$

where

$R_P$  = the parallel equivalent resistance  
 $X_P$  = the parallel equivalent reactance.

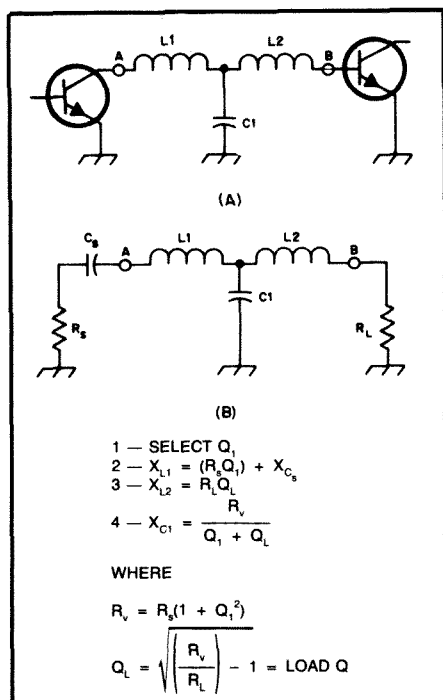

Fig. 8 — Network-solution equations and circuit for a T network. Actual circuit (A) and series equivalent (B).

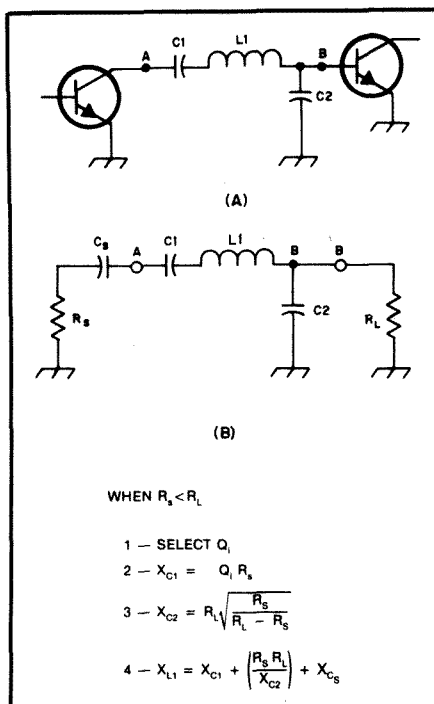

Fig. 10 — Circuit and equations for a series C, L network. Actual circuit (A) and series equivalent (B).

The pi network may also be used in amplifier matching. Harmonic suppression in a pi network is a function of the impedance transformation ratio and the  $Q_L$  of the circuit. Second harmonic attenuation is approximately 35 dB for a load impedance of 2000  $\Omega$  in a pi network with a  $Q_L$  of 10. The third harmonic is typically 10 dB lower and the fourth harmonic approximately 7 below that. Again, the techniques described earlier in the book can be used to calculate exact theoretical values for different impedances and  $Q_L$  values. A typical pi network as used in the output circuit of a tube amplifier is shown in Fig. 11. The component values for a pi network with a  $Q_L$  of 12 are stated in Table 1. Other values of  $Q_L$  can be used by applying the formulas

$$\frac{Q_N}{12} = \frac{C_N}{C_{12}} \quad \text{and} \quad \frac{Q_N}{12} = \frac{L_{12}}{L_N}$$

where

$Q_N$  = the new  $Q_L$  value for the network  
 $C_{12}$  and  $L_{12}$  = the different component values taken from Table 1

$C_N$  and  $L_N$  = the component values for a pi network with a  $Q_L$  of  $Q_N$ .

The pi-L network is a combination of a pi network followed by an L network. The pi network transforms the load resistance to an intermediate impedance level called the image impedance. Typically, the image impedance is chosen to be between 300 and 700  $\Omega$ . The L section then transforms from the image impedance down to 50  $\Omega$ . The output capacitor of the pi network is combined with the input capacitor for the L network, as shown in Fig. 12. The pi-L configuration attenuates harmonics better than a pi network. Second harmonic levels for a pi-L network with a  $Q_L$  of 10 is approximately 52 dB down from the fundamental. The third harmonic is attenuated 65 dB and the fourth harmonic approximately 75 dB. Component values for a pi-L network with a  $Q_L$  of 12 are given in Table 2. Other component values can be calculated for different values of  $Q_L$  by using the formulas described previously for the pi network.

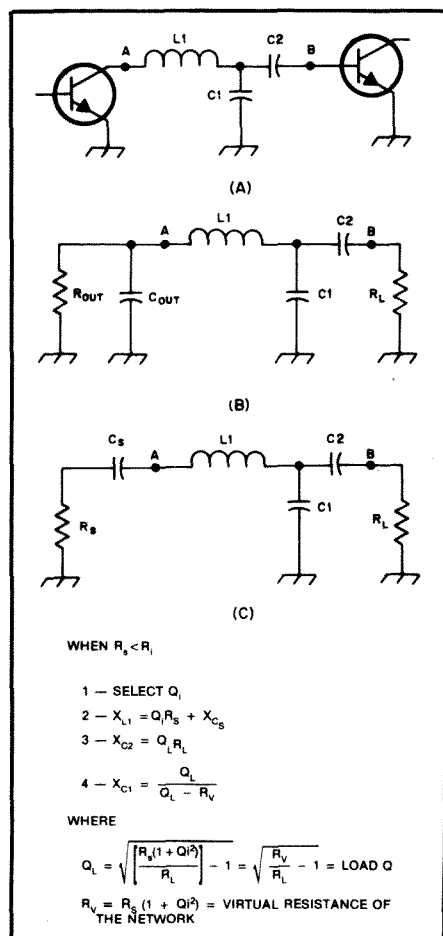

Fig. 9 — Circuit and mathematical solution for a shunt C, L network. Actual circuit (A), parallel equivalent (B) and series equivalent (C).

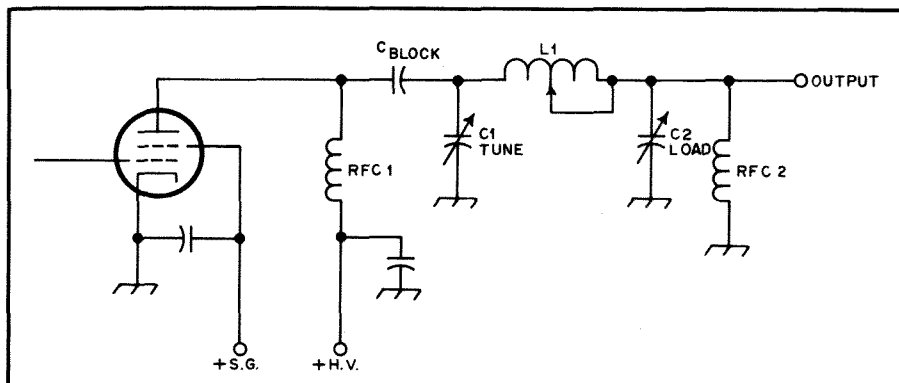

Fig. 11 — A pi matching network used at the output of a tetrode power amplifier. RFC2 is used for protective purposes in the event  $C_{\text{block}}$  fails.

The values for L and C in Tables 1 and 2 are based on purely resistive impedances. Any reactance modifies these values. Stray circuit reactances as well as tube or capacitor reactances all should be included as part of the matching network. Very often these reactances will render most of the matching circuits impractical. Either unacceptable loaded Q values or unrealistic component values are required. A compromise must be made once all the matching network alternatives have been investigated and found unacceptable.

Above 30 MHz, transistor and tube reactances completely dominate circuit impedances. At the lower impedances found in transistor circuits, the standard networks can be applied as long as suitable components are used. Capacitors rarely exhibit their marked values above 50 MHz because of internal reactances in addition to lead inductance, and must be compensated for. Tuned circuits frequently take the form of strip lines or other transmission lines in order to obtain "pure" inductances. The choice of components is often more significant than the type of network used.

The high impedances encountered in VHF tube amplifier plate circuits are not easily matched with the typical networks. The tube output capacitance is usually of such a high value that most matching networks are unsuitable. The usual practice is to resonate the tube output capacitance with a low-loss inductance connected in parallel. The result is a very high Q tank circuit. Component losses must be kept to an absolute minimum in order to achieve reasonable tank efficiency. Output impedance transformation is usually performed by a link inductively coupled to the tank circuit or by a parallel transformation of the output resistance through a series capacitor.

## Transformers

Broadband transformers are often used in matching to the input impedance or optimum load impedance in a power amplifier. Multioctave power amplifier performance can be achieved by appropriate application of these transformers. The input and output transformers are two of the most critical components in a broadband amplifier. Amplifier efficiency, gain flatness, input SWR and even linearity are all affected by the transformer design and use. There are two transformer types, as described earlier in this Handbook; the conventional transformer and the transmission-line transformer.

The conventional transformer is wound much the same way as a power transformer. The primary and secondary windings are wound around a high-permeability core, usually made from a ferrite or powdered-iron material. Coupling between the secondary and primary is made as tight as possible to minimize leakage inductance. At low frequencies, the coupling between windings is predominantly

Fig. 12 — The pi-L network uses a pi network to transform the input impedance ( $R_L$ ) to the image impedance ( $Z_{IMAGE}$ ). An L network transforms  $Z_{IMAGE}$  to  $R_O$ .

These component values are for use with the circuit of Fig. 11 and were provided by W6FFC and K1JX.

magnetic. As the frequency rises, the permeability in the core decreases and the leakage inductance increases; transformer losses increase as well.

Typical examples of conventional transformers are shown in Fig. 13. In Fig. 13A, the primary windings consist of brass or copper tubes, inserted into ferrite sleeves. The tubes are shorted together at one end by a piece of copper-clad printed circuit board material. The secondary winding is threaded through the tubes. Since the low-impedance winding is only a single turn, the transformation ratio is limited to the squares of integers — 1, 4, 9, 16, etc. The lowest effective transformer frequency is determined by the inductance of the one-turn winding. It should have a reactance at least four times greater than the impedance it is connected to, for extended low-frequency response.

The coupling coefficient between the two windings is a function of the primary tube diameter and its length, and the diameters and insulation thickness of the wire used in the high-impedance winding. High im-

pedance ratios, greater than 36:1, should use large-diameter secondary windings. Miniature coaxial cable (using only the braid as the conductor) works very well. Another use for coaxial cable braid is illustrated in Fig. 13B. Instead of using tubing for the primary winding, the secondary winding is threaded through copper braid. Performance of the two units is almost identical.

The cores used must be large enough so the core material will not saturate at the power level applied to the transformer. Core saturation can cause permanent changes to the core permeability, as well as overheating. Transformer nonlinearity also develops at core saturation. Harmonics and other distortion products are produced, clearly an undesirable situation. Multiple cores can be used to increase the power capabilities of the transformer. The core size required can be calculated through the use of formulas presented in an earlier chapter of this Handbook in the discussion of ferromagnetic transformers and inductors.

Operating Q — 12. Output load — 52 ohms. Computer data provided by Bill Imamura, JA6GW and Clarke Greene, K1JX.

(A)

(B)

Fig. 13 — The two methods of constructing the transformers as outlined in the text. At (A), the one-turn loop is made from brass tubing; at (B), a piece of coaxial cable braid is used for the loop.

Transmission line transformers are similar to conventional transformers, but can be used over wider frequency ranges. In a conventional transformer, the high-frequency losses are caused by leakage inductance, rising with frequency. In a transmission line transformer, the windings are arranged so there is tight capacitive coupling between the two. A high coupling coefficient is maintained up to a high frequency.

Fig. 14 shows two types of 4:1 transformers, and a method for connecting two of them in series to effect a 16:1 transformation. The circuit at E is often used between a 50- $\Omega$  source and the base of an RF power transistor.

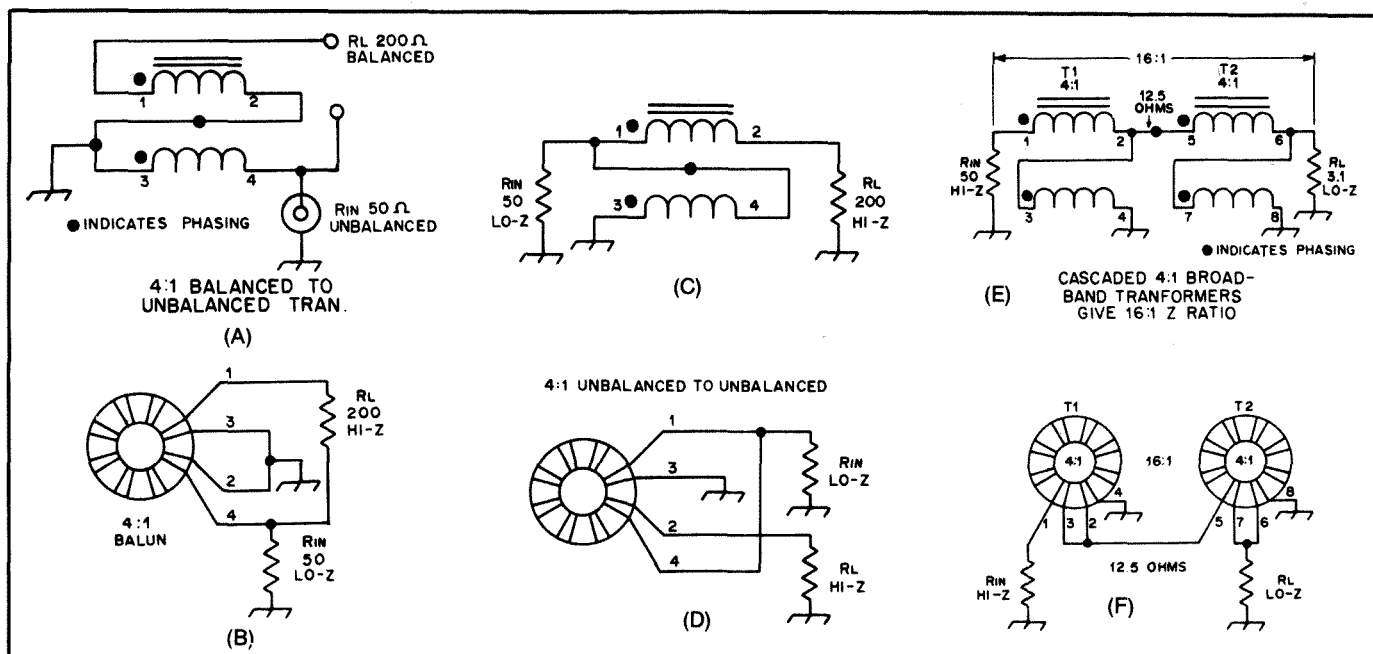

Fig. 14 — Circuit illustrations of 4:1 broadband transformers.

Two types of 9:1 transformers are illustrated in Fig. 15. Phase reversal, 1:1 balanced to unbalanced and hybrid combiner transformers are shown in Fig. 16. The circuit at E is used to combine the output of two simultaneously driven amplifiers into a common load. When the amplitude and phase of the signal sources are identical, all of the power is delivered to the load, R4. The amplifiers are effectively isolated from each other.

### Output Filtering

Filtering of the amplifier output is sometimes necessary to meet spurious-signal requirements. Broadband amplifiers, by definition, provide little if any suppression of harmonic energy. Amplifiers using tank circuits in their output often require further attenuation of undesired harmonics. High level signals, particularly at multiple transmitter sites, can travel down the feedline and mix in a power amplifier, causing spurious outputs. For example, an HF transceiver signal radiated from a tri-band beam is picked up by a VHF FM antenna on the same mast. The signal saturates the low-power FM transceiver output stage, even with power off, and is reradiated by the VHF antenna. Proper use of filters can reduce spurious energy considerably.

The type of filter used will depend on the application and the level of spurious attenuation needed. Band-pass filters attenuate spurious signals above and below the band for which they are designed. Low-pass filters attenuate signals above the desired output frequency, while high-pass filters reduce energy below the design frequency.

The filters shown in Fig. 17 are low-pass and high-pass versions of Chebyshev filters.

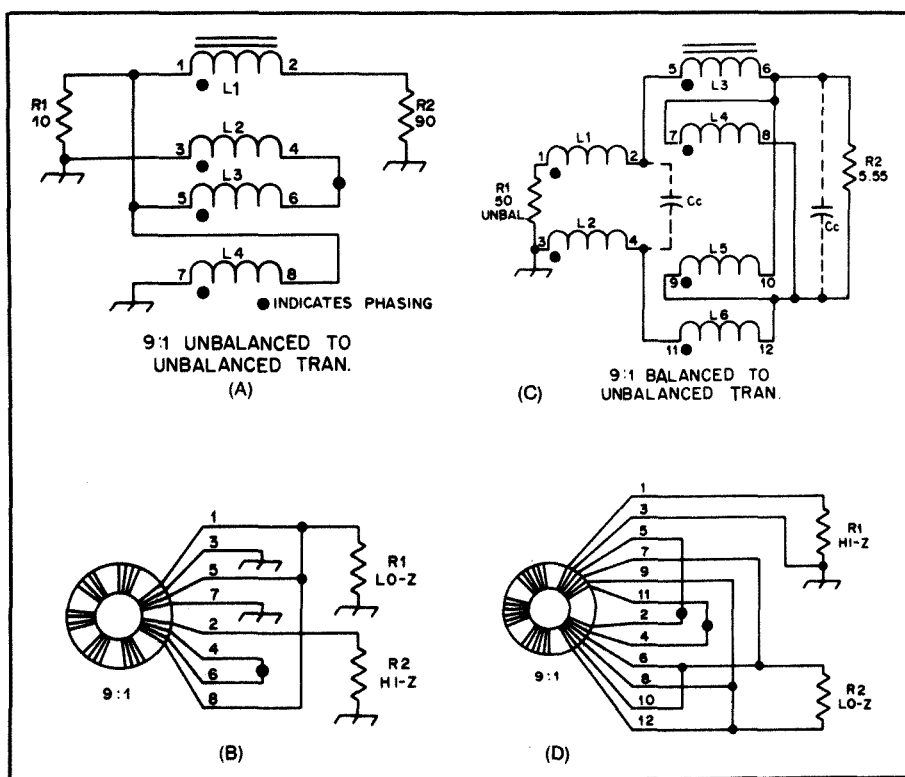

Fig. 15 — Circuit examples of 9:1 broadband transformers (A and C).

The filters may be realized in either a T or pi configuration. In this design, the number of filter circuit elements is determined by the desired stop-band frequency roll-off and the tolerable passband ripple. Steeper roll-off requires more circuit elements as does lower passband ripple. Passband ripple manifests itself by increased pass-band SWR.

In order to select a suitable filter design, the builder must determine the amount of attenuation required in the stopband. Additionally the builder must determine the maximum amount of passband ripple, and therefore the SWR of the filter. Table 3 and Fig. 18 show attenuation values achieved with the various filters and passband ripples. The attenuation levels are quoted at

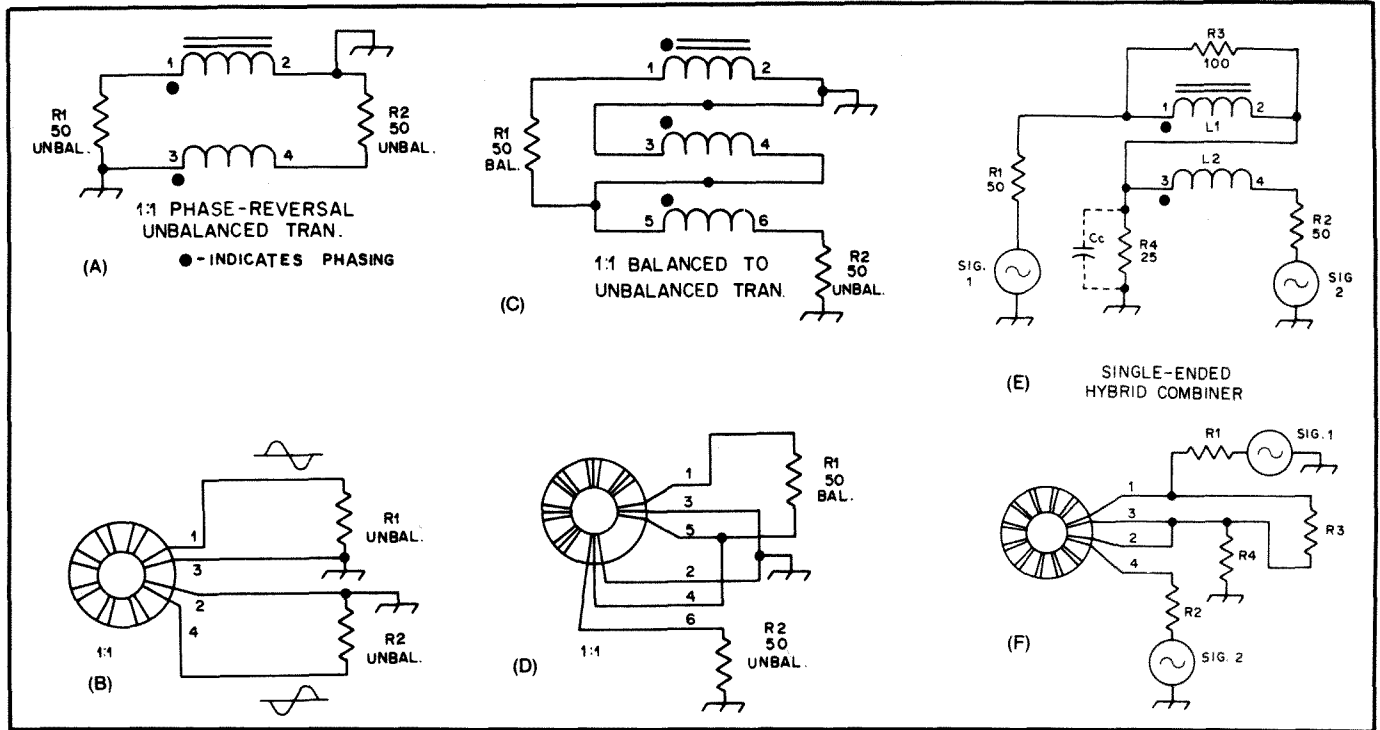

Fig. 16 — Assorted broadband transformers.

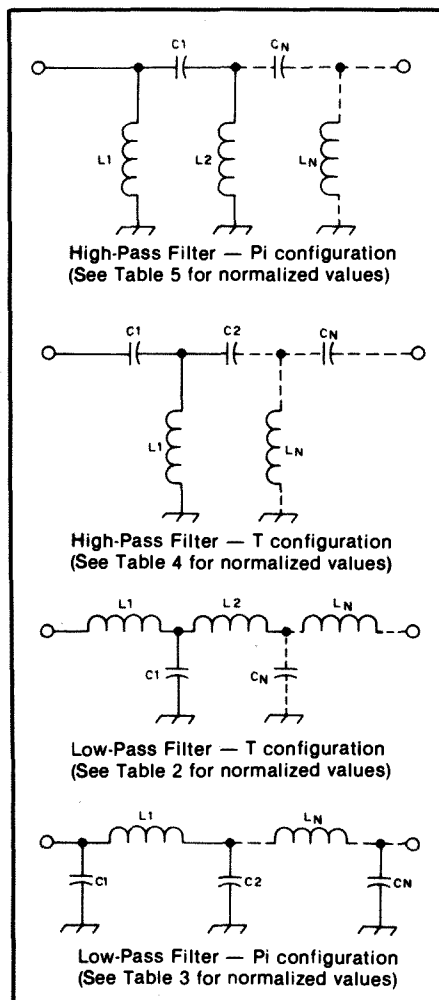

Fig. 17 — The four filter types discussed in the text and Tables 3 through 8.

Note: For high-pass filter configuration  $2f_c$  becomes  $f_c/2$ , etc.

Fig. 18 — A representative drawing of the attenuation levels that could be expected from a 5-pole, low-pass filter designed from the information contained in Tables 4 or 5. The exact amount of attenuation (theoretical) can be obtained from Table 3. This drawing shows how passband ripple and roll-off slope are interrelated.

integer multiples of the fundamental frequency (for the low-pass case) or integer submultiples of the fundamental frequency (for the high-pass application). The values given are theoretical and assume perfect components, no coupling between filter sections and no signal leakage around the filter. A working model should follow these values down to the 60- to 70-dB attenuation level. Beyond this point, the theoretical response will likely be degraded somewhat by the factors just mentioned.

Once the filter is chosen, the component values can be found. The filters listed in Tables 4 through 7 are normalized to a frequency of 1 MHz and an input and output impedance of 50 ohms. The 1 MHz value represents a cut-off frequency. The attenuation increases rapidly above or below this frequency into the stopband. In order to translate these designs to other frequencies, it is necessary to divide the component values by the new frequency in megahertz. For example, if a low-pass filter is desired to reduce harmonics from the 10-meter FM transceiver, the cut-off frequency should be 29.7 MHz. The inductance and capacitance values shown in the tables would then be divided by 29.7. Other impedance levels can also be used by multiplying the inductor values by the ratios  $Z_0/50$  and the capacitor values by  $50/Z_0$ , where  $Z_0$  is the new impedance. The correction factor should be applied in addition to any factors for frequency translation.

In many cases the calculated capacitor values will be such that a standard-value unit may be used. Alternatively, a combination of fixed-value silver mica capacitors and mica compression trimmers can be used in parallel to obtain the chart values. Toroidal inductors, because of their self-shielding properties, are ideal for use in these filters. Miniductor stock can also be used. However, it is much bulkier and will not offer the same degree of shielding between filter sections. Disc ceramic or paper capacitors are not suitable for use in RF filters. Standard mica or silver mica types are recommended.

Fig. 19 shows a filter that was designed with the information contained in Table 5. It is a 7-element, low-pass type of pi configuration. The unit is housed in a small aluminum Minibox and makes use of BNC connectors for the input and output connections.

## TRANSMITTING DEVICE RATINGS

### Plate Dissipation

The ultimate determination of the power-handling capability of a tube is its plate dissipation. It is the measure of how many watts of heat the tube can safely dissipate without exceeding critical temperatures. Excessive temperature can weaken or even melt internal tube connections or the seals that retain vacuum in the tube. The result — tube failure. The same tube may have different ratings, depending

on the conditions under which it is operated, but all the ratings are based primarily upon the heat that the tube can safely dissipate.

Efficiency for amplifiers runs between 25 and 75 percent, depending on the operating class. The efficiency indicates how much of the stage's power is useful RF; the rest

is wasted power in the form of heat, dissipated through the plate. By knowing the plate-dissipation limit of the tube, and the efficiency expected from the chosen class of operation, the maximum power output and input levels can be determined. The maximum power output possible is

$$P_{\text{OUT}} = \frac{P_D N_p}{100 - N_p}$$

where

$P_{\text{OUT}}$  = the power output in watts  
 $P_D$  = the plate dissipation in watts  
 $N_p$  = the efficiency (as a percentage).

The dc input power would simply be

$$P_{\text{IN}} = \frac{100 P_{\text{OUT}}}{N_p}$$

Almost all tube-type power amplifiers in amateur service today operate as linear amplifiers (Class AB or B) with an efficiency of approximately 60%. That means a useful power output of approximately 1.5 times the plate dissipation can be reliably expected from a linear amplifier (assuming everything else works right).

The amplifier duty cycle determines the dissipation rating. Some types of operation are less efficient than others, meaning that

the tube must dissipate more heat. Some forms of modulation, such as CW or SSB are intermittent in nature, causing less average heating than modulation formats in which there is continuous transmission, such as RTTY. Power tube manufacturers use two different rating systems to allow for the variations in service. CCS — Continuous Commercial Service — is the more conservative rating and is used for specifying tubes that are in constant use. The second rating system is based on intermittent, low-duty-cycle operation, and is known as ICAS — Intermittent Commercial and Amateur Service. ICAS ratings are normally used by amateurs who wish to obtain maximum power output with reasonable tube life in CW and SSB service. The conservative CCS ratings should be used for FM, RTTY and SSTV applications. (Plate power transformers for amateur service are also rated in CCS and ICAS terms.)

#### Maximum Ratings

Tube manufacturers publish sets of maximum values for the tubes they produce. No single maximum value should ever be used, unless all other ratings are simultaneously held substantially below their maximum values. As an example, a tube may have a maximum plate-voltage rating of 2000, a maximum plate-current rating of 300 mA, and a maximum plate power-input rating of 400 W. Therefore, if the maximum plate voltage of 2000 is used, then the plate current should be limited to 200 mA (not 300 mA) to stay within the maximum power-input rating of 400 W.

The manufacturers also publish sets of typical operating values that should result in good efficiency and long tube life. These values for many tubes can also be found in Chapter 35.

#### TRANSISTOR POWER DISSIPATION

RF power amplifier transistors are

limited in power-handling capability by the amount of heat the device can safely dissipate. Power dissipation for a transistor is expressed symbolically as  $P_D$ . The maximum rating is based on maintaining a case temperature of 25 °C. If greater temperatures are anticipated, the device has to be derated in milliwatts per °C, as specified by the manufacturer for that particular device. The efficiency considerations described earlier in reference to plate dissipation apply here, also. A rule of thumb for selecting a  $P_D$  rating suitable for a given RF power output level is to choose a transistor that has a maximum dissipation of twice the desired output power.

#### Maximum Transistor Ratings

Transistor data sheets specify the maximum operating voltage for several conditions. Of particular interest is the  $V_{\text{CEO}}$  specification (collector to emitter voltage, with the base open). In RF amplifier service the collector to emitter voltage can rise to twice the dc supply potential. Thus, if a 12-V supply is used, the transistor should have a  $V_{\text{CEO}}$  of 24 or greater to preclude damage.

The maximum collector current is also specified by the manufacturer. This specification is actually limited by the current-carrying capabilities of the internal bonding wires. Of course, the collector current must stay below the level that generates heat higher than the allowable device power dissipation. Many transistors are also rated for the load mismatch they can safely withstand. A typical specification might be for a transistor to tolerate a 30:1 SWR at all phase angles.

Transistor manufacturers publish data sheets that describe all the appropriate device ratings. Typical operating results are also given in these data sheets. In addition, many manufacturers publish application notes illustrating the use of their devices in practical circuits. Construction details are usually given. Perhaps owing to the popularity of Amateur Radio among electrical engineers, most of the notes describe applications especially suited to the Amateur Service. Specifications for some of the more popular RF power transistors are found in Chapter 35.

#### PASSIVE COMPONENT RATINGS

##### Output Tank Capacitor Ratings

The tank capacitor in a high-power amplifier should be chosen to allow sufficient spacing between plates to preclude high-voltage breakdown. The peak RF voltage present across a tank circuit under load, but without modulation, may be taken conservatively as being equal to the dc plate or collector voltage. If the dc supply voltage also appears across the tank capacitor, this must be added to the peak RF voltage, making the total peak voltage twice the dc supply voltage. At the higher

voltages, it is usually desirable to design the tank circuit so that the dc supply voltages do not appear across the tank capacitor, thereby allowing the use of a smaller capacitor with less plate spacing. Capacitor manufacturers usually rate their products in terms of the peak voltage between plates. Typical plate spacings are given in Table 8.

Output tank capacitors should be mounted as close to the tube as temperature considerations will permit, to make possible the shortest capacitive path from plate to cathode. Especially at the higher frequencies, where minimum circuit capacitance becomes important, the capacitor should be mounted with its stator plates well spaced from the chassis or other shielding. In circuits in which the rotor must be insulated from ground, the capacitor should be mounted on ceramic insulators of a size commensurate with the plate voltage involved and — most important of all, from the viewpoint of safety to the operator — a well-insulated coupling should be used between the capacitor shaft and the dial. The section of the shaft attached to the dial should be well grounded. This can be done conveniently through the use of panel shaft-bearing units.

#### High-Frequency Tank Coils

Tank coils should be mounted at least their diameter away from shielding to prevent a marked loss in Q. Except perhaps at 28 MHz, it is not important that the coil be mounted quite close to the tank capacitor. Leads up to 6 or 8 inches are permissible. It is more important to keep the tank capacitor, as well as other components, out of the immediate field of the coil. For this reason, it is preferable to mount the coil so that its axis is parallel to the capacitor shaft, either alongside the capacitor or above it.

Many factors must be taken into consideration in determining the size of wire (see Table 9) that should be used in winding a tank coil. The considerations of form factor and wire size which will produce a coil of minimum loss are often of less importance in practice than the coil size that will fit into available space or that will handle the required power without excessive heating. This is particularly true in the case of input circuits for screen-grid tubes where the relatively small driving power required can be easily obtained even if the losses in the driver are quite high. It may be considered preferable to take the power loss if the physical size can be kept down by making the coils small.

The wire sizes in Table 9 are larger than those typically used in modern commercial and home-built equipment. That is because their values were derived for AM service, where there is a continuous carrier and modulation peaks have a PEP four times the carrier value. Thus, the no. 10 wire required for 1000-W input on 75-meter AM would be adequate for at least 4-kW PEP in SSB service.

**Table 8**

#### Typical Tank-Capacitor Plate Spacings

Spacing Inches	Peak Voltage	Spacing Inches	Peak Voltage	Spacing Inches	Peak Voltage
0.015	1000	0.07	3000	0.175	7000
0.02	1200	0.08	3500	0.25	9000
0.03	1500	0.125	4500	0.35	11000
0.05	2000	0.15	6000	0.5	13000

Larger wire size than required for current handling capabilities is often used to maximize unloaded Q. Particularly at higher frequencies where skin depth considerations increase losses, the greater surface area of large diameter windings can be beneficial. Small-diameter copper tubing, up to 0.25-in outer diameter, can be used successfully for tank coils up through the lower VHF range. Silver plating the tubing further reduces losses. This is especially true as the tubing ages, and oxidizes. Silver oxide is a much better conductor than copper oxides, so silver-plated tank coils maintain their low-loss characteristics even after years of use.

At VHF and above, tank circuits take on forms less reminiscent of the familiar coil inductor. The inductances required to resonate tank circuits of reasonable Q at these higher frequencies is small enough that only strip lines or coaxial lines are practical. Since these are constructed from sheet metal or large-diameter tubing, current-handling capabilities normally are not a relevant factor.

#### RF Chokes

The characteristics of any RF choke will vary with frequency, from characteristics resembling those of a parallel-resonant circuit of high impedance, to those of a series-resonant circuit, where the impedance is lowest. In between these extremes, the choke will show varying amounts of inductive or capacitive reactance.

In series-feed circuits, these characteristics are of relatively small importance because the RF voltage across the choke is negligible. In a parallel-feed circuit, however, the choke is shunted across the tank circuit, and is subject to the full tank RF voltage. If the choke does not present a sufficiently high impedance, enough power will be absorbed by the choke to burn it out. To avoid this, the choke must have a sufficiently high reactance to be effective at the lowest frequency, and yet have no series resonances near the higher frequency bands. These potential resonances should be carefully investigated with a dip meter. A resonant choke failure in a high power amplifier can be very dramatic and damaging!

#### Blocking Capacitors

A series capacitor is usually used at the input of every amplifier output circuit. Its purpose is to block dc from appearing on

**Table 9**

#### Wire Sizes for Transmitting Coils for Tube Transmitters

Power Input (Watts)	Band (MHz)	Wire Size
1000	28-21	6
	14.7	8

75	28-21	14
	14.7	18
	3.5-1.8	22
25 or less*	28-21	18
	14.7	24
	3.5-1.8	28

\*Wire size limited principally by consideration of Q.

any of the matching circuit components and the antenna. As mentioned in the section on tank capacitors, output circuit component ratings can be relaxed somewhat when only the ac component of the output voltage is present.

The voltage rating for a blocking capacitor should be equal to at least twice the dc voltage applied. The peak voltage in a tank circuit can approach this value. A large safety margin is desirable, since blocking capacitor failure can bring catastrophic results.

The blocking capacitor should be low impedance at the amplifier operating frequencies. Since all the amplifier RF output current flows through the capacitor, a low impedance is necessary to avoid dissipation of RF power in the capacitor. Not only is that power wasted, but also the power-dissipation capabilities of most capacitors is minimal. A reasonable capacitance value for a blocking capacitor is one that limits its dissipation to less than 0.1% of the amplifier output power. This implies a capacitive reactance less than one thousandth the circuit impedance.

The current flowing through the blocking capacitor is dependent on circuit loaded Q. High levels of current flow in typical power amplifier output circuits. The capacitor must be capable of withstanding these currents. Below a couple of hundred watts at the high frequencies, suitable voltage rating disc ceramic capacitors work

well in high-impedance tube amplifier output circuits. Above that power level and at VHF, ceramic doorknob capacitors are needed for their low losses and high current handling capabilities. The so-called "TV doorknob" breaks down at high RF current levels and should be avoided.

The very high values of  $Q_L$  found in many VHF and UHF tube-type amplifier tank circuits often require custom fabrication of the blocking capacitor. This can usually be accommodated through the use of a Teflon "sandwich" capacitor. Here, the blocking capacitor is formed from two parallel plates separated by a thin layer of Teflon. This capacitor often is part of the tank circuit itself, forming a very low-loss blocking capacitor. Teflon is rated for a minimum breakdown voltage of 2000 volts per mil of thickness, so voltage breakdown should not be a factor in any practically realized circuit.

The capacitance formed from such a Teflon sandwich can be calculated from the information presented earlier in this Handbook (use a dielectric constant of 2.1 for Teflon). In order to prevent any potential irregularities caused by dielectric thickness variations (including air gaps), Dow-Corning DC-4 silicone grease should be evenly applied to both sides of the Teflon dielectric. This grease has similar properties to Teflon, and will fill in any surface irregularities that might cause problems.

The very low impedances found in transistorized amplifiers present special problems. In order to achieve the desired low blocking capacitor impedance, large-value capacitors are required. Special ceramic chips and mica capacitors are available that meet the requirements for high capacitance, large current carrying capability, and low associated inductance. These capacitors are more costly than standard disc-ceramic or silver-mica units, but their level of performance easily justifies their price. Most of these special-purpose capacitors can be identified by the fact that they are either leadless or come with wide straps instead of normal wire leads. Disc-ceramic and other wire-lead capacitors are generally not suitable for transistor power amplifier service.

## SOURCES OF OPERATING VOLTAGES

### Tube Filament or Heater Voltage

The heater voltage for the indirectly heated cathode-type tubes found in low-power classifications may vary 10 percent above or below rating without seriously reducing the life of the tube. The voltage of the higher-power, filament-type tubes should be held closely between the rated voltages as a minimum and five percent above rating as a maximum. Because of internal tube heating at UHF and higher, the manufacturers' rated filament voltage often is reduced at these higher frequencies. The derated filament voltages should be fol-

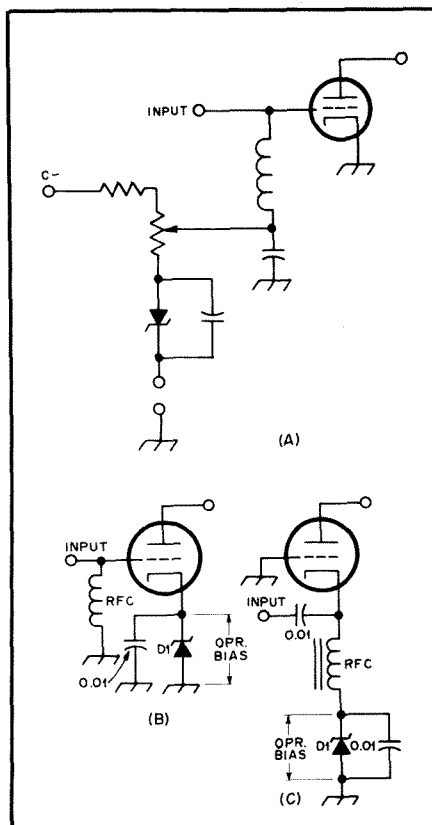

Fig. 20 — Various techniques for providing operating bias with tube amplifiers.

lowed carefully to maximize tube life. Series dropping resistors may be required in the filament circuit to attain the correct voltage. The voltage should be measured at the filament pins of the tube socket while the amplifier is running. The filament choke and the interconnecting wiring all have voltage drops associated with them. The high current drawn by a power tube heater circuit causes substantial voltage drops to occur across even a small resistance. Also, make sure that the plate power drawn from the power line does not cause a drop in filament voltage below the proper value when plate power is applied.

Thoriated-type filaments lose emission when the tube is overloaded appreciably. If the overload has not been too prolonged, emission sometimes may be restored by operating the filament at rated voltage with all other voltages removed for a period of 10 minutes, or at 20% above rated voltage for a few minutes.

### Vacuum Tube Plate Voltage

Dc plate voltage for the operation of RF amplifiers is most often obtained from a transformer-rectifier-filter system (see Chapters 6 and 27) designed to deliver the required plate voltage at the required current. It is not unusual for a power tube to arc over internally. This is usually caused by the intrusion of a charged subatomic particle into the tube. The flashover by itself is not normally dangerous to the tube, as long as the event is short lived. Damage,

to both the high-voltage supply and the tube, usually occurs when the flashover totally discharges the power supply capacitor bank. The subsequent high-current discharge into the tube not only damages the tube, but also frequently destroys the rectifiers in the power supply.

A good preventative measure against this is the inclusion of a 50- to 100- $\Omega$ , high-wattage power resistor in series with the plate voltage circuit. The additional resistance in the line lengthens the time constant associated with the capacitor-load resistance circuit. Short-duration flashovers are dampened by the RC low-pass action of the plate circuit, once the resistor is added. Any future flashovers probably will go undetected. Even at high plate-current levels, the addition of the resistor does little to affect the dynamic regulation of the plate supply. The wattage rating of the resistor may be calculated from the expected maximum dc plate current drawn by the tube. A safety factor of at least two should be applied to ensure resistor reliability.

### Grid Bias

The grid bias for a linear amplifier should be highly filtered and very well regulated. Any ripple or other voltage change in the bias circuit modulates the amplifier. This causes hum to appear on the signal as well as distortion. Since most linear amplifiers draw only small amounts of grid current, these bias supply requirements are not hard to meet.

Fixed bias is usually obtained from a variable-voltage regulated supply. Voltage adjustment allows setting bias level to give the desired resting plate current. Fig. 20 shows a simple Zener-diode-regulated bias supply. The dropping resistor is chosen to allow approximately 10 mA of Zener current. Bias is then regulated for all drive conditions up to a grid current level of about 5 mA. The potentiometer allows the bias level to be adjusted between  $V_{Zener}$  to approximately 15 volts higher. This range is usually adequate to allow for variations in the operating conditions between different tubes. Under stand-by conditions, when it is desirable to cut off the tube entirely, the Zener ground return is interrupted so the full bias supply voltage is applied to the grid.

In Fig. 20B and C, bias is obtained from the voltage drop across a Zener diode in the cathode (or filament center-tap) lead. Operating bias is obtained by the voltage drop across D1 as a result of plate (and screen) current flow. The diode voltage drop effectively raises the cathode potential relative to the grid. The grid is therefore lower in potential than the cathode by the Zener voltage of the diode. Assigning an arbitrary potential of zero to the cathode gives a grid bias equal to the Zener drop. The Zener-diode wattage rating should be twice the product of the maximum cathode current times the developed bias. There-

fore, a tube requiring 15 volts of bias during a maximum cathode current flow of 100 mA would dissipate 1.5 W in the Zener diode. The diode rating, to allow a suitable safety factor, would be 3 W or greater. The circuit of Fig. 20C illustrates how D1 would be used with a cathode driven (grounded grid) amplifier as opposed to the grid-driven example at B.

In all cases the Zener diode should be bypassed by a 0.01  $\mu$ F capacitor of suitable voltage. Current flow through any type of diode generates shot noise. If not bypassed, this noise would modulate the amplified signal, causing distortion in the amplifier output.

### Screen Voltage For Tubes

Power tetrode screen current varies widely with both excitation and loading. The current may be either positive or negative. In a linear amplifier the screen voltage should be well regulated for all values of screen current. The power output from a tetrode is very sensitive to screen voltage, and any dynamic change in the screen potential can cause distorted output. Voltage regulator tubes or Zener diodes are usually used for screen regulation.

Fig. 21 shows a typical example of a regulated screen supply for a power tetrode amplifier. The voltage from a fixed dc supply is dropped to the Zener stack voltage by the current-limiting resistor. A screen bleeder resistor is connected in parallel with the Zener stack to allow for the negative screen current developed under certain tube operating conditions. The bleeder current is chosen to be somewhat greater than the expected maximum negative screen current. For external anode tubes in the 4CX250 family, a typical value would be 20 mA. For the 4CX1000 family, a screen bleeder current of 70 mA is required. The idling current for the Zeners is set to be approximately 10 mA higher than the expected maximum screen current, plus the screen bleeder-resistor current. The screen voltage is then regulated for all values of current between maximum negative screen current and maximum positive screen current.

A tetrode should never be operated without plate voltage and load; otherwise the screen would act like an anode and draw excessive current. Supplying the screen through a series dropping resistor from the plate supply affords a measure of protection, since the screen voltage only appears when there is plate voltage. Alternatively, a fuse can be placed between the regulator and the bleeder resistor. The fuse should not be installed between the bleeder resistor and the tube, because the tube should never be operated without a load on the screen. Without a load, the screen potential tends to rise to the anode voltage. Any screen bypass capacitors or other associated circuitry would likely be damaged by this high voltage.

In Fig. 21, a varistor is connected from

Fig. 21 — A Zener-regulated screen supply for use with a tetrode. Protection is provided by a fuse and a varistor.

screen to ground. If, because of some circuit failure, the screen voltage should rise substantially above its nominal level, the varistor will conduct and clamp the screen voltage to ground. This usually causes a fuse to blow in the power supply, and power is interrupted before any damage occurs. The varistor voltage should be chosen to be approximately 50 percent higher than normal screen voltage.

### Transistor Biasing

Solid-state power amplifiers generally operate in Class C or AB. When some bias is desired during Class C operation (Fig. 22A), a resistance of the appropriate value can be placed in the emitter return as shown. Most transistors will operate in Class C without adding bias externally, but in some instances the amplifier efficiency can be improved by means of emitter bias. Reverse bias supplied to the base of the Class C transistor should be avoided because it will lead to internal breakdown of the device during peak drive periods. The damage is frequently a cumulative phenomenon, leading to gradual destruction of the transistor junction.

A simple method for Class AB biasing is shown in Fig. 22B. D1 is a silicon diode that acts as a bias clamp at approximately 0.7 V. The forward bias establishes linear-amplification conditions. That value of bias is not always optimum for a specified transistor in terms of IMD. Variable bias of the type illustrated in Fig. 22C permits the designer sufficient variance to locate the operating point for best linearity. The diode clamp or the reference for another type of regulator is usually thermally bonded to the power transistor. The bias level then tracks the thermal characteristics of the output transistor. Since a transistor's current transfer characteristics are a function of temperature, thermal tracking of the bias is necessary to maintain device linearity and to prevent thermal runaway and the subsequent destruction of the transistor.

### AMPLIFIER COOLING

#### Tube Cooling

Vacuum tubes must be operated within

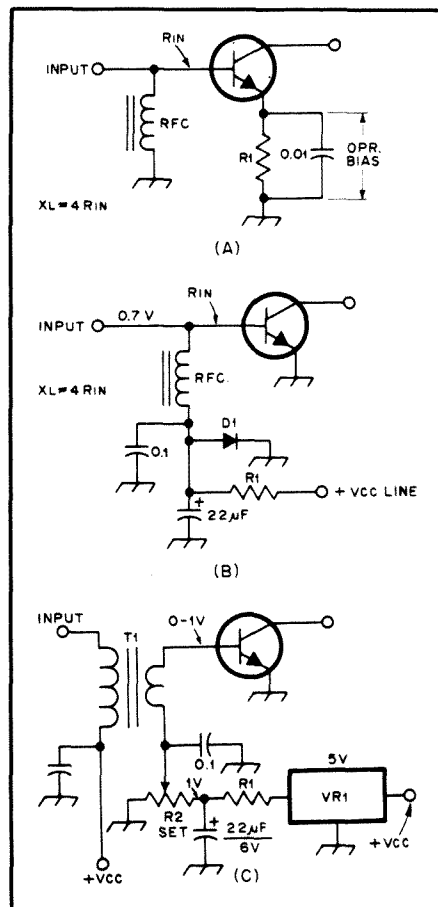

Fig. 22 — Biasing methods for use with transistor amplifiers.

the temperature range specified by the manufacturer if long tube life is to be achieved. Tubes with glass envelopes rated at up to 25 W plate dissipation may be run without forced-air cooling, if a moderate amount of cooling by convection can be arranged. If a perforated metal enclosure is used, and a ring of 1/4-inch-diameter holes are placed around the tube socket, normal air flow can be relied on to remove excess heat at room temperatures.

For tubes with greater plate dissipation, or those operated with plate currents in excess of the manufacturer's ratings, forced-

These values are for sea-level elevation. For locations well above sea level (Denver, Colorado, for example), add an additional 20% to the figure listed.

**Fig. 23** — Air is forced into the chassis by the blower and exits through the tube socket. The manometer is used to measure system back pressure, which is an important factor in determining the proper size blower.

**Fig. 24** — At A the blower is "off" and the water will seek its own level in the manometer. At B the blower is "on" and the amount of back pressure in terms of inches of water can be measured as indicated.

air cooling with a fan or blower is needed. Most manufacturers rate tube cooling requirements for continuous-duty operation. Their literature will indicate the required volume of air flow, in cubic feet per minute (CFM), at some particular back pressure.

Back pressure is the pressure that is built up inside an imperfect air passage when pressurized by an air source such as a blower. A perfect air passage offers no resistance to air flow, so the volume of air entering the passage flows out at the same rate. Any practical air passage is finite in size, and restricts the volume of air that can flow through. The difference between the potential volume of air that is available for flow through the air passage and the volume that actually flows manifests itself as back pressure. Anything that represents resistance to the air flow develops back pressure.

Tubes and their associated components are obstacles to the free passage of air and so develop back pressure to an air stream. The exact amount of pressure will depend on the blower, tube socket, tube and chimney characteristics. Blowers vary in their ability to work against back pressure so the matter of blower selection should not be taken lightly.

Values of CFM and back pressure for some of the more popular tubes, sockets and chimneys are given in Table 10. The back pressure is specified in inches of water and can be measured easily in an operational air passage as indicated in Figs. 23 and 24. The pressure differential between the air passage and the atmospheric pressure is measured with a device called a manometer. A manometer is nothing more than a piece of clear tubing, open at both ends and fashioned in the shape of a "U." The manometer is temporarily connected to the chassis and is removed after the measurements are completed. As shown in the diagrams, a small amount of water is placed in the tube. At Fig. 24A the blower is "off" and the water will seek its own level, because the air pressure (ordinary atmospheric pressure) is the same at both ends of the manometer tube. At B, the blower is "on" (socket, tube and chimney in place) and the pressure difference, in terms of inches of water, is measured. For most applications a standard scale can be used for the measurement and the results will be sufficiently accurate.

Table 11 illustrates the performance specifications for Dayton blowers, which are available through W. W. Grainger outlets throughout the U.S. Blowers having wheel diameters similar to those in Table 11 will likely have similar flow and back-pressure characteristics. If in doubt about specifications, consult the manufacturer. The setup of Fig. 24 is the authoritative determinant of cooling adequacy. As an example, assume that an amplifier is to be built using a 3-1000Z tube. A blower capable of supplying 25 CFM at a back pressure of 0.38 inch of water is required.

It appears (from Table 11) that the second blower listed would be suitable, although it may be marginal since it can supply only 25 CFM into a back pressure of 0.4 inch of water. The next larger size would provide a margin of safety.

When a pair of tubes is used, the CFM rating is doubled, but the back pressure remains the same as that for one tube. A pair of 3-1000Z tubes, for example, would require 50 CFM at a back pressure of 0.38 inch of water. In this case the fifth blower listed in the table would be suitable since it can supply 85 CFM at a back pressure of 0.4 inch of water. Always choose a blower that can supply at least the required amount of air. Smaller blowers will almost certainly lead to shortened tube life.

One method for directing the flow of air around a tube envelope or through tube cooling fins involves the use of a pressurized chassis. This system is shown in Fig. 23. A blower is attached to the chassis and forces air up through the tube socket and around the tube. A chimney (not shown in this drawing) is used to guide the air around the tube as it leaves the socket. A chimney will prevent the air from being dispersed as it hits the envelope or cooling fins, concentrating the flow for maximum cooling.

A less conventional approach is shown in Fig. 25. Here the anode compartment is pressurized by the blower. A special chimney is installed between the anode heat exchanger and a ventilation hole in the compartment cover. The blower pressurizes the anode compartment, and the only paths for air flow are through the anode and its chimney, and through the air system socket. Measurements by Dick Jansson, WD4FAB, indicate a nearly even split of the air flow between the anode and the air system socket. The pressure losses in a test made on an amplifier using a 4CX250 indicates a back pressure of only 0.33 inch of water with this scheme. This compares to a measured back pressure of 0.76 inch of water encountered by conventional base-to-anode cooling. Blower requirements are reduced considerably.

Table 10 also contains the part numbers for air-system sockets and chimneys to be used with the tubes that are listed. The builder should investigate which of the sockets listed for the 4CX250R, 4CX300A, 4CX1000A and 4CX1500A best fit the circuit needs. Some of the sockets have certain tube elements grounded internally through the socket. Others have elements bypassed to ground through capacitors that are integral parts of the sockets.

Depending on one's design philosophy and tube sources, some compromises in the cooling system may be appropriate. For example, if glass tubes are available inexpensively as broadcast pulls, a shorter lifespan may be acceptable. In such a case, an increase of convenience and a reduction in cost, noise and complexity can be had by using a pair of "muffin" fans. One fan may be used for the filament seals and one

**Table 11**

for the anode seal, dispensing with a blower and air-system socket and chimney. The air flow path for this scheme is not as uniform as with the use of a chimney. The tube envelope cylinder mounted in a cross flow has flow stagnation points and low heat transfer in certain regions of the cylinder. These points become hotter than the rest of the envelope. The use of multiple fans to disturb the cross air flow can significantly reduce this problem. Many amateurs have used this cooling method successfully in low-duty-cycle CW and SSB operation, but it is not recommended for AM, SSTV or RTTY service.

The true test of the effectiveness of a forced air cooling system is the amount of heat conducted away from the tube by the air stream. The power dissipated can be calculated from the air flow temperatures. The dissipated power is

$$P = 169Q_A [(T_2/T_1) - 1]$$

where

- P = the dissipated power in watts
- $Q_A$  = the air flow in CFM
- $T_1$  = the inlet air temperature (normally room temperature)
- $T_2$  = the amplifier exhaust temperature.

The exhaust temperature can be measured with a cooking thermometer at the air outlet. The thermometer should not be placed inside the anode compartment because of the high voltage present.

#### Transistor Cooling

Transistors used in power amplifiers dissipate significant amounts of power, and the heat so generated must be effectively removed to maintain acceptable device temperatures. Some bipolar power transistors have the collector connected directly to the case of the device, as the collector must dissipate most of the heat generated when the transistor is in operation. Others have the emitter connected to the case. However, even the larger case designs cannot conduct heat away fast enough to keep the operating temperature of the device within the safe area, the maximum temperature that a device can stand without damage. Safe area is usually specified in a device data sheet, often in graphical form. Germanium power transistors may be operated at up to 100° C while the silicon

**Fig. 25** — Anode compartment pressurization is more efficient than grid compartment pressurization. Air exits through the tube anode, through a chimney, and through the tube socket.

types may be run at up to 200° C. Leakage currents in germanium devices can be very high at elevated temperatures; thus, silicon transistors are preferred for power applications.

A thermal sink, properly chosen, will remove heat at a rate that keeps the transistor junction temperature in the safe area. For low-power applications a simple clip-on heat sink will suffice, while for 100-W input power a massive cast-aluminum finned radiator will be necessary. The appropriate size heat sink can be calculated based on the thermal resistance of the transistor case to ambient temperature. The first step is to calculate the total power dissipated by the transistor:

$$P_D = P_{DC} + P_{RFin} - P_{RFout}$$

where

- $P_D$  = the total power dissipated by the transistor in watts
- $P_{DC}$  = the dc power into the transistor in watts
- $P_{RFin}$  = the RF power into the transistor in watts
- $P_{RFout}$  = the RF output power from the transistor in watts.

The value of  $P_D$  is then used to obtain the  $\theta_{CA}$  value from

$$\theta_{CA} = \frac{T_C - T_A}{P_D}$$

where

- $\theta_{CA}$  = the thermal resistance of the device case to ambient
- $T_C$  = the device case temperature
- $T_A$  = the ambient temperature (room temperature).

A suitable heat sink can then be chosen from the manufacturer's specifications for  $\Theta_{CA}$ . The heat generated by the transistor must be radiated to the ambient by the heat sink so a low  $\Theta_{CA}$  is needed. A well designed heat sink system minimizes thermal path lengths and has a large cross-sectional area. The thermal bonding of the transistor to the heat sink should have minimum thermal loss. In general, the heat sink mounting surface must be flat and the transistor firmly attached to the heat sink so intimate contact is made between the two. The use of thermal silicone based heat sink compounds offer considerable improvement in thermal transfer. The ther-

mal resistance of this grease is considerably less than that of air, but is not nearly as good as that of aluminum. The quantity of grease should be kept to an absolute minimum. Enough should be used only to fill in any air gaps between the transistor and the heat sink surface.

The maximum temperature rise in the transistor junction may easily be calculated by using the equation

$$T_J = (\Theta_{JC} + \Theta_{CA}) P_D + T_A$$

where

$T_J$  = the transistor junction temperature

$\Theta_{JC}$  = the manufacturer's published thermal resistance of the transistor from junction to case

$\Theta_{CA}$  = the thermal resistance of the device case to ambient

$P_D$  = the power dissipated by the transistor

$T_A$  = the ambient temperature.

The value of  $T_J$  must be kept below the manufacturer's recommended junction temperature to prevent transistor failure. Measured values of the ambient temperature and the device case temperature can be used in the preceding formulas to calculate junction temperature.

## Design Guidelines and Examples

Most of the design problems facing an amplifier builder are not theoretical, but have to do with real-world component limitations. There is no such thing as a "pure" resistance or "pure" inductance or capacitance. The tubes and transistors used in RF amplifiers have stray reactances and resistances associated with every element of their construction. Every passive component has stray reactance and resistance to go along with its "advertised" function. Some of these factors can be ignored at some frequencies, but successful design and construction accounts for all of these "facts of life" and their effects.

A simplified equivalent schematic of an amplifying device is shown in Fig. 26A. The input is represented by a resistance in parallel with a capacitance. The output consists of a current generator in parallel with a resistance and capacitance. This is an accurate description of both a transistor and a vacuum tube, regardless of circuit configuration (as demonstrated in Fig. 26B and C). Both the input and output impedances have a resistive component in parallel with a reactive component.

The amplifier input and output matching networks must transform the complex impedances found in the amplifying device to the transmission line impedance (usually 50 ohms). Other impedances associated with the amplifier circuit, such as the impedance of a dc-supply choke, must also be included in the matching-network design. The matching networks and the associated components are influenced by each other's presence, and proper consideration must be made to account for their effects.

Perhaps the best way to explain the design considerations necessary to implement a particular amplifier function is through example. The following examples are representative of the various problems associated with power amplifier design. They are not intended to be detailed con-

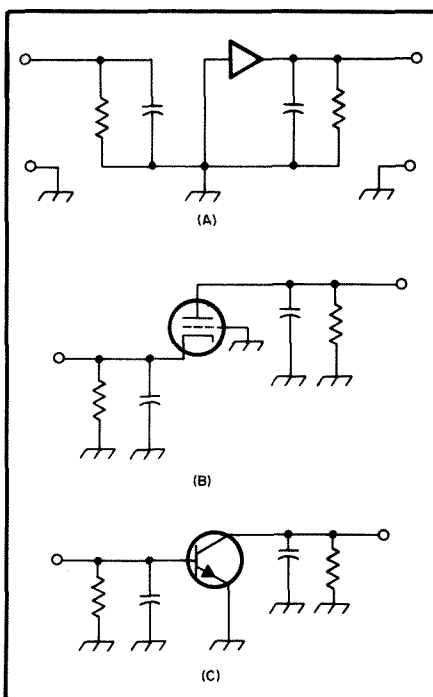

Fig. 26 — The electrical equivalents for power amplifiers. In A, the input is represented by a resistor in parallel with a capacitor and the output is a current source in parallel with another resistor and capacitor. These effects are applied to tubes and transistors in B and C.

struction plans; they only demonstrate the approach one would take in designing similar projects.

### DESIGN EXAMPLE 1: A HIGH-POWER VACUUM TUBE HF AMPLIFIER

Most popular HF transceivers produce approximately 100-W output. According to the manufacturer's specifications, the EIMAC 8877 is a suitable candidate for use in a power amplifier capable of the maximum legal power output with this much ex-

citation. The 8877 can develop 1500-W output for approximately 60-W of drive when used in a grounded grid circuit. Grounded-grid operation is usually the easiest tube amplifier circuit to implement. The input impedance is relatively low, not too different from 50  $\Omega$ . The negative feedback inherent in the grounded-grid configuration reduces the likelihood of amplifier instability. Fewer supply voltages are needed in this configuration compared to others; only high-voltage dc for the plate and low-voltage ac for the filament are needed.

The first step in the amplifier design process is to verify that the tube is actually capable of producing the anticipated results, and still stay within manufacturer's ratings. The plate dissipation expected during normal operation of the amplifier is computed first. Since the amplifier will be used for SSB operation among others, a class of operation producing linear amplification must be used. Class AB operation is a very good compromise between linearity and good efficiency, with an expected efficiency of about 60%. Based on efficiency formulas presented earlier, an input power of 2500 W is needed to produce the desired 1500-W output. Operated under these conditions, the tube dissipates 1000 W — well within the manufacturer's specifications.

The specification for maximum grid current must be adhered to closely in high-mu triodes, for maximum tube life. The grid structure in these tubes is the most fragile element, since it is closely spaced to the cathode and carefully aligned to achieve high current gains. For a fixed level of drive, grid current tends to decrease with increasing plate potential. The maximum plate voltage allowable for the 8877 is specified to be 4000 V. A plate potential of 3500 V is chosen to minimize grid current, which is well within the published guidelines. In order to reach the 2500-W input power, 714 mA of plate current must

be drawn at this plate voltage.

The next step in the design process is to calculate the optimum plate load resistance at this plate voltage and current for Class AB operation. From the earlier equations,  $R_L$  is calculated to be  $3268 \Omega$ . This result is approximate since the value for  $K$  in Class AB is only approximately 1.5. For ease in further calculations, the plate resistance can be rounded off to  $3500 \Omega$ .

The first decision that has to be made is to choose input and output matching networks. Almost any network can be used at the output to transform the  $3500\text{-}\Omega$  plate impedance down to  $50 \Omega$ , but experience shows that the pi and pi-L networks yield the most practical component values. Additionally, these two networks provide reasonable harmonic attenuation. The pi-L does give significantly greater harmonic attenuation than the pi, so it is usually a better choice. The penalty of using a pi-L network is the additional burden of the "L" inductor and band-switching this inductor in multiband amplifiers.

The input impedance of a grounded-grid 8877 is specified to be approximately  $54 \Omega$ . While this is close enough to  $50 \Omega$  to cause only minimal SWR at the input, the impedance varies with drive level. The fluctuating impedance can present problems for the exciter output matching network, increasing the intermodulation distortion level from the exciter. A tank circuit matching network at the amplifier input can stabilize the impedance through its "flywheel effect." The matching circuit must have a  $Q_L$  of at least two for this to occur. The pi network is a suitable choice for this application.

Fig. 27 illustrates these input and output networks applied in the amplifier circuit. The schematic shows the major components in the amplifier RF section, but with band switching omitted.  $C_1$  and  $C_2$  and  $L_1$  form the input pi network.  $C_3$  is a blocking capacitor to keep the cathode dc potential isolated from the exciter.

The filament in an 8877 is in close proximity to the cathode — it has to be to adequately heat the cathode. A capacitance of several picofarads is formed between the two. Particularly at high frequencies where these few picofarads represent a relatively low reactance, RF drive intended for the cathode can be capacitively coupled into the filament, where it becomes heat. To keep the drive where it belongs in the cathode, the filament must be kept at a high RF impedance above ground. The high impedance minimizes RF current flow in the filament circuit; RF dissipated in the filament becomes virtually zero. The dc resistance should be kept to a minimum to lessen voltage drops in the high-current filament circuit.

The best type of choke for use in this application is a pair of heavy gauge bifilar windings over a ferrite rod. The ferrite core raises the inductive reactance throughout the HF region so that a minimum of wire

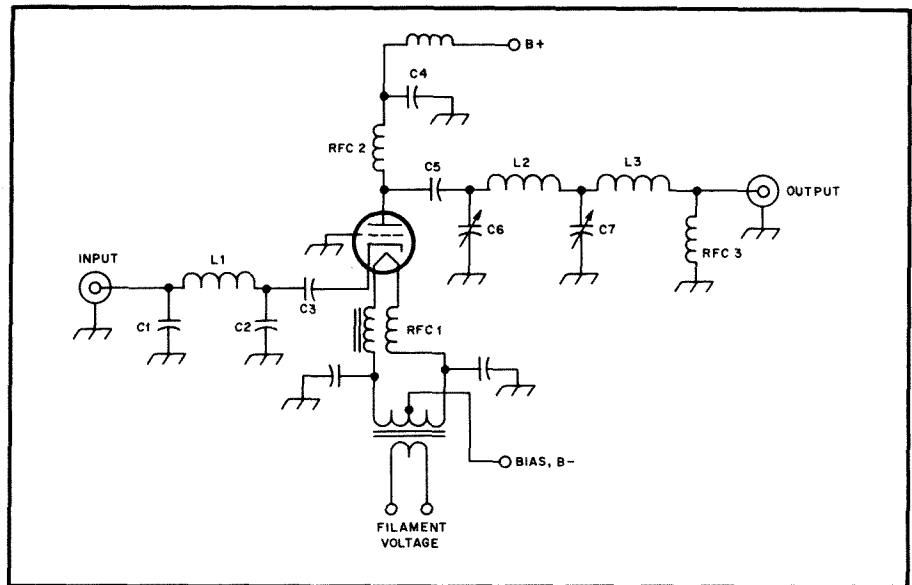

Fig. 27 — A simplified schematic of a grounded-grid amplifier using a pi network input and a pi-L network output.

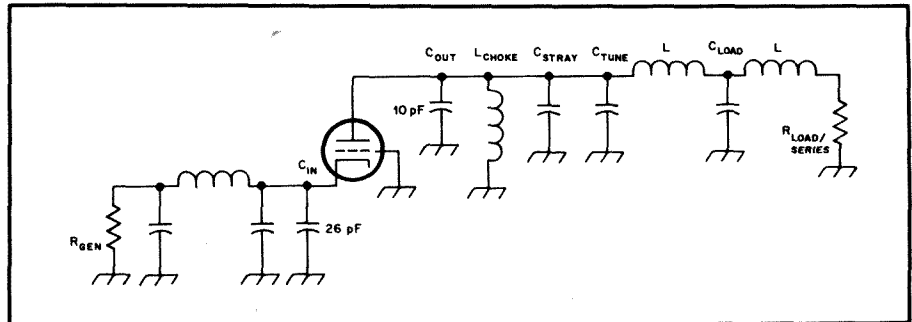

Fig. 28 — The effective reactances for the amplifier in Fig. 27.

is needed, keeping filament-circuit voltage drops low. The bifilar winding technique adds to the bandwidth of the choke and assures that both filament terminals are at the same RF potential.

Plate voltage is supplied to the tube through RFC2.  $C_5$  is the plate blocking capacitor. The output pi-L network is composed of tuning capacitor  $C_6$ , loading capacitor  $C_7$ , pi coil  $L_2$  and L coil  $L_3$ . RFC3 is a high-inductance RF choke placed at the output for safety purposes. Its value, usually 1 to 2 millihenrys, is high enough so that it appears as an open circuit across the output connector for RF. However, should the plate blocking capacitor fail and allow high voltage onto the output matching network, RFC3 would short the dc to ground and blow the power-supply fuse. This prevents dangerous high voltage from appearing on the feed line or antenna.

The next calculations to be made involve the design of the input and output matching networks. The resistances to be matched have already been defined. The tube input resistance is specified by the manufacturer to be  $54 \Omega$ . The calculated plate resistance

is  $3500 \Omega$ . Both have to be transformed to  $50 \Omega$ , the impedance of the connecting cables. Unfortunately, neither of these impedances is purely resistive. As shown in Fig. 26, the tube input and output impedances are composed of both resistance and internal capacitances. These capacitances must be taken into account when designing the matching networks. Additionally, any reactance introduced into the networks by dc supply line chokes and interconnecting leads must be accounted for.

Fig. 28 shows the various reactances in the amplifier circuit. At the tube input, the impedance is  $54 \text{ ohms}$  in parallel with  $C_{IN}$ ,  $26 \text{ pF}$ . In the output circuit  $C_{OUT}$  is the tube output capacitance,  $10 \text{ pF}$ . The reactance presented by the plate choke is shown as  $L_{CHOKE}$ .  $C_{STRAY}$  represents the combined stray capacitances of the interconnecting leads in the output circuit, the enclosure metal work in proximity to the tube, and the parasitic reactances in the tuning capacitor. The rest of the components  $C_{TUNE}$ ,  $C_{LOAD}$  and the two  $L$ s form the pi-L network.

Design of the input matching circuit is straightforward. The pi network circuit equations from Chapter 2 are used to calculate component values. A  $Q_L$  of between two and three should be used. Higher  $Q$  values reduce the network's bandwidth, perhaps requiring the inclusion of a front-panel control for use across an entire amateur band. The purpose of this input network is to stabilize the impedance presented to the exciter, not to offer selectivity. The value of the capacitor at the tube input end of the pi network should be reduced by 26 pF; that value of capacitance is automatically added in parallel to the pi-network capacitor by the tube input impedance.

The output matching network is usually the most difficult section of an amplifier to design. The tables presented earlier in the chapter greatly simplify the effort. Both the pi and pi-L design tables were calculated around a loaded  $Q$  value of 12. Loaded  $Q$ s lower than 10 do not provide adequate harmonic suppression; values much higher than 18 increase matching network losses caused by high circulating currents. A  $Q_L$  value of 12 is a good compromise between harmonic suppression and circuit losses. Theoretical matching network component values can be taken right from the chart for the 3500- $\Omega$  plate impedance. These values can then be adjusted to allow for the previously described circuit reactances.

First, the low frequency component values should be examined. At 3.5 MHz the tuning capacitor value from Table 2 is 174 pF. Fig. 28 shows three reactances directly in parallel with  $C_{TUNE}$ . The tube output capacitance,  $C_{OUT}$ , adds 10 pF directly in parallel to  $C_{TUNE}$ . Strays in the circuit, represented by  $C_{STRAY}$ , also are directly added in parallel to  $C_{TUNE}$ . An exact value for  $C_{STRAY}$  is difficult to define, so an educated guess must be made. In a well constructed, carefully thought out power amplifier,  $C_{STRAY}$  can be estimated to be approximately 10 pF. Between  $C_{OUT}$  and  $C_{STRAY}$ , 20 pF of pi-L network input capacitance is already accounted for. The inductance of the plate choke is also in parallel with  $C_{TUNE}$ . A popular plate choke used in many amplifiers has an inductance of 90  $\mu$ H. At 3.5 MHz this is an inductive reactance of 1979  $\Omega$ . When combined in parallel with the 174 pF (261  $\Omega$  at 3.5 MHz) at the input of the pi-L network, an effective capacitance of 151 pF results. Since the pi-L network requires an effective capacitance of 174 pF at its input, the value of  $C_{TUNE}$  must be increased to compensate for the plate choke inductance. A total capacitance at the pi-L input of 197 pF, in parallel with the 90- $\mu$ H plate choke, gives an effective capacitance of 174 pF. Of the 197 pF required, 10 pF comes from circuit strays, 10 pF comes from  $C_{OUT}$ , and 177 pF must come from the tuning capacitor,  $C_{TUNE}$ . A tuning capacitor with a maximum capacitance

Fig. 29 — The effect of a series inductance in vacuum tube output circuit. In this case, the 3500- $\Omega$  plate resistance is transformed down to 1481 ohms.

around 200 pF should be used to allow for loads with higher than a 1:1 SWR.

The component values for the high end of the amplifier frequency range should also be examined. At 29.7 MHz, Table 2 calls for an input capacitance of 18 pF. Since  $C_{OUT}$  and  $C_{STRAY}$  already account for 20 pF of pi-L input capacitance, a problem exists. Nothing can be done to reduce  $C_{OUT}$ ;  $C_{STRAY}$  presumably is at a minimum also. Additionally, the tuning capacitor probably has a minimum capacitance around 15 pF. The minimum circuit capacitance found at the pi-L input is already 35 pF, nearly twice the required value.

There are potentially three solutions to this dilemma. The first is probably the simplest to implement. A higher loaded  $Q$  for the pi-L network will require more capacitance at the input. Raising  $Q_L$  to 24 changes the input capacitance requirement to 36 pF, which is within the range of the circuit as described. Many amplifier builders, both commercial and amateur, take this approach. The major drawback is substantially increased tank circuit losses caused by the increased  $Q$ .

Another potential solution is to reduce the minimum capacitance provided by  $C_{TUNE}$ . Vacuum variable capacitors have minimum capacitances as low as three to five pF, and can be used at  $C_{TUNE}$ . This reduces the minimum effective circuit capacitance to 25 pF. A pi-L network with a loaded  $Q$  of 17 needs only 26 pF at its input. While not optimum, a  $Q_L$  of 17 is perfectly acceptable from a tank circuit loss perspective. Unfortunately, vacuum variables are very expensive and cumbersome mechanically.

A third possibility is the use of an additional reactance in the output circuit. An inductance connected in series between the tube and the tuning capacitor will act as an L network in conjunction with  $C_{OUT}$  and transform the plate load resistance to a lower value. This is shown in Fig. 29. Lower input impedance-matching networks require higher input capacitances while maintaining a  $Q_L$  of 12. For example, a matching network designed for a plate impedance of 1500  $\Omega$  requires 43 pF of input capacitance at 29.7 MHz. In order to

calculate the L network, the series equivalent impedance for the tube must be computed. The plate impedance is 3500  $\Omega$  in parallel with 10 pF ( $C_{OUT}$ ). At 10 meters, this is 3500  $\Omega$  in parallel with  $-j535$  ohms.

Using the equivalence formulas described earlier, this converts to an equivalent series impedance of  $80 - j523$   $\Omega$ . A 1- $\mu$ H inductor, having an impedance of  $j187$  ohms at 29.7 MHz, can be added as the series inductance for the L network. A series equivalent resistance of  $80 - j523$  plus  $j187$  or  $80 - j336$   $\Omega$  results. This converts to an equivalent parallel impedance of 1491  $\Omega$  in parallel with  $-j355$   $\Omega$ , which is equal to 1491 ohms (rounded to 1500  $\Omega$ ) in parallel with 15 pF at 29.7 MHz. This new impedance is what the pi-L must now match.  $C_{OUT}$  is now effectively 15 pF, and when combined with the 10 pF of  $C_{STRAY}$  and the 15 pF minimum capacitance of  $C_{TUNE}$ , gives an effective input capacitance of 40 pF.  $C_{TUNE}$  must be adjusted to a value of 18 pF to give the required pi-L input capacitance of 43 pF for this new impedance level. The L inductor should be a high- $Q$  coil wound from copper tubing to keep losses low. The L inductor has a decreasing yet significant effect on progressively lower frequencies. A similar calculation to the above should be made on each band to determine the transformed equivalent plate impedance, before referring to Table 2.

The 90- $\mu$ H plate choke still remains in parallel with  $C_{TUNE}$ . At 29.7 MHz its impedance is in excess of 16,000 ohms and has very little effect on the RF characteristics of the circuit.

An analysis like this should be performed on every band the amplifier will operate on. Only then can the actual impedance levels be calculated and acted upon. Since the other components in the circuit, L2, L3 and C7, have no other reactances associated with them, their use is straightforward.

This amplifier is made operational on multiple bands by switching in additional inductances for L2 and L3 as the operating frequency is lowered. The usual practice is to use a shorting switch that will short out the unused portions of the total inductors for the band in use. The wiring to the switch and the switch itself add stray inductance and capacitance to the circuit. To minimize these effects at the higher frequencies, the unswitched 10-meter L2 should be placed closest to the high-impedance end of the network at C6. The effects of stray reactance diminish as the impedance level goes down. Reactances associated with the switch are effectively placed in parallel with C7 where the impedance level is between 300 and 700 ohms. The coil taps are best determined in an empirical fashion.

The impedance match in both the input and output networks can be checked without applying dc voltage, once the amplifier is built. In actual operation, the

tube input and output resistances are the product of current flow through the tube. Without dc present, these resistances don't exist; the tube is an open circuit for dc. The input and output resistances can be easily simulated by ordinary quarter- or half-watt resistors (not wirewound, though; they are more inductive than resistive at RF). Resistors having the same value as the input and output resistances, connected in parallel with the tube input and output, present the same termination resistances to the matching networks as the tube does in operation.  $C_{IN}$  and  $C_{OUT}$  are physical properties of the tube, and are there whether dc is applied or not.

With the termination resistors in place, the impedance matches achieved by the matching networks can be measured by means of a noise bridge or return loss measurement set-up. For measuring the input match, the bridge is connected to the amplifier input. The matching network can then be adjusted for the desired match. To measure the output match, the bridge is connected to the amplifier output. Since the output matching network is bilateral (it works in both directions), the matching effectiveness of the network can be measured in either direction; obviously it's easier to measure from the 50- $\Omega$  end of the network. The taps on the inductors are then determined experimentally, adjusting the taps and the variable capacitors for best match. Once the best tap points are found, the connecting wires can be soldered in place and the termination resistors removed. The amplifier is now ready for full-voltage testing.

### Design Example 2: A Medium Power 144-MHz Amplifier

For several decades the 4CX250 family of power tetrodes has been used successfully up through 500 MHz. The latest versions in the family are still state-of-the-art products. They are relatively inexpensive, produce high gain and lend themselves to relatively simple amplifier designs. In amateur service at VHF, the 4CX250 is a particularly attractive choice for an amplifier. Most VHF exciters used now by amateurs are solid-state and usually develop 10 W or less output. The drive requirement for the 4CX250 in grounded cathode, Class AB operation ranges between 2 and 8 watts for full power output, depending on frequency. At 144 MHz, manufacturer's specifications suggest an available output power of over 300 W. This is clearly a substantial level improvement over 10 W, so a 4CX250B will be used in this amplifier.

The first design step is the same as performed in the previous example — verify that the proposed tube will perform as desired while staying within the manufacturer's ratings. Again assuming a basic amplifier efficiency of 60% for Class AB operation, 300 W of output requires a plate input power of 500 W. Tube dissipation is

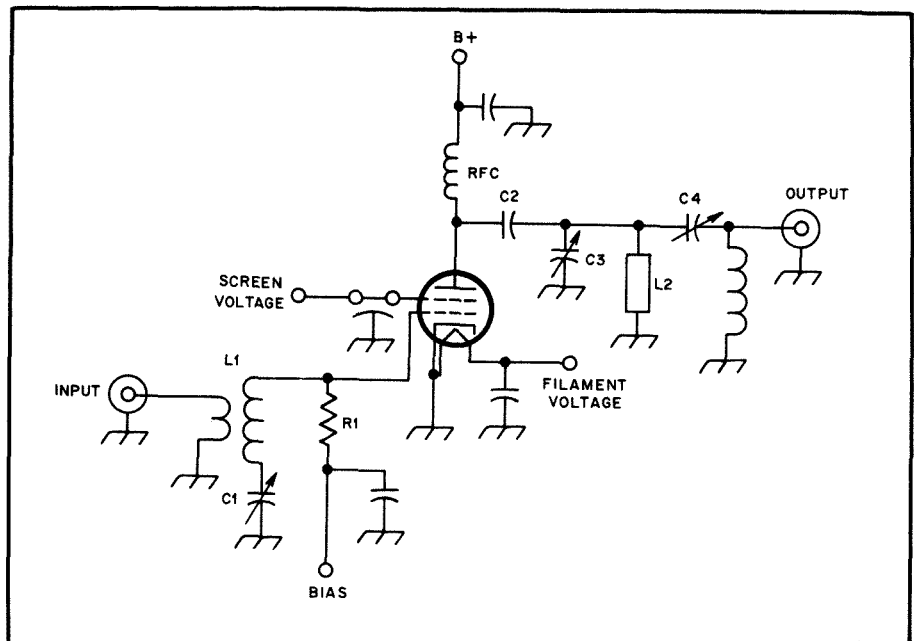

Fig. 30 — The simplified schematic for a VHF power amplifier using a power tetrode. The output circuit is a parallel-tuned tank circuit with series reactance output matching.

rated at 250 W, so plate dissipation is apparently not a problem as the tube will only be dissipating 200 W in this amplifier. The recommended maximum plate potential is 2000 V; the tube will be running near its maximum ratings. Plate current for 500-W input is then 250 mA, which is within the manufacturer's ratings. The plate load resistance can now be calculated. Using the same formula as before, the value is determined to be 5333  $\Omega$ .

The next step is to investigate the output circuit. The manufacturer's specification for  $C_{OUT}$  is 4.7 pF. The inevitable circuit strays along with the tuning capacitor add to the circuit capacitance. A carefully built amplifier might only have 7 pF of stray capacitance, and a specially-made tuning capacitor can be fabricated to have a mid-range value of 3 pF. The total circuit capacitance adds up to about 15 pF. At 144 MHz this represents a capacitive reactance of only 74  $\Omega$ . The  $Q_L$  of a tank circuit with this reactance in parallel with a plate load resistance of 5333  $\Omega$  is over 72. A pi output matching network would be totally impractical. The L required would be extremely small and circuit losses would be prohibitive. The best solution is the simplest: Connect an inductor in parallel with the circuit capacitance to form a parallel-resonant tank circuit.

To keep tank circuit losses low with such a high  $Q_L$ , a very high Q inductor must be used. The lowest loss inductors are formed from transmission line sections. These can take the form of either coaxial lines or strip lines. Both have their advantages and disadvantages, but the strip line is so much easier to fabricate that it is almost exclusively used in VHF tank circuits today.

The reactance of a terminated transmis-

sion line section is a function of both its characteristic impedance and its length (see Chapter 16). The reactance of a line terminated in a short circuit is

$$X_{in} = Z_0 \tan \ell$$

where

$X$  = is the circuit reactance

$Z_0$  = the line impedance

$\ell$  = the transmission line length in degrees.

For lines shorter than a quarter wavelength ( $90^\circ$ ) the circuit reactance is inductive.

In order to resonate with the tank circuit capacitive reactance the transmission line reactance must be the same value, but inductive. This requires an inductive reactance of 74 ohms. Examination of the formula for transmission-line circuit reactance suggests that a wide range of lengths can yield the same inductive reactance as long as the line  $Z_0$  is appropriately scaled. Based on circuit Q considerations, the best bandwidth in a tank circuit results when the ratio of  $Z_0$  to  $X_{in}$  is between one and two. This implies that transmission line lengths between  $26.5^\circ$  and  $45^\circ$  give the best bandwidth. Between these two limits, and with some adjustment of  $Z_0$ , practical transmission lines can be designed. A transmission line length of  $35^\circ$  is 8 inches long at 144 MHz, which is a workable dimension mechanically. Substitution of this value into the transmission line equation gives a  $Z_0$  of 105  $\Omega$  for the transmission line.

The width of the strip line and its placement relative to the ground planes determine the line impedance. Other stray capacitances such as mounting standoffs

Fig. 31 — Series reactance matching as applied to the amplifier in Fig. 30.

also affect the impedance. Accurate calculation of the line impedance for most physical configurations requires extensive application of Maxwell's equations and is beyond the scope of this book. The specialized case in which the strip line is parallel to and located halfway between two ground planes has been documented in *ITT Reference Data for Radio Engineers*. According to charts presented in that book, a 105- $\Omega$  strip line impedance is obtained by placing a line with a width of approximately 0.4 times the ground plane separation halfway between the ground planes. Assuming the use of a standard 3-inch-deep chassis for the plate compartment, this yields a strip line width of 1.2 in. A strip line 1.2 in. wide located 1.5 in above the chassis floor and grounded at one end has an inductive reactance of 74 ohms at 144 MHz.

The resulting amplifier schematic diagram is shown in Fig. 30.  $L_2$  is the strip-line inductance just described.  $C_3$  is the tuning capacitor, made from two parallel brass plates whose spacing is adjustable. One of the plates is connected directly to the strip line while the other is connected to ground through a wide, low-inductance strap.  $C_2$  is the plate blocking capacitor. This can be either a ceramic doorknob capacitor such as the Centralab 850 series or a homemade "Teflon sandwich." Both are equally effective at 144 MHz.

Impedance matching from the plate resistance down to 50 ohms can be either through an inductive link or through capacitive reactance matching. Mechanically, the capacitive approach is simpler to implement. Fig. 31 shows the development of reactance matching through a series capacitor ( $C_4$  in Fig. 30). By using the parallel equivalent of the capacitor in series with the 50- $\Omega$  load, the load resistance can be transformed to the 5333- $\Omega$  plate resistance. Substitution of the known values into the parallel-to-series equivalence formulas reveals that a 2.15 pF capacitor at  $C_4$  matches the 50- $\Omega$  load to the plate resistance. The resulting parallel equivalent for the load is 5333  $\Omega$  in parallel with 2.13 pF. The 2.13-pF capacitor is effectively in parallel with the tank circuit.

A new plate line length must now be calculated to allow for the additional capacitance. The equivalent circuit diagram containing all the various reactances is shown in Fig. 32. The total circuit capacitance is now just over 17 pF, which

Fig. 32 — The reactances and resistances for the amplifier in Fig. 30.

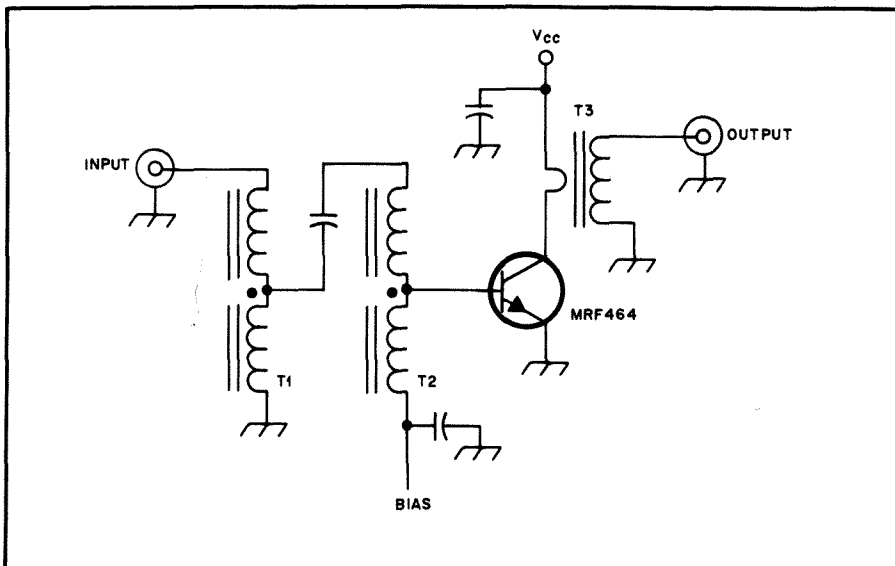

Fig. 33 — A simplified schematic of a broadband HF transistorized power amplifier. T1 and T2 are 4:1 broadband transformers to match the low input impedance of the transistor.

is a reactance of 64  $\Omega$ . Keeping the strip-line width and thus its impedance constant at 105  $\Omega$  dictates a new resonant line length of  $31^\circ$ . This calculates to be 7.14 in for 144 MHz.

The alternative coupling scheme is through the use of an inductive link. The link can be either tuned or untuned. The length of the link can be estimated based on the amplifier output impedance, in this case 50  $\Omega$ . For an untuned link, the inductive reactance of the link itself should be approximately equal to the output impedance, 50  $\Omega$ . For a tuned link, the length depends on the link  $Q_L$ . The link  $Q_L$  should generally be greater than two, but usually less than five. For a  $Q_L$  of three this implies a capacitive reactance of 150  $\Omega$ , which at 144 MHz is just over 7 pF. The self inductance of the link should of course be such that its impedance at 144 MHz is 150  $\Omega$  (0.166  $\mu$ H) at 144 MHz. Adjustment of the link placement determines the transformation ratio of the circuit line. Some fine adjustment of this parameter can be made through adjustment of the link series tuning capacitor. Placement of the

link relative to the plate inductor is an empirical process.

The input circuit is shown in Figs. 30 and 32.  $C_{IN}$  is specified to be 18.5 pF for the 4CX250. This is only 60  $\Omega$  at 2 meters, so the pi network again is unsuitable. Since a surplus of drive is available with a 10-W exciter, circuit losses at the amplifier input are not as important as at the output. An old-fashioned "split stator" tuned input can be used.  $L_1$  in Fig. 30 is series tuned by  $C_{IN}$  and  $C_1$ . The two capacitors are effectively in series (through the ground return). A 20-pF variable at  $C_1$  set to 18.5 pF gives an effective circuit capacitance of 9.25 pF. This will resonate at 144 MHz with an inductance of 0.13  $\mu$ H at  $L_1$ .  $L_1$  can be wound on a toroid core for mechanical convenience. The 50- $\Omega$  input impedance is then matched by link coupling to the toroid. The grid impedance is primarily determined by the value for  $R_1$ , the grid bias feed resistor.

### Design Example 3: A Broadband HF Solid-State Amplifier

Linear power amplifier design using

transistors at HF is a fundamentally simple process. An appropriate transistor meeting the desired design specifications is selected on the basis of dissipation and power output. The transistor manufacturers greatly simplify the design by specifying each RF power transistor according to its frequency range and power output. The amplifier designer need only match to the device input and output and provide appropriate dc bias currents to the transistor.

The Motorola MRF464 is an RF power transistor capable of 80-W PEP output with low distortion. Its usable frequency range is up through 30 MHz. At a collector potential of 28 V, a collector efficiency of 40% is possible.

Fig. 33 shows the schematic diagram of a 2- to 30-MHz broadband linear amplifier using the MRF464. The input impedance of the transistor is specified by the manufacturer to be  $1.4 - j0.30 \Omega$  at 30 MHz and drops down to  $9.0 - j5.40$  at 2 MHz. Transformers T1 and T2 match the 50-ohm amplifier input impedance to an approximate median value of the transistor input impedance. They are both 4:1 step-down ratio transmission-line transformers. A single 16:1 transformer could be used in place of T1 and T2, but 16:1 transformers are more difficult to fabricate for broadband service.

The manufacturer specifies the transistor output resistance to be approximately 6 ohms (in parallel with an equivalent output capacitance) across the frequency range. T3 is a ferrite-loaded conventional transformer with a step-up ratio of approximately 8:1. This matches the transistor output to 50  $\Omega$ .

The amplifier has a falling gain characteristic with rising frequency. To flatten out the gain across the frequency range, negative feedback could be applied. However, most power transistors have highly reactive input impedances and large phase errors would occur in the feedback loop. Instability could potentially occur.

A better solution is to use an input correction network. This network is used as a frequency-selective attenuator for amplifier drive. At 30 MHz, where transistor gain is least, the input power loss is designed to be minimal (less than 2 dB). The loss increases lower in frequency to compensate for the increased transistor gain. The MRF464 has approximately 12 dB more gain at 1.8 MHz than at 30 MHz; the compensation network is designed to have 12 dB loss at 1.8 MHz. A properly designed compensation network will result in an overall gain flatness of approximately 1 dB.

## AMPLIFIER STABILIZATION

### Stable Operating Conditions

Purity of emissions and the useful life of the active devices in a tube or transistor circuit depend heavily on stability during operation. Oscillations can occur at the

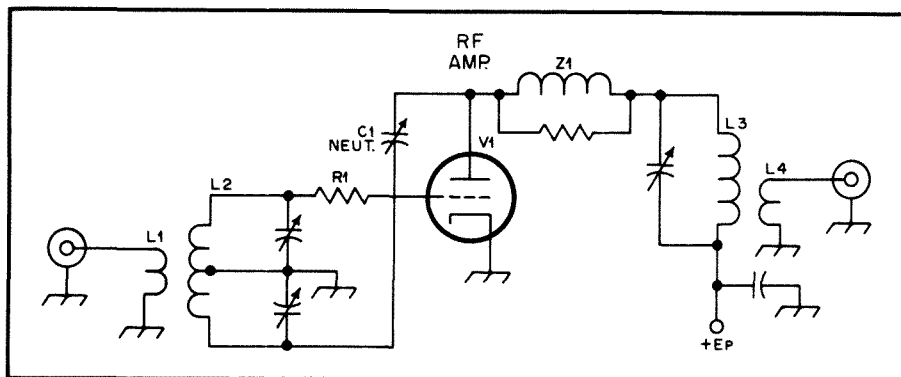

Fig. 34 — Single-ended, neutralized RF amplifier. Z1 is a parasitic suppressor, see text.

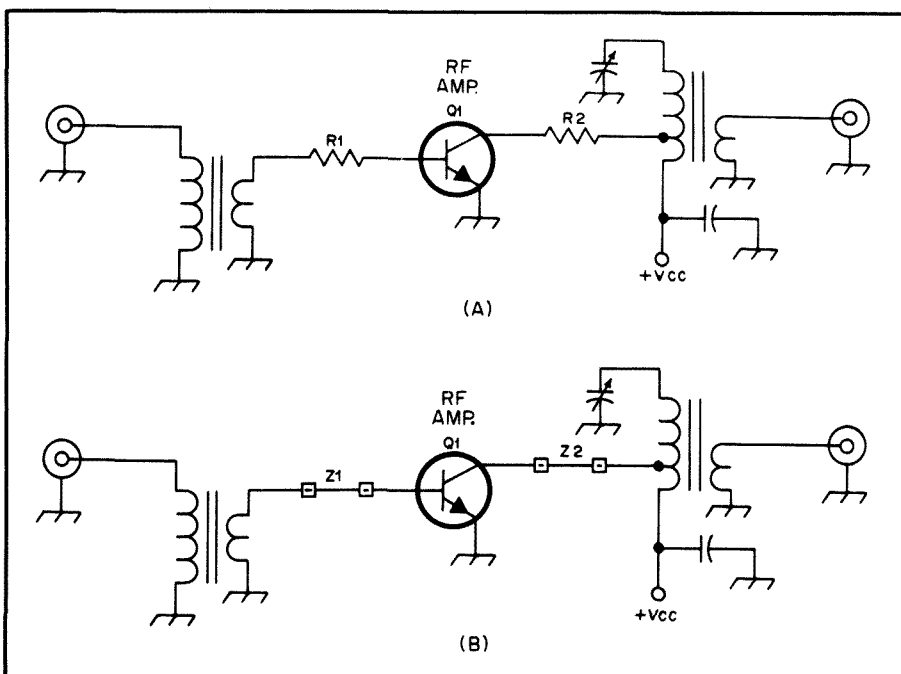

Fig. 35 — Suppression methods for VHF and UHF parasitics in solid-state amplifiers.

operating frequency or far from it because of undesired positive feedback in the amplifier. Unchecked, these oscillations pollute the RF spectrum and can lead to tube or transistor overdissipation and subsequent failure. Each type of oscillation has its own cause and its own cure.

A linear amplifier operates with its input and output circuits tuned to the same frequency. Unless the coupling between these two circuits is kept to a minimum, some energy from the output will be coupled in phase back to the input and the amplifier will oscillate. Care should be used in arranging components and wiring of the two circuits so that there will be negligible opportunity for coupling external to the tube or transistor itself. Complete shielding between input and output circuits usually is required. All RF leads should be kept as short as possible, and particular attention should be paid to the RF return paths from

input and output tank circuits to emitter or cathode.

In general, the best arrangement using a tube is one in which the input circuit and the output circuit are on opposite sides of the chassis. Individual compartments for the input and output circuitry add to the isolation. Transistor circuits are somewhat more forgiving, since all the impedances are relatively low. However, the high currents found on most amplifier circuit boards can easily couple into unintended circuits. Proper layout, the use of double-sided circuit board material (with one side used exclusively as a ground plane and low-inductance ground return), and heavy doses of bypassing on the dc supply lines can keep most solid-state amplifiers from oscillating.

### VHF and UHF Parasitic Oscillations

Z1 of Fig. 34 is a parasitic choke. This network will help dampen oscillations at

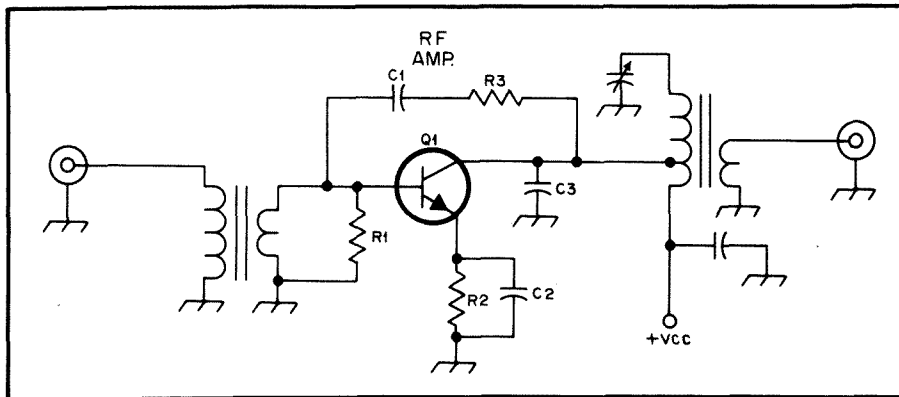

Fig. 36 — Illustration of shunt feedback in a transistor amplifier. C1 and R3 comprise the feedback network.

VHF and UHF. It acts as a high series impedance at these frequencies to break up the unwanted VHF/UHF circuit path causing oscillation. Z1 consists of a non-inductive resistor, between 51 and 100  $\Omega$ , with a coil wound around the resistor body. This forms a broadband RF choke that presents a high impedance at VHF and higher, but looks like a low reactance in the HF region and lower. The resistance in parallel with the inductor lowers the Q of the choke, and dissipates undesired VHF energy.

A typical parasitic suppressor for a power level up to 150 W uses 6 to 8 turns of no. 20 wire wound around a 56- $\Omega$ , 1-W composition resistor. The coil ends are soldered to the resistor pigtails near the body of the resistor. Z1 is then placed in series with the output circuit, as close to the tube plate pin or cap as possible. For higher RF powers a high-wattage Global resistor, or a 25-W noninductive (NIT) power resistor in parallel with the minimum inductance that will stop the oscillations should be used. Larger inductances will affect operation at the upper end of HF (particularly 10 meters). A few turns of no. 12 or 14 wire around the resistor body should suffice. Additional parasitic suppression can be attained, if needed, by connecting a low value resistor (10 to 51  $\Omega$ ) in series with the tube input, near the tube socket. This is illustrated by R1 of Fig. 34.

Parasitic oscillations can be dampened in low-power solid-state amplifiers by using a small amount of resistance in series with the base or collector lead as shown in Fig. 35A. The value of R1 or R2 typically should be between 10 and 22  $\Omega$ . The use of both resistors is seldom necessary, but an empirical determination must be made. R1 or R2 should be located as close to the transistor as practical.

At power levels in excess of approximately 0.5 W, the technique of parasitic suppression shown in Fig. 35B is effective. The voltage drop across a resistor would be prohibitive at the higher power levels, so one or more ferrite beads placed over

connecting leads can be substituted (Z1 and Z2). A bead permeability of 125 presents a high impedance at VHF and above without affecting HF performance. The beads need not be used at both circuit locations. Generally, the terminal carrying the least current is the best place for these suppression devices. This suggests that the resistor or ferrite beads should be connected in the base lead of the transistor.

C3 of Fig. 36 can be added to some power amplifiers to dampen VHF/UHF parasitic oscillations. The capacitor should be low in reactance at VHF and UHF, but must present a high reactance at the operating frequency. The exact value selected will depend upon the collector impedance. A reasonable estimate is to use an  $X_c$  of 10 times the collector impedance at the operating frequency. Silver-mica or ceramic chip capacitors are suggested for this application. An additional advantage is seen in the bypassing action for VHF and UHF harmonic energy in the collector circuit. C3 should be placed as close to the collector terminal as possible, using short leads. The effects of C3 in a broadband amplifier are relatively insignificant at the operating frequency. However, when a narrow band collector network is used, the added capacitance of C3 must be absorbed into the network design in the same manner as the  $C_{OUT}$  of the transistor.

#### Low-Frequency Instability

Bipolar transistors exhibit a rising gain characteristic as the operating frequency is lowered. To preclude low-frequency instabilities because of the high gain, shunt and degenerative feedback are often used. In the regions where low-frequency self-oscillations are most likely to occur, the feedback increases by nature of the feedback network, reducing the amplifier gain. In the circuit of Fig. 36, C1 and R3 provide negative feedback, which increases progressively as the frequency is lowered. The network has a small effect at the desired operating frequency but has a pronounced effect at the lower frequencies.

Fig. 37 — The equivalent feedback path due to the internal capacitance of the tube grid plate structure in a power amplifier.

The values for C1 and R3 are usually chosen experimentally. C1 will usually be between 220 pF and 0.0015  $\mu$ F for HF-band amplifiers while R3 may be a value from 51 to 5600  $\Omega$ .

R2 of Fig. 36 develops emitter degeneration at low frequencies. The bypass capacitor, C2, is chosen for adequate RF bypassing at the intended operating frequency. The impedance of C2 rises progressively as the frequency is lowered, thereby increasing the degenerative feedback caused by R2. This lowers the amplifier gain. R2 in a power stage is seldom greater than 10  $\Omega$ , and may be as low as 1  $\Omega$ . It is important to consider that under some operating and layout conditions R2 can cause instability. This form of feedback should be used only in those circuits in which unconditional stability can be achieved.

R1 of Fig. 36 is useful in swamping the input of an amplifier. This reduces the chance for low-frequency self-oscillations, but has an effect on amplifier performance in the desired operating range. Values from 3 to 27  $\Omega$  are typical. When connected in shunt with the normally low base impedance of a power amplifier, the resistors lower the effective device input impedance slightly. R1 should be located as close to the transistor base terminal as possible, and the connecting leads must be kept short to minimize stray reactances. The use of two resistors in parallel reduces the amount of inductive reactance introduced compared to a single resistor.

Although the same concepts can be applied to tube-type amplifiers, the possibility of self-oscillations at frequencies lower than VHF is significantly lower than in solid-state amplifiers. Tube amplifiers will usually operate stably as long as the input-to-output isolation is greater than the stage gain. Proper shielding and dc power lead bypassing essentially eliminate feedback paths, except for those through the tube itself.

#### Amplifier Neutralization

Depending on the inner electrode capacitances of tubes, a neutralization circuit may be necessary. Output energy can be capacitively coupled back to the input

as shown in Fig. 37. Neutralization involves coupling a small amount of the output energy (which by the tube phase relationships is out of phase with the input energy) and feeding it back to the amplifier input. There the neutralization circuit energy cancels the unwanted in-phase (positive) feedback. A typical circuit is given in Fig. 38. L2 provides a 180° phase reversal because it is center tapped. C1 is connected between the plate and the lower half of the grid tank. C1 is then adjusted so that the energy coupled from the tube output through the neutralization circuit is equal in amplitude and exactly 180° out of phase with the energy coupled from the output back through the tube. The two signals then cancel and the oscillation ceases.

The easiest way to adjust a neutralization circuit is to connect an RF source to the amplifier output tuned to the amplifier operating frequency. An RF detector of some kind is then connected to the amplifier input. The amplifier should remain turned off for this test. The amplifier tuning and loading controls, as well as any input network adjustments should then be peaked for maximum indication on the RF detector connected at the input. C1 is then adjusted for minimum response on the detector. This null indicates that the neutralization circuit is canceling energy coupled back to the amplifier input through the tube (or transistor) internal capacitances.

#### Screen-Grid Tube Neutralizing Circuits

The plate-to-grid capacitance in a screen-grid tube is reduced to a fraction of a picofarad by the interposed grounded screen. Nevertheless, the power sensitivity of these tubes is so great that only a very small amount of feedback is necessary to start oscillation. To assure a stable tetrode amplifier, it is usually necessary to load the grid circuit, or to use a neutralizing circuit.

A capacitive neutralizing system for screen-grid tubes is shown in Fig. 39. C1 is the neutralizing capacitor. The value of C1 should be chosen so that at some adjustment of C1,

$$\frac{C_1}{C_3} = \frac{\text{Tube grid-plate capacitance (or } C_{gp})}{\text{Tube input capacitance (or } C_{IN})}$$

The grid-to-cathode capacitance must include all strays directly across the tube capacitance, including the capacitance of the tuning capacitor stator to ground. This may amount to 5 to 20 pF.

#### Grid Loading

The use of a neutralizing circuit may often be avoided by loading the grid circuit if the driving stage has some power capacity to spare. Loading by tapping the grid down on the grid tank coil or by a resistor from grid to cathode is effective in stabiliz-

Fig. 38 — Example of neutralization of a single-ended RF amplifier.

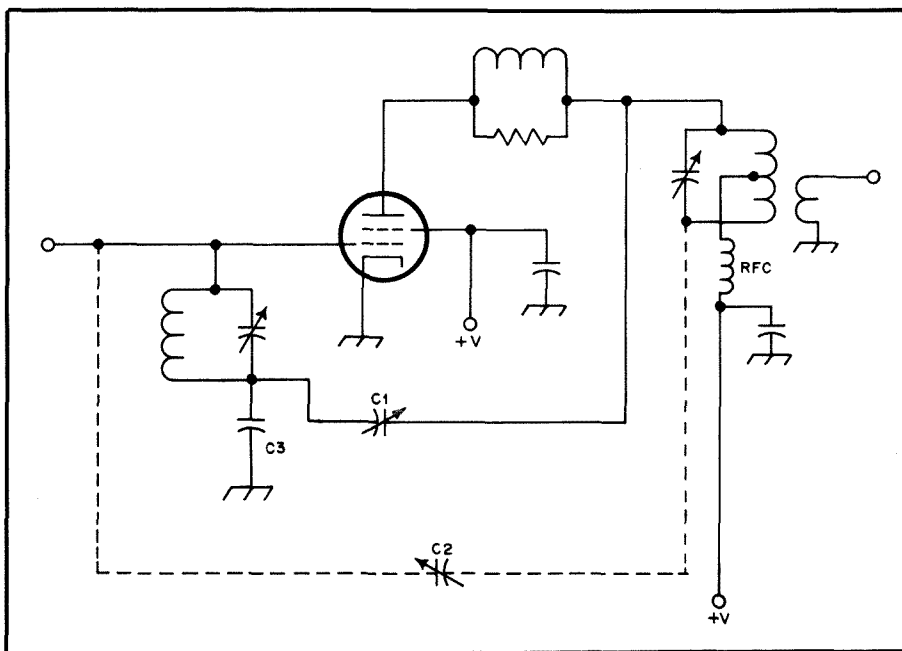

Fig. 39 — A neutralization circuit may use either C1 or C2 to cancel the effect of the tube internal capacitance.

ing an amplifier. Either measure reduces the gain and the sensitivity of the amplifier somewhat, lessening the possibility of oscillation. Substitution of a resistor for the grid circuit bias supply choke accomplishes the same goal.

# Transmission Lines

The place where RF power is generated is very frequently not the place where it will be used. A transmitter and its antenna are a good example. To radiate well, the antenna should be high above the ground and should be kept clear of trees, buildings and other objects that might absorb energy. The transmitter itself, however, is most conveniently installed indoors, where it is readily accessible.

A *transmission line* is the means by which RF energy is conveyed from one point to another. The types of transmission lines include simple two-conductor configurations, such as the familiar coaxial cable and TV parallel-wire line. Such lines are useful from power-line frequencies to well into the microwave region, and they form the most commonly used class. Waveguide is representative of a second type. Here the conductor configuration is complex, and ordinary concepts such as voltage and current tend to become obscure. As a consequence, various waveguide parameters are expressed in terms of the electric and magnetic fields associated with the line. The propagation of electromagnetic energy through waveguides is closely related to similar phenomena in space itself.

## Transmission Lines and Circuits

A transmission line differs from an ordinary circuit in one very important aspect. *Propagation delays* exist from one end of the transmission line to the other. The speed at which electrical energy travels, while tremendously high when compared to mechanical motion, is not infinite. Propagation times are often of no significance in circuit design, as the layout dimensions are small in terms of signal wavelength. This is not true for transmission-line considerations, where finite propagation time becomes a factor of paramount importance. This is illustrated in Fig. 1. A transmission line connects a source at point S to a load at point L, separated by a distance  $\ell$ .

Suppose that the distance  $\ell$  is 300 meters (nearly 1000 feet). Also suppose for a moment that the source is a battery, rather than the RF generator shown at the left in Fig. 1. At the instant the battery is connected to the two wires of the transmission line, an electric current can be detected in

Fig. 1—Source and load connected by means of a transmission line. VF (velocity factor) and  $Z_0$  (characteristic impedance) are properties of the line, as discussed in the text.

the wires near the battery terminals. This current does not flow instantaneously throughout the length of the wires, however.

The electric field that causes the current cannot travel faster than the speed of light, so a measurable interval of time elapses before the currents become evident even a relatively short distance away. The current could not be detected at the load, 300 meters away, until one microsecond (one millionth of a second) after the connection was made. By ordinary standards this is a very short length of time, but in terms of radio frequencies it represents the time for one complete cycle of a 1-MHz radio signal. It also represents the time for 10 complete cycles of a 10-MHz signal.

In a practical transmission line the energy travels somewhat slower than the speed of light (typically from 65 to 97 percent of light speed), depending on the type of transmission line. This line characteristic is called the *velocity factor* (VF) of the line.

The transmission-line current charges the capacitance between the two wires. The conductors of this "linear" capacitor also have inductance, however. The transmission line may be thought of as being composed of a whole series of small inductors and capacitors connected as shown in Fig. 2. Each inductor represents the inductance of a very short section of one wire, and each capacitor represents the capacitance between two such short sections.

## CHARACTERISTIC IMPEDANCE

Consider an infinitely long chain of inductors and capacitors connected as shown in Fig. 2. All the small inductors have the same value, as do all the small capacitors. This line has an important property. To an electrical impulse applied at one end, the combination appears to have an impedance. This is called the *characteristic impedance* or *surge impedance*, often abbreviated  $Z_0$ . Its value is approximately equal to  $\sqrt{L/C}$ , where L and C are the inductance and capacitance per unit length.

In the equivalent transmission line of Fig. 2 there are no resistors, and thus no power is lost in the line. In this case,  $Z_0$  becomes a pure resistance,  $R_0$ . (Lost power is represented by  $I^2R$ , or power dissipated in the line.) With no resistance, there is no power loss no matter what the line length may be. This may not seem consistent with calling the impedance a pure resistance, because the word *resistance* implies that some power will be dissipated if current flows. But with an infinitely long line, the effect (as far as the source of power is concerned) is exactly the same as if the line were replaced by a pure resistance. This is because the energy leaves

Fig. 2—Equivalent of a transmission line in lumped circuit constants.

the source and travels outward forever along the line.

The characteristic impedance of a line determines the amount of current that can flow when a given voltage is applied to an infinitely long line. The impedance limits the flow of current in the same way that a definite value of actual resistance limits current flow when a voltage is applied.

All practical transmission lines exhibit some power loss. These losses occur in the resistance that is inherent in the conductors that make up the line, and from leakage currents flowing in the dielectric material between the conductors. Because of these losses, the characteristic impedance (or  $Z_0$ ) of practical lines contains a small reactive component. This component is usually capacitive, but it is small enough that its effects may be disregarded in Amateur Radio applications.

The inductance and capacitance per unit length of line depend on the size of the conductors and the spacing between them. The smaller the spacing between the two conductors and the greater their diameter, the higher the capacitance and the lower the inductance. A line with closely spaced large conductors will have low impedance, while one with widely spaced small conductors will have relatively high impedance.

### Matched Lines

Actual transmission lines do not extend to infinity, but have a definite length. In use they are connected to, or *terminate* in, a load at the output end of the line, as illustrated in Fig. 1. If the load is a pure resistance of a value equal to the characteristic impedance of the line, the line is said to be *matched*. To current traveling along the line, such a load just looks like still more transmission line of the same characteristic impedance.

In other words, a short line terminated in a purely resistive load equal to the characteristic impedance of the line acts just as if the line was infinitely long. In a matched transmission line, energy travels outward along the line from the source until it reaches the load, where it is completely absorbed.

### RF on Lines

Assume now that a very short burst of power is emitted from the source in Fig. 1. This is represented by the vertical line at the left of the series of lines in Fig. 3. As the pulse voltage appears across the load  $Z_a$  of Fig. 1, all the energy may be absorbed, or part of it may be reflected in much the same manner that energy in a water wave is reflected as the wave hits a steep breakwater or the end of a container. This reflected wave is represented by the second line in the series, and the arrow above the line indicates the direction of travel. As the second wave reaches the source, the process is repeated, with all

Fig. 3—Component magnitudes for forward and reverse traveling waves produced by a short pulse on a transmission line.

of the energy being either absorbed or partially reflected.

Even though the back-and-forth cycle is actually infinite, after a few reflections the intensity of the traveling wave becomes very small. If, instead of a short pulse, a continuous RF voltage is applied to the terminals of a transmission line, the voltage at any point along the line will consist of a sum of voltages—the composite of waves traveling toward the right and waves traveling toward the left. The sum of the waves traveling toward the right is called the *forward wave* or incident wave, while the one traveling toward the left is called the *reflected wave*. If  $Z_a$  contains resistance, there will be a net flow of energy from the source to the load.

### Line Factors and Equations

In practical applications of transmission lines, one factor is very important: the manner in which the source and load are connected. Some “impedance lump” effects may arise from connectors and from the method of connecting the source and the load. These effects may cause the line to “see” a different impedance than would be indicated if the measurements were made directly at the load terminals. This is shown in Fig. 1 by the abrupt change in dimensions at each end of the line,  $\ell$ . Even though the short line connecting the generator to the main transmission line (and the one connecting the load to the line) might have the same characteristic impedance, a mismatch will still occur if the physical sizes are different, unless the adapter connecting the lines is tapered to effect a smooth change between the different dimensions. This effect can usually be neglected at HF, but it becomes important as the frequency of operation is extended into the VHF region and above.

In the example shown in Fig. 3, the ratio of the voltage in the reflected wave to the voltage in the incident wave is defined as the voltage reflection coefficient. This coefficient is designated by the Greek letter rho ( $\rho$ ). The relationship between the out-

put resistance ( $R_a$ ), the output reactance ( $X_a$ ), the line impedance ( $Z_0$ ) and the magnitude of the reflection coefficient is

$$\rho = \sqrt{\frac{(R_a - R_0)^2 + X_a^2}{(R_0 + R_a)^2 + X_a^2}} \quad (\text{Eq. 1})$$

Note that if  $R_a$  is equal to  $R_0$  and  $X_a$  is 0, the reflection coefficient is 0. This represents a matched condition where all the energy in the incident wave is transferred to the load. In effect, it is as if there is an infinite line of characteristic impedance  $Z_0$  connected at A. On the other hand, if  $R_a$  is 0, regardless of the value of  $X_a$ , the reflection coefficient is 1.0. This means that *all* the power is reflected, in much the same manner as radiant energy is reflected from a mirror.

If there are no reflections from the load, the voltage distribution along the line is constant or “flat.” A line operating under these conditions is often referred to as a *flat line*. If reflections exist, a voltage standing-wave pattern will result. The ratio of the maximum voltage on the line to the minimum value (provided the line is longer than a quarter wavelength) is defined as the *voltage standing wave ratio*, or VSWR. Reflections from the load also result in a standing-wave pattern of current flowing in the line. The ratio of maximum to minimum current, or ISWR, is identical to the VSWR in a given line. In amateur literature the abbreviation SWR is commonly used for standing-wave ratio, as the results are identical when taken from proper measurements of either current or voltage. The SWR is related to the reflection coefficient by

$$\text{SWR} = \frac{1 + \rho}{1 - \rho} \quad (\text{Eq. 2})$$

and

$$\rho = \frac{\text{SWR} - 1}{\text{SWR} + 1} \quad (\text{Eq. 3})$$

The definition of Eq. 3 is a more general one, valid for any line length. Often, the actual load impedance is unknown. An alternative way of expressing the reflection coefficient is

$$\rho = \sqrt{\frac{P_r}{P_f}} \quad (\text{Eq. 4})$$

where

$P_r$  = the power in the reflected wave  
 $P_f$  = the power in the forward wave

The parameters are relatively easy to measure with a directional RF wattmeter (power meter), either homemade or purchased. It should be obvious, however, that there can be no other power sources at the load if the definition above is to hold. For instance, assume the reflection coefficient ( $\rho$ ) of the generator in the example

shown in Fig. 3 is 0.9. This value could be obtained by substituting the generator resistance and reactance into Eq. 1, but not by measurement if the source is activated.

It is possible to determine the input resistance and reactance of a terminated line if the load resistance and reactance are known. The line length and characteristic impedance must also be known. The equations are

$$R_{in} = \frac{R_a (1 + \tan^2 \ell)}{\left(1 - \frac{X_a}{Z_0} \tan \ell\right)^2 + \left(\frac{R_a}{Z_0} \tan \ell\right)^2} \quad (\text{Eq. 5})$$

$$X_{in} = \frac{X_a (1 - \tan^2 \ell) + \left(Z_0 - \frac{R_a^2 - X_a^2}{Z_0}\right) \tan \ell}{\left(1 - \frac{X_a}{Z_0} \tan \ell\right)^2 + \left(\frac{R_a}{Z_0} \tan \ell\right)^2} \quad (\text{Eq. 6})$$

where

- $R_{in}$  = resistive component of the impedance at the input end of the line
- $X_{in}$  = reactive component of the impedance at the input end of the line
- $R_a$  = load resistance
- $X_a$  = load reactance
- $\ell$  = electrical line length in degrees or radians

To determine the value of the tangent function, the line length, along with the frequency in MHz and the velocity factor (VF), can be substituted into the following expression:

$$\ell (\text{degrees}) = 0.366 f_{(\text{MHz})} \times \ell_{(\text{feet})} / \text{VF} \quad (\text{Eq. 7})$$

### Lost Power

Often it is mistakenly assumed that power reflected from a load represents power that is lost in some way. With proper matching at the input end of the line, this is true only if there is considerable loss in the line itself. In addition to the forward loss, some reflected power is dissipated on the way back to the source.

If the terminating resistance is zero, the input reactance consists of a pure reactance, which is given by

$$X_{in} = Z_0 \tan \ell \quad (\text{Eq. 8})$$

If the line termination is infinite in value (an open circuit), the input reactance is given by

$$X_{in} = Z_0 \cot \ell \quad (\text{Eq. 9})$$

A short length of line (less than a quarter wavelength) with a short circuit as a terminating load appears as an inductance, while an open-circuited line appears as a capacitance.

Fig. 4 — Field distribution in a rectangular waveguide. The  $TE_{1,0}$  mode of propagation is depicted.

### Waveguides

A waveguide is a conducting tube through which energy is transmitted in the form of electromagnetic waves. The tube is not considered as carrying a current in the same sense that the wires of a two-conductor line do, but rather a boundary which confines the waves to the enclosed space. Skin effect prevents any electromagnetic effects from being evident outside the guide. The energy is injected at one end, either through capacitive or inductive coupling or by radiation, and is received at the other end. The waveguide merely confines the energy of the fields, which are propagated through it to the receiving end by means of reflections against its inner walls.

Analysis of waveguide operation is based on the assumption that the guide material is a perfect conductor of electricity. Typical distributions of electric and magnetic fields in a rectangular guide are shown in Fig. 4. It will be observed that the intensity of the electric field is greatest (as indicated by closer spacing of the lines of force) at the center along the X dimension, Fig. 4B, diminishes to zero at the end walls. Zero field intensity is a necessary condition at the end walls, since the existence of any electric field parallel to the walls at the surface would cause an infinite current to flow in a perfect conductor. This represents an impossible situation.

### Modes of Propagation

Fig. 4 represents a relatively simple

Table 1  
Wavelength Formulas for Waveguide

	Rectangular	Circular
Cut-off wavelength	2X	3.41R
Longest wavelength transmitted with little attenuation	1.6X	3.2R
Shortest wavelength before next mode becomes possible	1.1X	2.8R

distribution of the electric and magnetic fields. An infinite number of ways exist in which the fields can arrange themselves in a guide, as long as there is no upper limit to the frequency to be transmitted. Each field configuration is called a mode. All modes may be separated into two general groups. One group, designated TM (transverse magnetic), has the magnetic field entirely transverse to the direction of propagation, but has a component of electric field in that direction. The other type, designated TE (transverse electric) has the electric field entirely transverse, but has a component of magnetic field in the direction of propagation. TM waves are sometimes called E waves, and TE waves are sometimes called H waves. The TM and TE designations are preferred, however.

The particular mode of transmission is identified by the group letters followed by subscript numerals; for example  $TE_{1,0}$ ,  $TM_{1,1}$ , etc. The number of possible modes increases with frequency for a given size of guide. There is only one possible mode (called the dominant mode) for the lowest frequency that can be transmitted. The dominant mode is the one normally used in practical work.

### Waveguide Dimensions

In the rectangular guide the critical dimension in Fig. 4C is X; this dimension must be more than one-half wavelength at the lowest frequency to be transmitted. In practice, the Y dimension usually is made about equal to  $\frac{1}{2}$  X to avoid the possibility of operation at other than the dominant mode. Other cross-sectional shapes than the rectangle can be used, the most important being the circular pipe. Many of the same considerations apply as in the rectangular shape.

Wavelength formulas for rectangular and circular guides are given in Table 1, where X is the width of a rectangular guide and R is the radius of a circular guide. All figures are in terms of the dominant mode.

### Coupling to Waveguides

Energy may be introduced into or extracted from a waveguide or resonator by means of either the electric or magnetic field. The energy transfer takes place frequently through a coaxial line. Two methods for coupling are shown in Fig. 5. The probe at A is simply a short extension

Fig. 5 — Coupling to waveguide and resonators.

of the inner conductor of the coaxial line, oriented so it is parallel to the electric lines of force. The loop shown at B is arranged to enclose some of the magnetic lines of force. The point at which maximum coupling will be obtained depends on the particular mode of propagation in the guide or cavity; the coupling will be maximum when the coupling device is in the most intense field.

Coupling can be varied by rotating the probe or loop through 90 degrees. When the probe is perpendicular to the electric lines the coupling will be minimum; similarly, when the plane of the loop is parallel to the magnetic lines, the coupling will be minimum.

#### Evolution of a Waveguide

Suppose an open-wire line is used to carry VHF energy from a generator to a load. If the line has any appreciable length, it must be well insulated from the supports to avoid high losses. Since high-quality insulators are difficult to make for microwave frequencies, it is logical to support the transmission line with quarter-wavelength stubs, shorted at the far end. The open end of such a stub presents an infinite impedance to the transmission line, provided the shorted stub is nonreactive. However, the shorting link has finite length and, therefore, some inductance. This inductance can be nullified by making the RF current flow on the surface of a plate rather than through a thin wire. If the plate is large enough, it will prevent the magnetic lines of force from encircling the RF current.

An infinite number of these quarter-wave stubs may be connected in parallel without affecting the standing waves of voltage and current. The transmission line may be supported from the top as well as the bottom, and when infinitely many supports are added, they form the walls of a waveguide at its cutoff frequency. Fig. 6 illustrates how a rectangular waveguide evolves from a two-wire parallel transmission line. This simplified analysis also shows why the cutoff dimension is a half wavelength.

While the operation of waveguides is usually described in terms of fields, current flows on the inside walls, just as fields exist between the conductors of a two-wire transmission line. At the waveguide cutoff frequency, the current is concentrated in the

Fig. 6 — At its cutoff frequency a rectangular waveguide can be analyzed as a parallel two-conductor transmission line supported from top and bottom by an infinite number of quarter-wavelength stubs.

center of the walls, and disperses toward the floor and ceiling as the frequency increases.

#### MATCHING THE ANTENNA TO THE LINE

The load for a transmission line may be any device capable of dissipating RF energy. When lines are used in applications involving transmitters, the most common load is an antenna. When a transmission line is connected between an antenna and a receiver, the receiver input circuit is the load (not the antenna), because the power taken from a passing wave is delivered to the receiver.

Whatever the application, the conditions existing at the load, and *only* the load, determine the standing-wave ratio on the line. If the load is purely resistive and equal to the characteristic impedance of the line, there will be no standing waves. If the load is not purely resistive, or is not equal to the line  $Z_0$ , there will be standing waves. No adjustments can be made at the input end of the line to change the VSWR. Neither is the VSWR affected by changing the line length.

Only in a few special cases is the load inherently of the proper value to match a practicable transmission line. In all other cases it is necessary either to operate with a mismatch and accept the VSWR that results, or else to take steps to bring about a proper match between the line and load by means of transformers or similar devices. Impedance-matching transformers may take a variety of physical forms, depending on the circumstances.

Note that it is essential, if the VSWR is to be made as low as possible, that the load at the point of connection to the transmission line be purely resistive. In general, this requires that the load be tuned to resonance. If the load itself is not resonant at the operating frequency, the tuning can

Fig. 7 — "Q" matching section, a quarter-wave impedance transformer.

sometimes be accomplished in the matching system.

#### The Antenna as a Load

Every antenna system, no matter what its physical form, will have a definite value of impedance at the point where the line is connected. The problem is to transform this antenna input impedance to the proper value to match the line. In this respect there is no "best" type of line for a particular antenna system, because it is possible to transform impedances in any desired ratio. Consequently, any type of line may be used with any type of antenna. There are frequently reasons other than impedance matching that dictate the use of one type of line in preference to another, such as ease of installation, inherent loss in the line, and so on, but these are not considered in this section.

Although the input impedance of an antenna system is seldom known accurately, it is often possible to make a close estimate of its value. Matching circuits can be built with ordinary coils and capacitors, but these are not used extensively because they must be supported at the antenna and must be weatherproofed. The systems described below use *linear transformers*.

#### The Quarter-Wave Transformer or "Q" Section

As mentioned previously, a quarter-wave

transmission line may be used as an impedance transformer. See Fig. 7. If the antenna impedance and the characteristic impedance of the line to be matched are known, the characteristic impedance of a matching section is

$$Z = \sqrt{Z_1 Z_0}$$

where

$Z_1$  = antenna impedance

$Z_0$  = characteristic impedance of the line to which it is to be matched.

Example: To match a 600-ohm line to an antenna presenting a 72-ohm load, the quarter-wave matching section would require a characteristic impedance of

$$\sqrt{72 \times 600} = \sqrt{43,200} = 208 \text{ ohms}$$

The spacing between conductors and the conductor size determine the characteristic impedance of the transmission line. As an example, for the 208-ohm transmission line required above, the line could be made from 1/2-inch-diameter tubing spaced 1.5 inches between conductors.

The length of the quarter-wave matching section may be calculated from

$$\text{Length (feet)} = \frac{246 \text{ VF}}{f}$$

$$\text{Length (meters)} = \frac{75 \text{ VF}}{f}$$

where

VF = velocity factor

f = frequency in MHz

Example: A quarter-wave transformer of RG-11 is to be used at 28.7 MHz. From Table 2, VF = 0.66.

$$\text{Length} = \frac{246 \times 0.66}{28.7} = 5.66 \text{ feet}$$

= 5 feet 8 inches

The antenna must be resonant at the operating frequency. Setting the antenna length by formula is accurate enough with single-wire antennas, but in other systems, particularly close-spaced arrays, the antenna should be adjusted to resonance before the matching section is connected.

When the antenna input impedance is not accurately known, it is advisable to construct the matching section so the spacing between conductors can be changed. The spacing may then be adjusted to give the lowest SWR on the transmission line.

### Series-Section Transformers

The *series-section transformer* has advantages over the quarter-wave transformer. The material in this section is based on a QST article by Frank A. Regier, OD5CG/WA1ZQC (Ref. 1 of the bibliography at the end of this chapter). The transformer illustrated in Fig. 8 closely resembles the 1/4-wave transformer. (Actually, the 1/4-wave transformer is a special case of the series-section transformer.) The important dif-

Fig. 8 — Series section transformer  $Z_1$  for matching transmission-line  $Z_0$  to load,  $Z_L$ .

ferences are: first, that the matching section need not be located exactly at the load; second, that it may be less than a quarter wavelength long; and third, that there is great freedom in the choice of the characteristic impedance of the matching section.

In fact, the matching section can have any characteristic impedance that is not too close to that of the main line. Because of this freedom, it is almost always possible to find a length of commercially available line that will be suitable as a matching section. As an example, consider a 75- $\Omega$  line, a 300- $\Omega$  matching section, and a purely resistive load. It can be shown that such a section may be used to match any resistance between 5  $\Omega$  and 1200  $\Omega$  to the main line.

The design of a series-section transformer consists of determining (1) the length  $l_2$  of the series or matching section and (2) the distance  $l_1$  from the load to the point where the section should be inserted into the main line. Three quantities must be known: the characteristic impedances of the main line and of the matching section, both assumed purely resistive, and the complex load impedance,  $Z_L$ .

The two lengths,  $l_1$  and  $l_2$ , are to be determined from the characteristic impedances of the main line and the matching section,  $Z_0$  and  $Z_1$ , respectively, and from the load impedance ( $Z_L = R_L + jX_L$ ). The first step is to determine the normalized impedances.

$$n = \frac{Z_1}{Z_0}$$

$$r = \frac{R_L}{Z_0}$$

$$x = \frac{X_L}{Z_0}$$

Next,  $l_2$  and  $l_1$  are determined from

$$l_2 = \arctan B$$

$$l_1 = \arctan A$$

where

$$B = \pm \sqrt{\frac{(r-1)^2 + x^2}{r\left(n - \frac{1}{n}\right)^2 - (r-1)^2 - x^2}}$$

$$A = \frac{\left(n - \frac{r}{n}\right) B + x}{r + xnB - 1}$$

Lengths  $l_2$  and  $l_1$  thus determined are electrical lengths in degrees. Actual lengths are obtained by dividing by 360° and multiplying by the wavelength measured along the line (main line or matching

Fig. 9 — Example of series-section matching. A 38- $\Omega$  antenna is matched to 50- $\Omega$  coax by means of a length of 75- $\Omega$  cable.

section, as the case may be), taking the velocity factor of the line into account.

The sign of B may be chosen either positive or negative, but the positive sign is preferred because it results in a shorter matching section. The sign of A may not be chosen, but may turn out to be either positive or negative. If a negative sign occurs and an electronic calculator is used to determine  $l_1$ , a negative electric length will result. If this happens, add 180°. The resultant electrical length will be correct both physically and mathematically.

In calculating B, if the quantity under the radical is negative, an imaginary value for B results. This means that  $Z_1$ , the impedance of the matching section, is too close to  $Z_0$  and should be changed.

Limits on the characteristic impedance of  $Z_1$  may be calculated in terms of the standing-wave ratio produced by the load on the main line without matching. For matching to occur,  $Z$  should either be greater than  $Z_0 \sqrt{\text{VSWR}}$  or less than  $Z_0 \sqrt{\text{VSWR}}$ .

### An Example

Suppose we want to feed a 29-MHz ground-plane vertical antenna with RG-58-type foam-dielectric coax (Fig. 9). We'll assume the antenna impedance to be 38 ohms pure resistance, and use a length of RG-59 foam-dielectric coax as the series section.

$Z_0$  is 50 ohms,  $Z_1$  is 75 ohms, and both cables have a velocity factor of 0.79. (From above,  $Z_1$  must have an impedance greater than 57.4  $\Omega$  or less than 43.6  $\Omega$ .) The design steps are as follows.

From the earlier equations,  $n = 1.5$ ,  $r = 0.76$  and  $x = 0$ .

Further,  $B = 0.3500$  (positive sign chosen),  $l_2 = 19.29^\circ$  and  $A = -1.4486$ . Calculating  $l_1$  yields  $-55.38^\circ$ . Adding 180° to obtain a positive result gives  $l_1 = 124.62^\circ$ .

To find the physical lengths  $l_1'$  and  $l_2'$ , we first find the free-space wavelength.

$$\lambda_0 = \frac{984}{f_{\text{MHz}}} \text{ feet}$$

and the transmission-line wavelength

$$\lambda = \lambda_0 \times \text{velocity factor}$$

In the present case we find  $\lambda = 26.81$  ft. Finally, we have

$$\ell_1' = \frac{\ell_1 \times \lambda}{360} = 9.28 \text{ ft, and}$$

$$\ell_2' = \frac{\ell_2 \times \lambda}{360} = 1.44 \text{ ft.}$$

This completes the calculations. Construction consists of cutting the main coax at a point 9.28 ft from the antenna and adding a 1.44-ft length of the 75- $\Omega$  cable.

### The Quarter-Wave Transformer

The antenna in the preceding example could have been matched by a  $\lambda/4$ - $\lambda$  transformer at the load. Such a transformer would have a characteristic impedance of 43.6  $\Omega$ . It is interesting to see what happens in the design of a series-section transformer if this value is chosen as the characteristic impedance of the series section.

Following the same steps as before, we find  $n = 0.872$ ,  $r = 0.76$  and  $x = 0$ .

From these values we find  $B = \infty$  and  $\ell_2 = 90^\circ$ . Further,  $A = 0$  and  $\ell_1 = 0^\circ$ . These results represent a quarter-wave section at the load, and indicate that, as stated earlier, the quarter-wave transformer is indeed a special case of the series-section transformer.

### Folded Dipoles

If a half-wave antenna element is split into two or more parallel conductors, it can be made to match various line impedances. The transmission line is attached at the center of only one conductor. Various forms of such "folded dipoles" are shown in Fig. 10. Currents in all conductors are in phase in a folded dipole and, since the conductor spacing is small, the folded dipole is equivalent in radiating properties to an ordinary single-conductor dipole. However, the current flowing into the input terminals of the antenna from the line is the current in one conductor only, and the entire power from the line is delivered at this value of current. This is equivalent to saying that the input impedance of the antenna has been raised by splitting it up into two or more conductors.

The ratio by which the input impedance of the antenna is stepped up depends not only on the number of conductors in the folded dipole but also on their relative diameters, since the distribution of current between conductors is a function of their diameters. (When one conductor is larger than the other, as in Fig. 10C, the larger one carries the greater current.) The ratio also depends on the spacing between the conductors, as shown by the graphs of Figs. 11 and 12. An important special case is the two-conductor dipole with conductors of equal diameter; as a simple antenna, not a part of a directive array, it has an input impedance close enough to 300 ohms to afford a good match to 300-ohm twin-lead.

Fig. 11 indicates the required ratio of conductor diameters in a 2-conductor

Fig. 10 — The folded dipole, a method for using the antenna element itself to provide an impedance transformation. Depending on the velocity factor of the line used for the flat top, the conductors should be shorted part-way in from the end. This is because the sections must be resonant both as quarter-wave transmission-line stubs and quarter-wavelength single-wire radiators. A flat top made from 300-ohm twin-lead would have shorting straps at about 85 percent of the distance from center to end. However, no straps are necessary when open-wire line is used in the flat top. This is because the velocity factor of the line (about 97 percent) is very close to the percentage of a physical half wavelength needed for electrical resonance in the "thick" antenna thus created.

Fig. 11 — Impedance transformation ratio, two-conductor folded dipole. The dimensions  $d_1$ ,  $d_2$  and  $s$  are shown on the inset drawing. Curves show the ratio of the impedance (resistive) seen by the transmission line to the radiation resistance of the resonant antenna system.

dipole to give a desired impedance ratio. Similar information for a three-conductor dipole is given in Fig. 12. This graph applies if all the three conductors are in the same plane. The two conductors not con-

Fig. 12 — Impedance transformation ratio, three-conductor folded dipole. The dimensions  $d_1$ ,  $d_2$  and  $s$  are shown on the inset drawing. Curves show the ratio of the impedance (resistive) seen by the transmission line to the radiation resistance of the resonant antenna system.

Fig. 13 — The T match and gamma match.

nected to the transmission line must be equally spaced from the fed conductor, and must have equal diameters. The fed conductor may have a different diameter, however. The unequal-conductor method has been found particularly useful in matching to low-impedance antennas such as directive arrays using close-spaced parasitic elements.

The antenna element should be approximately self-resonant at the median operating frequency. The length is seldom critical, because a folded dipole tends to have the characteristics of a "thick" antenna and thus has a relatively broad frequency-response curve.

### T and Gamma Matching Sections

The method of matching shown in Fig. 13A is based on the fact that the impedance between any two points equidistant from the center along a resonant antenna is resistive, and has a value that depends on the spacing between the two points. It is

therefore possible to choose a pair of points between which the impedance will have the right value to match a transmission line. In practice, the line cannot be connected directly at these points because the distance between them is much greater than the conductor spacing of a practical transmission line. The T arrangement in Fig. 13 overcomes this difficulty by using a second conductor paralleling the antenna to form a matching section to which the line may be connected.

The T is particularly suited to use with a parallel-conductor line. The operation of this system is somewhat complex. Each T conductor (Y in the drawing) forms a short section of transmission line with the antenna conductor opposite it. Each of these transmission-line sections can be considered to be terminated in the impedance that exists at the point of connection to the antenna. Thus, the part of the antenna between the two points carries a transmission-line current in addition to the normal antenna current. The two transmission-line matching sections are in series, as seen by the main transmission line.

If the antenna by itself is resonant at the operating frequency, its impedance will be purely resistive. In this case the matching-section lines are terminated in a resistive load. As transmission-line sections, these matching sections are terminated in a short, and are shorter than a quarter wavelength. Thus their input impedance, i.e., the impedance seen by the main transmission line looking into the matching-section terminals, will be reactive as well as resistive. This prevents a perfect match to the main transmission line, since its load must be purely resistive for perfect matching. The reactive component of the input impedance must be tuned out before a proper match can be obtained.

One way to do this is to detune the antenna just enough, by changing its length, to cause reactance of the opposite kind to be reflected to the input terminals of the matching section, thus canceling the reactance introduced. Another method, which is considerably easier to adjust, is to insert a variable capacitor in series with each matching section where it connects to the transmission line, as shown in Chapter 19. The capacitors must be protected from the weather.

The method of adjustment commonly used is to cut the antenna for approximate resonance and then make the spacing X some value that is convenient constructionally. The distance Y is then adjusted, while maintaining symmetry with respect to the center, until the VSWR on the transmission line is as low as possible. If the VSWR is not below 2:1 after this adjustment, the antenna length should be changed slightly and the matching section taps adjusted again. This procedure may be continued until the VSWR is close to 1:1.

When the series-capacitor method of reactance compensation is used, the anten-

Fig. 14 — Radiator with coaxial feed (A) and methods of preventing unbalanced currents from flowing on the outside of the transmission line (B and C). The half-wave phasing section shown at D is used for coupling between an unbalanced circuit when a 4:1 impedance ratio is desired or can be accepted.

na should be the proper length for resonance at the operating frequency. Trial positions of the matching-section taps are then taken, each time adjusting the capacitor for minimum VSWR, until the standing waves on the transmission line are brought down to the lowest possible value. The unbalanced (gamma) arrangement in Fig. 13B is similar in principle to the T, but is adapted for use with single coax line. The method of adjustment is the same.

## LOADS AND BALANCING DEVICES

The most important practical load for a transmission line is an antenna, which in most cases will be “balanced” — that is, constructed symmetrically with respect to the feed point. A balanced antenna should be fed with a balanced feeder system in order to preserve symmetry with respect to ground. This will avoid difficulties with unbalanced currents on the line and consequent undesirable radiation from the transmission line itself. Line radiation can be prevented by a number of devices that detune or decouple the line for “antenna” currents, and thus greatly reduce their amplitude.

Often the antenna is fed through coaxial line, which is inherently unbalanced. In such a case, some method should be used for connecting the line to the antenna without upsetting the symmetry of the antenna itself. This requires a circuit that will isolate the balanced load from the unbalanced line while providing efficient power transfer. Devices for doing this are

called baluns (a contraction for “balanced to unbalanced”).

An antenna with open ends, of which the half-wave dipole is an example, is inherently a balanced radiator. When the antenna is opened at the center and fed with a parallel-conductor line, this balance is maintained throughout the system, as long as external causes of unbalance are avoided.

If the antenna is fed at the center through a coaxial line, as indicated in Fig. 14A, this balance is upset because one side of the radiator is connected to the shield while the other is connected to the inner conductor. On the side connected to the shield, current can flow down over the outside of the coaxial line. The fields thus set up cannot be canceled by the fields from the inner conductor because the inside fields cannot escape through the shielding of the outer conductor. Hence these “antenna” currents flowing on the outside of the line will be responsible for radiation.

## Linear Baluns

Fig. 14B shows a balun arrangement known as a *bazooka*, which uses a sleeve over the transmission line. The sleeve, with the outside of the outer conductor, forms a shorted quarter-wave line section. As described earlier in this chapter, the impedance looking into the open end of such a section is very high, so the end of the outer conductor of the coaxial line is effectively isolated from the part of the line below the sleeve. The length is an electrical

quarter wave, and may be physically shorter if the insulation between the sleeve and the line is other than air. The bazooka (and the balun form shown in Fig. 14C) have no effect on antenna impedance at the frequency where the  $\frac{1}{4}$ -wave sleeve (and the line section in C are resonant. However, the sleeve and line section both add inductive shunt reactance at frequencies lower, and capacitive shunt reactance at frequencies higher than the  $\frac{1}{4}$ -wave-resonant frequency.

Another method that gives an equivalent effect is shown at C. Since the voltages at the antenna terminals are equal and opposite (with reference to ground), equal and opposite currents flow on the surfaces of the line and second conductor. Beyond the shorting point, in the direction of the transmitter, these currents combine to cancel out. The balancing section "looks like" an open circuit to the antenna, since it is a quarter-wave parallel-conductor line shorted at the far end, and thus has no effect on the normal antenna operation. This is not essential to the line-balancing function of the device, however, and baluns of this type are sometimes made shorter than a quarter wavelength to provide the shunt inductive reactance required in certain matching systems.

Fig. 14D shows a third balun, in which equal and opposite voltages, balanced to ground, are taken from the inner conductors of the main transmission line and half-wave phasing section. Since the voltages at the balanced end are in series while the voltages at the unbalanced end are in parallel, there is a 4:1 step-down in impedance from the balanced to the unbalanced side. This arrangement is useful for coupling between a 300-ohm balanced line and a 75-ohm coaxial line, for example.

### Coil Baluns

The coil balun is based on the principles of a linear-transmission-line balun as shown in the upper drawing of Fig. 15. Two transmission lines of equal length having a characteristic impedance  $Z_0$  are connected in series at one end and in parallel at the other. At the series-connected end the lines are balanced with respect to ground and will match an impedance equal to  $2Z_0$ . At the parallel-connected end the lines will be matched by an impedance equal to  $Z_0/2$ . One side may be connected to ground at the parallel-connected end, provided the two lines have a length that is an odd multiple of a quarter wavelength.

A definite line length is required only for decoupling purposes and, as long as there is adequate decoupling, the system will act as a 4:1 impedance transformer regardless of line length. If each line is wound into a coil, as in the lower drawing, the inductances so formed will act as choke coils and will tend to isolate the series-connected end from any ground connection that may be placed on the parallel-connected end. Balun coils made in this way will operate over a

Fig. 15 — Baluns for matching between push-pull and single-ended circuits. The impedance ratio is 4:1 from the push-pull side to the unbalanced side. Coiling the lines (lower drawing) increases the frequency range over which satisfactory operation is obtained.

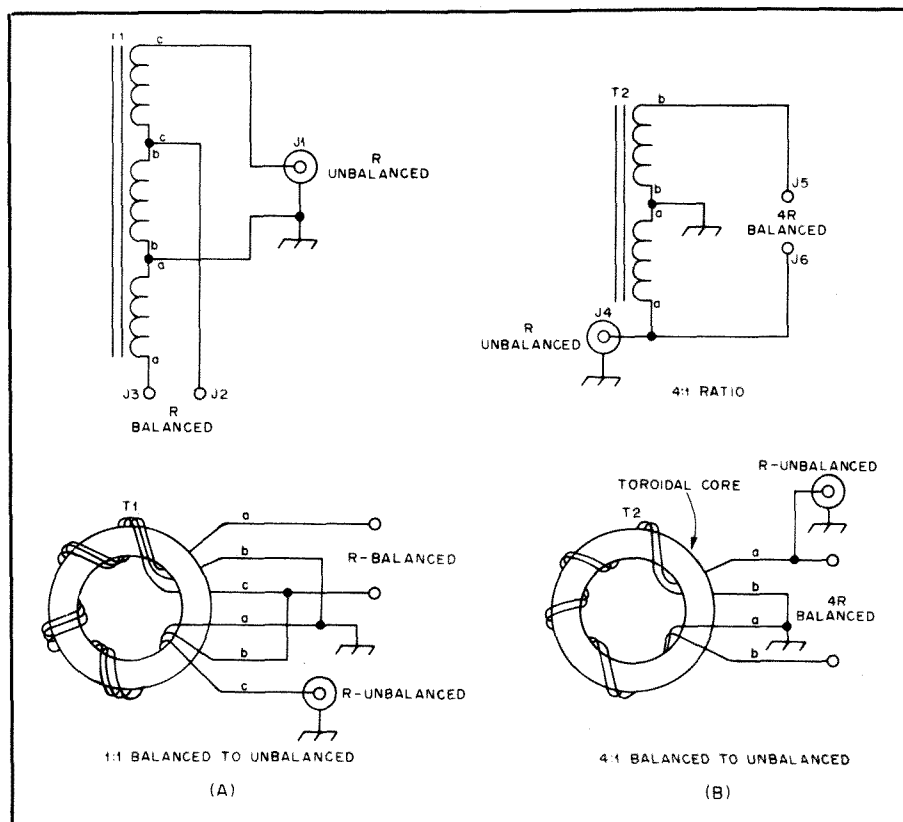

Fig. 16 — Schematic and pictorial representations of balun transformers. The windings are labeled a, b and c to show the relationship between the pictorial and schematic illustrations. Construction information on baluns of this type is given in Chapter 33.

wide frequency range, since the choke inductance is not critical. The lower frequency limit is where the coils are no longer effective in isolating one end from the other; the length of line in each coil should be about equal to a quarter wavelength at the lowest frequency to be used.

The principal application of such coils is in going from a 300-ohm balanced line to a 75-ohm coaxial line. This requires that the  $Z_0$  of the lines forming the coils be 150 ohms.

A balun of this type, when matched, is simply a fixed-ratio transformer. It cannot compensate for inaccurate matching

elsewhere in the system. With a "300-ohm" line on the balanced end, for example, a 75-ohm coaxial cable will not be matched unless the 300-ohm line actually is terminated in a 300-ohm load.

### Toroidal Baluns

Air-wound balun transformers are somewhat bulky when designed for operation in the 1.8- to 30-MHz range. A more compact broadband transformer can be made by using toroidal ferrite core material as the foundation for bifilar-wound coil balun transformers.

In Fig. 16 at A, a 1:1 ratio balanced-to-

Fig. 17 — An RF choke formed by coiling the feed line at the point of connection to the antenna. The inductance of the choke isolates the antenna from the remainder of the feed line.

unbalanced-line transformer is shown. This transformer is useful in converting a 50-ohm balanced line condition to one that is 50 ohms, unbalanced. Similarly, the transformer will work between balanced and unbalanced 75-ohm impedances. A 4:1 ratio transformer is illustrated in Fig. 16 at B. This balun is useful for converting a 200-ohm balanced condition to one that is 50 ohms, unbalanced. In a like manner, the transformer can be used between a balanced 300-ohm point and a 75-ohm unbalanced line.

Low-loss high-frequency ferrite core material is used for the toroidal forms. Power losses in the core are unavoidable, however, and the core size and wire size must be suitably chosen for the highest level of power that will be used. Similarly, the core must be chosen for the type of material that is suitable for the frequency range of operation.

Coil baluns may also be used as impedance transformers, as previously mentioned for the 4:1 balun of Fig. 16B. Be aware, however, that core saturation may occur at high power levels, thus nullifying a portion of the impedance-transformation capabilities. *Mismatches are masked at high powers because of this effect.* For this reason, power limitations and VSWR limitations are imposed on coil baluns. Further, a coil balun introduces an impedance transfer error, which causes skewing of the VSWR and impedance plots. Stated another way, the input impedance of a 1:1 coil balun that is terminated in a 50-ohm resistance will not be precisely 50 ohms of resistance. Depending on the balun construction, there will usually be an inductive reactance in addition to the resistance. But if the limitations of coil baluns are understood and respected, such baluns can be quite useful in an antenna system. Construction information on this type of balun is presented in the chapter on antenna projects.

### Choke Baluns

The unbalanced coupling that results from connecting coaxial line to a balanced antenna may be nullified by choking off the current from flowing on the outside of the feed line. Strictly speaking, the baluns of Fig. 14B and 14C are a form of choke

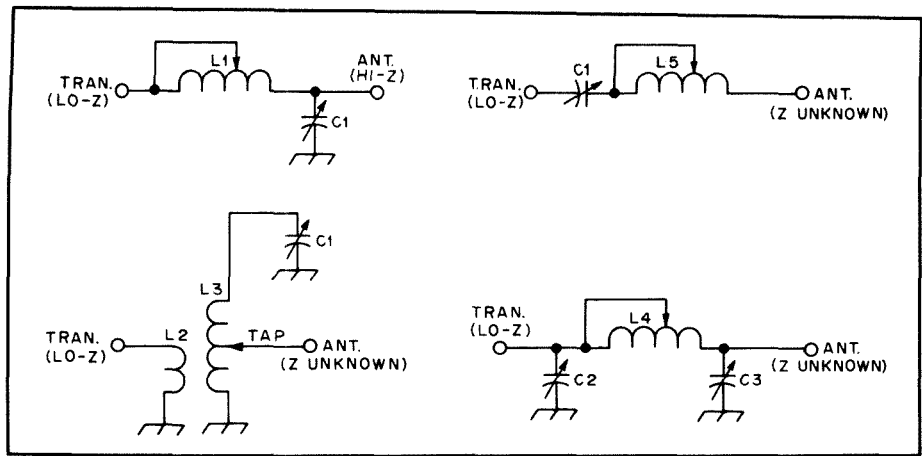

Fig. 18 — Networks for matching a low-impedance transmitter output to a random-length end-fed wire antennas.

balun. These baluns, by their nature, are frequency sensitive, however.

A more direct approach to the objective of choking off outside currents on a coaxial feeder is shown in Fig. 17, where the line itself is formed into a coil at the antenna feed point. Choke baluns of this type are broadband in nature. Ten turns of coaxial line coiled at a diameter of 6 or 8 inches form an inductor with enough series reactance to minimize unwanted currents at frequencies from 14 to 30 MHz. (The turns may be held in place with electrical tape.) The effectiveness of a choke of this type decreases at the higher frequencies because of the distributed capacitance among the turns. At lower frequencies, too much coiled-up feed line would be required to yield enough isolation of the remainder of the line from the antenna.

In addition to broad bandwidth, choke baluns avoid the core saturation that occurs at high power levels with toroidal baluns. Also, there are no limitations on the maximum power or VSWR to which the balun may be subjected. Further, there is no skewing of the impedance with a choke balun.

The frequency range of the choke balun can be extended to well below 2 MHz by using a core of high-permeability ferrite instead of air. With higher core permeability, the choke inductance increases dramatically, thereby increasing the reactance at lower frequencies. Of great importance, no core saturation occurs at high power levels in the choke balun because there is no high level of primary current that exists in coil baluns.

Another type of choke balun that is very effective was originated by M. Walter Maxwell, W2DU. (See Ref. 2 of the bibliography at the end of this chapter.) One or more ferrite beads may be placed over the outer shield of the coax where it is connected to the antenna. The beads present a high impedance to RF currents that would otherwise tend to flow on the outer conductor. If beads are stacked, the total impedance at a given frequency is in approximate proportion to the number of

beads. For a given number of beads, the impedance generally increases with frequency, but this depends on the type of bead material.

Bead materials of various sizes and RF characteristics are available. By using a stack or a "sleeve" of appropriate beads over ordinary coaxial line, a choke balun may be made to cover a broad frequency range, such as from 2 to 250 MHz.

### Nonradiating Loads

Not all loads terminating transmission lines are radiators. Typical examples of nonradiating loads are the grid circuit of a power amplifier, the input circuit of a receiver and another transmission line. This last case includes the "antenna tuner." (Some prefer the term "antenna coupler" because such a device is used to couple a transmission line to a transmitter. ARRL publications use the word *Transmatch*, a coined word covering devices that match the transmitter output to whatever load it sees.)

### Coupling to a Receiver

A good match between an antenna and its transmission line does not guarantee a low standing-wave ratio on the line when the antenna system is used for receiving. The VSWR is determined wholly by what the line "sees" at the receiver antenna-input terminals. For minimum VSWR the receiver input circuit must be matched to the line. The rated input impedance of a receiver is a nominal value that varies over a considerable range with frequency. Most HF receivers are sensitive enough that exact matching is not necessary. The most desirable condition is when the receiver is matched to the  $Z_0$  of the line, which in turn is matched to the antenna. This transfers maximum power from the antenna to the receiver with the least transmission line loss.

### Coupling to Random-Length Antennas

Several Transmatch schemes are shown in Fig. 18, permitting random-length wires to be matched to normal low-Z transmit-

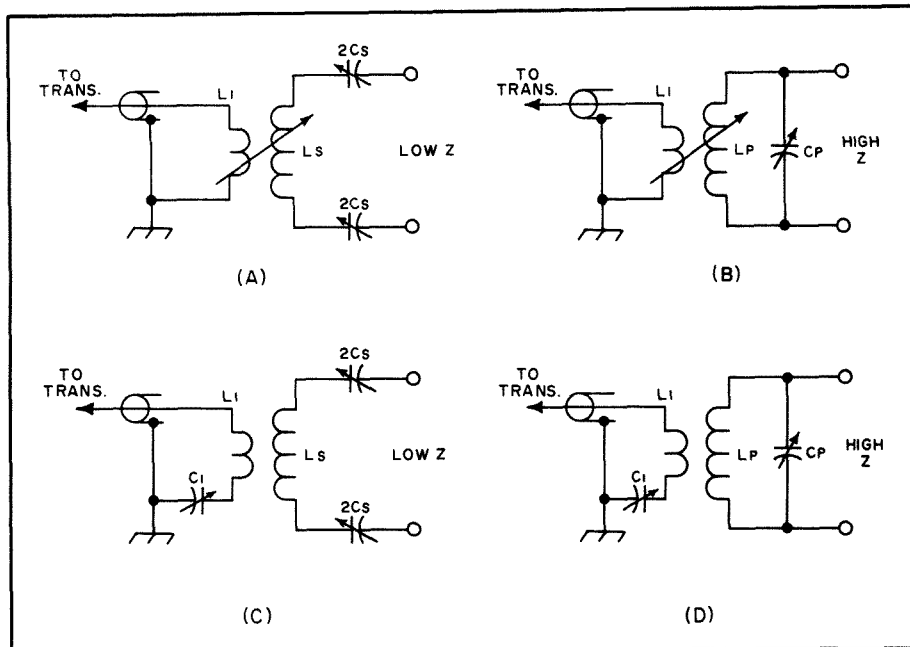

Fig. 19 — Simple circuits for coupling a transmitter to a balanced line that presents a load different than the transmitter output impedance. A and B respectively are series- and parallel-tuned circuits using variable inductive coupling between coils. C and D are similar but use fixed inductive coupling and a variable series capacitor, C1. A series-tuned circuit works well with a low-impedance load; the parallel circuit is better with high-impedance loads (several hundred ohms or more).

ter outputs. The circuit to be used will depend on the length of the antenna wire and its impedance at the desired operating frequency. Ordinarily one of the four methods shown will provide a suitable impedance match to an end-fed random wire, but the configuration will have to be determined experimentally. A VSWR bridge should be used as a match indicator.

#### Coupling the Transmitter to the Line

The type of coupling system needed to transfer maximum power from the final RF amplifier to the transmission line depends almost entirely on the input impedance of the line. The input impedance is determined by the standing-wave ratio, the line length and the  $Z_0$  of the line. The simplest case is that in which the line is terminated in its characteristic impedance. In this case the VSWR is 1:1 and the input impedance is equal to the  $Z_0$  of the line, regardless of line length. For this condition the line is said to be "flat."

Coupling systems that will deliver power into a flat line can be readily designed. For practical purposes the line can be considered flat if the VSWR is no greater than about 1.5:1. That is, a coupling system designed to work into a pure resistance equal to the line  $Z_0$  will have enough leeway to take care of the small variations in input impedance that will occur when the line length is changed, if the VSWR is higher than 1:1 but no greater than 1.5:1.

Current practice in transmitter design is to provide an output circuit that will work into such a line, usually a coaxial line of 50 to 75 ohms characteristic impedance. If

the input impedance of the transmission line differs appreciably from the transmitter output design impedance, then a matching network must be inserted between the transmitter and the line input terminals.

#### Impedance-Matching Circuits for Transmission Lines

As shown earlier in this chapter, the input impedance of a line that is operating with a high standing-wave ratio can vary over quite wide limits. The simplest type of circuit that will match such a range of impedances to 50 or 75 ohms is a simple series- or parallel-tuned circuit, approximately resonant at the operating frequency. If the load presented by the line at the operating frequency is low (below a few hundred ohms), a series-tuned circuit should be used. When the load is higher than this, the parallel-tuned circuit is easier to use.

Typical simple circuits for coupling between the transmitter with 50- to 75-ohm coaxial-line output and a balanced transmission line are shown in Fig. 19. The inductor L1 should have a reactance of about 60 ohms when adjustable inductive coupling is used (Figs. 19A and 19B). When a variable series capacitor is used, L1 should have a reactance of about 120 ohms. The variable capacitor, C1, should have a reactance at maximum capacitance of about 100 ohms.

On the secondary side,  $L_s$  and  $C_s$  should be capable of being tuned to resonance at about 80 percent of the operating frequency. In the series-tuned circuits, for a given low-impedance load, looser coupling can

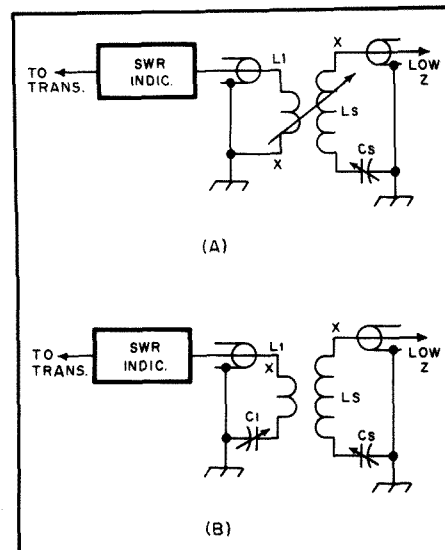

Fig. 20 — Coupling from a transmitter designed for 50- to 75-ohm output to a coaxial line with a 3 or 4:1 VSWR is readily accomplished with these circuits. Essential difference between the circuits is adjustable inductive coupling at A, and fixed inductive coupling with variable series capacitor at B. In either case the circuit can be adjusted to give a 1:1 VSWR in the line to the transmitter. The coil ends marked X should be adjacent, for minimum capacitive coupling.

be used between L1 and  $L_s$  as the  $L_s$ -to- $C_s$  ratio is increased. In the parallel-tuned circuits, for a given high-impedance load, looser coupling can be used between L1 and  $L_p$  as the  $C_p$ -to- $L_p$  ratio is increased. The constants are not critical; the rules of thumb are mentioned to assist in correcting a marginal condition where sufficient transmitter loading cannot be obtained.

Coupling to a coaxial line that has a high VSWR, and that consequently may present the transmitter with a load it cannot couple to, is done with an unbalanced version of the series-tuned circuit, as shown in Fig. 20. The rule given above for coupling ease and  $L_s$ -to- $C_s$  ratio applies to these circuits as well.

The most satisfactory way to set up any of the circuits of Fig. 19 or 20 initially is to connect a coaxial VSWR indicator in the line to the transmitter, as shown in Fig. 20. The RF-wattmeter type of bridge, which can handle the full transmitter power and may be left in the line for continuous monitoring, is excellent for this purpose. A simple resistance bridge is perfectly adequate, however, requiring only that the transmitter output be reduced to a very low value so the bridge will not be overloaded. To adjust the circuit, make a trial setting of the coupling (coil spacing in Figs. 19A and B and 20A, C1 setting in others) and adjust  $C_s$  or  $C_p$  for minimum VSWR as indicated by the bridge. If the VSWR is not 1:1, readjust the coupling and retune  $C_s$  or  $C_p$ , continuing this procedure until the VSWR is at or near 1:1. The settings may then be logged for future reference.

In the series-tuned circuits of Figs. 19A

and C, the two capacitors should be adjusted for similar settings. The “ $2C_s$ ” indicates that a balanced series-tuned coupler requires twice the capacitance in each of two capacitors as does an unbalanced series-tuned circuit, all other things being equal.

It is possible to use circuits of this type without initially setting them up with a VSWR bridge. In such a case it is a matter of cut and try until adequate power transfer between the amplifier and main transmission line is obtained. Initial tuning can be done by listening on a receiver tuned to the intended operating frequency, and adjusting for maximum band noise or received signal strengths. Tuning without an SWR bridge, however, frequently results in high VSWR in the link with consequent power loss, “hot spots” in the coaxial cable and tuning that is critical with frequency. The VSWR indicator method is simple and gives the optimum operating conditions quickly and with certainty.

### THE CONJUGATE MATCH AND THE $Z_0$ MATCH

One purpose of matching impedances is to enable a power source or generator, having an optimum load impedance, to deliver its maximum available power to a load having a different impedance, usually through a transmission line having still another impedance. The same principles apply, and the same wave actions and reflections occur, whether the matching device is a stub on a line, a quarter-wave line transformer, or a network of lumped reactances such as a pi-network tank circuit or a Transmatch. (In ARRL literature, a Transmatch is considered to be a matching device used between the transmitter and the feed line.) To aid in understanding the principles of matching, we shall consider transmission lines and reactance components of the Transmatch as lossless elements, and then treat the effects of loss later.

The conjugate match is defined by the National Bureau of Standards as the condition for maximum power absorption by a load, in which the impedance seen looking toward the load at a point in the circuit is the complex conjugate of that seen looking toward the source. The  $Z_0$  match is the condition in which the impedance seen looking into a transmission line is equal to the characteristic impedance of the line.

If a generator, a load, and an ideal lossless line connecting them all have the same  $Z_0$ , both a  $Z_0$  match and a conjugate match exist. (A  $Z_0$  match is also a special condition of the conjugate match.) Under these conditions the generator delivers its maximum available power into the line, which transfers it to the load where it is completely absorbed.

If the  $Z_0$  load is now replaced by another, such as an antenna having an impedance  $Z_L = R + jX \neq Z_0$ , we have

two mismatches at the load, a  $Z_0$  mismatch and a conjugate mismatch. The  $Z_0$  mismatch creates a reflection having a magnitude

$$\rho = \frac{Z_L - Z_0}{Z_L + Z_0}$$

causing a reflection loss  $\rho^2$  that is referred back along the line to the generator. This in turn causes the generator to see the same magnitude of  $Z_0$  mismatch at the line input. This referred  $Z_0$  mismatch causes the generator to deliver less than its maximum available power by the amount equal to the reflection loss. There is no power lost in the line — only a reduction of power delivered. And all of the reduced power delivered is absorbed by the load.

If a matching device is now inserted between the line and the load, the device provides a conjugate match at the load by supplying a reflection gain which cancels the reflection loss, so the line sees a  $Z_0$  match at the input of the matching device. Since the line is terminated in a  $Z_0$  match, the generator now sees a  $Z_0$  match at the line input, and will again deliver its maximum available power into the line, to be completely absorbed by the load.

However, if a Transmatch is inserted between the generator and the line instead of a matching device at the load, the Transmatch provides the conjugate match at the line input, and the generator sees a  $Z_0$  match at the Transmatch input. At the load, the line now sees a conjugate match, but also sees a  $Z_0$  mismatch. The  $Z_0$  mismatch again causes a reflection loss that is referred back to the line input as before. With the Transmatch at the line input, the reflection gain, which again cancels the reflection loss, shields the generator from seeing the referred  $Z_0$  mismatch again appearing at the line input.

The reflection gain of the Transmatch also creates the conjugate match at the load, and thus enables the load to absorb the maximum available power delivered by the generator. Since the generator sees a  $Z_0$  match at the Transmatch input, it continues delivering its maximum available power into the line through the Transmatch, and the power is still completely absorbed by the load because of the conjugate match.

The amount of forward power flowing on a lossless line is determined by the expression

$$\frac{1}{1 - \rho^2}$$

where  $\rho$  = voltage coefficient of reflection.

On a real line with attenuation, forward power at the conjugate matching point is

$$\frac{1}{1 - \rho^2 e^{-4\alpha}}$$

where

$\alpha$  = line attenuation in nepers  
= dB/8.686

$e$  = 2.71828..., the base of natural logarithms

The power arriving at the mismatched load with attenuation in the line is

$$\frac{e^{-2\alpha}}{1 - \rho^2 e^{-4\alpha}}$$

and the power absorbed in the load is

$$\frac{(1 - \rho^2) e^{-2\alpha}}{1 - \rho^2 e^{-4\alpha}}$$

The power reflected is

$$\frac{\rho^2 e^{-2\alpha}}{1 - \rho^2 e^{-4\alpha}}$$

### The Conjugate Matching Theorem

To understand how a conjugate match is created at the load with the Transmatch at the line input, examine the Conjugate Matching Theorem and the wave actions which produce the conjugate match. It is the conjugate match that enables the load to absorb the maximum available power from the generator despite the  $Z_0$  load mismatch.

“If a group of four-terminal networks containing only reactances (or lossless lines) are arranged in tandem to connect a generator to its load, then if at any junction there is a conjugate match of impedances, there will be a conjugate match of impedances at every other junction in the system.”

To paraphrase from the NBS definition, “conjugate match” means that if in one direction from a junction the impedance has the dimensions  $R + jX$ , then in the opposite direction the impedance will have the dimensions  $R - jX$ . And according to the theorem, when a conjugate match is accomplished at any of the junctions in the system, any reactance appearing at any junction is canceled by an equal and opposite reactance, which also includes any reactance appearing in the load. This reactance cancellation results in a net system reactance of zero, establishing resonance in the entire system. In this resonant condition the generator delivers its maximum available power to the load, which is why an antenna operated away from its natural resonant frequency is tuned to resonance by a Transmatch connected at the input to the transmission line.

Conjugate matching is obtained through a controlled wave interference between two sets of reflected waves. One set of waves is reflected by the load mismatch, and the other by a complementary mismatch introduced by the reactances in the Transmatch. The mismatch introduced by the reactances of the Transmatch creates reflected waves of voltage and current at the matching point (the Transmatch input). These waves are equal in magnitude but opposite in phase relative to those arriving from the load mismatch. The two sets of reflected voltage and current waves created by the two mismatches combine at the matching point to produce resultant waves of voltage

and current that are respectively at 0° and 180° in phase relative to the source wave.

The phase relationship of 180° between the resultant voltage and current waves creates a virtual open circuit to waves traveling toward the source, which totally re-reflects both sets of reflected waves back into the line. This re-reflection prevents the reflected waves from traveling beyond the matching point, which is the reason an SWR indicator connected at the input of the Transmatch shows zero reflected power at the conclusion of the tune-up procedure. On re-reflection the voltage and current components of the reflected waves emerge in phase with the corresponding components of the source wave, so by superposition, all of the power contained in the reflected waves is added to the power in the source wave. Consequently, the forward power in the line is greater than the source power whenever the line is terminated in a  $Z_0$  mismatch. This is why the forward-power wattmeter connected at the output of the Transmatch indicates a value higher than the source power, by the amount equal to the reflected power.

This enlargement of the forward power is called "reflection gain." Reflection gain cancels the reflection loss, creating the conjugate match that enables the  $Z_0$ -mismatched load to absorb the maximum available power delivered by the generator. When the source power enlarged by the reflected power reaches the  $Z_0$ -mismatched load,  $Z_L$ , the power previously reflected and added to the source power is again subtracted by the  $Z_0$  mismatch reflection, leaving the source power to be completely absorbed by the load. This is why all power entering the line is absorbed in the load, regardless of the mismatch or SWR.

In lines having attenuation, all power entering the line is absorbed in the load, except for that lost because of attenuation. When the matching is performed at the line input, the attenuation increases as the  $Z_0$  load mismatch increases because, in addition to the attenuation of the forward power, the reflected power is also attenuated in the same proportion. However, when the matched-line attenuation is low, as it is in typical amateur installations, the additional loss because of  $Z_0$  mismatch is small. The additional losses are so low that even with moderate to high SWR values, the difference in power radiated compared to that with a 1:1 SWR is too small to be discerned by the receiving station. Information for calculating the additional power lost versus SWR is available from the graph in Fig. 23, Chapter 16 of this *Handbook*, and from Fig. 9 in December 1974 *QST*, p. 12.

## THE CONJUGATE MATCH AND THE PI-NETWORK TANK

In transceivers having tubes in the RF output stage, the pi network serves as a conjugate matching network as well as a harmonic-controlling tank circuit. When

properly adjusted, the pi network matches the optimum load resistance of the tubes to the impedance seen at the input of the coaxial line connected to the output of the network.

In the ever-present quest for the perfect 1:1 SWR, many amateurs are unaware that the pi network is usually capable of matching the optimum tube load resistance

to a wider range of output load impedances than defined by a 2:1 SWR; some will match to as high as 3:1, and sometimes even 4:1. During tune-up, if a resonance dip in plate current can be obtained at the proper loaded value of current within the range of the tuning and loading capacitors in the pi network, the network has correctly matched the tubes to whatever impedance

**Fig. 21 — Chart showing the characteristic impedance of spaced-conductor parallel transmission lines with air dielectric. Tubing sizes are given for outside diameters.**

is seen at the output. This is true no matter how high the SWR. When correctly tuned to the plate-current dip, the tubes see the desired resistive (nonreactive) load, the network has supplied a conjugate match, and any reflected power as shown by an SWR indicator has been re-reflected in the same manner as described above for the Transmatch. In other words, the pi network can serve as the Transmatch for whatever SWR it can load properly.

## TRANSMISSION LINE CHARACTERISTICS

Each type of line has a characteristic velocity factor, related to its insulating-material properties. The velocity factor must be taken into account when cutting a transmission line to a specific part of a wavelength — such as with a quarter-wavelength transformer. For example, if RG-8A were used to make a quarter-wavelength line at 3.5 MHz, the line dimension should be  $0.66 \times 246/f$  (MHz), because RG-8A has a velocity factor of 0.66. Thus, the line would be 46.4 feet long instead of the free-space length of 70.3 feet. Table 2 shows various velocity factors for the transmission lines commonly used by amateurs. Open-wire line has a velocity factor of essentially unity because it lacks a substantial amount of solid insulating material. Conversely, molded 300-ohm TV line has a velocity factor of 0.80 to 0.82.

Amateurs can construct their own parallel transmission lines by following the chart contained in Fig. 21. With wire conductors it is easy to fabricate open-wire feed lines. Spacers made of high-quality insulating material are used at appropriate distances apart to maintain the spacing between the wires.

### Characteristic Impedance

**Too great a distance between insulating spacers may yield variations in line**

impedance because of nonconstant conductor spacing, and may permit the conductors to short out. These considerations are more important in outdoor installations in windy weather. The characteristic impedance of an air-insulated parallel-conductor line, neglecting the effect of the insulating spacers, is given by

$$Z_0 = 276 \log \frac{2S}{d}$$

where

 $Z_0 =$  characteristic impedance

$S$  = center-to-center distance between conductors

$d$  = diameter of conductor (in same units as  $S$ )

The characteristic impedance of an air-insulated coaxial line is given by the formula

$$Z_0 = 138 \log \frac{b}{a}$$

where

 $Z_0 =$  characteristic impedance

$b$  = inside diameter of outer conductors

a = outside diameter of inner conductor (in same units as b)

It does not matter what units are used for  $a$  and  $b$  as long as they are the same units. The characteristic impedance of any transmission line can be expressed as a function

of the distributed capacitance and inductance:

$$Z_0 = \sqrt{L/C}$$

where

$Z_0$  = characteristic impedance

$L$  = inductance (henrys) per unit length

$C$  = capacitance (farads) per unit length

### Line Losses

The power loss in a transmission line is not directly proportional to the line length, but varies logarithmically with the length. That is, if 10% of the input power is lost in a section of line having a certain length, then 10% of the remaining power will be lost in the next section of the same length. For this reason it is customary to express line losses in terms of decibels per unit length, because the decibel is a logarithmic unit. Calculations are simple because the total loss in a line is merely the loss per unit length multiplied by the total number of units. Line loss is usually expressed in decibels per hundred feet. It is necessary to specify the frequency for which the loss applies, because the loss varies with frequency.

Fig. 22 shows the loss (or attenuation) per hundred feet versus frequency for several common types of lines, both coaxial and balanced types.

### Effect of VSWR

The power lost in a line is lowest when the line is terminated in a resistance equal to its characteristic impedance, and increases with an increase in the standing-wave ratio. This is because the average values of both current and voltage become larger as the VSWR becomes greater. The increase in effective current raises the  $I^2R$  (ohmic) losses in the conductors, and the increase in effective voltage increases the  $E^2/R$  losses in the dielectric.

The increased loss caused by a VSWR greater than 1 may or may not be serious. If the VSWR at the load is not greater than 2, the *additional* loss caused by the standing waves, as compared with the loss when the line is perfectly matched, does not amount to more than about 1/2 dB even on very long lines. Since 1/2 dB is an undetectable change in signal strength a VSWR of 2 or less is every bit as good as a perfect match, as far as losses are concerned.

The effect of VSWR on line loss is shown in Fig. 23. The horizontal axis is the attenuation, in decibels, of the line when

Fig. 23 — Increase in line loss because of standing waves (VSWR measured at the load). To determine the total loss in decibels in a line having a VSWR greater than 1, first determine the loss for the particular type of line, length and frequency, on the assumption that the line is perfectly matched (Table 2). Locate this point on the horizontal axis and move up to the curve corresponding to the actual VSWR. The corresponding value on the vertical axis gives the additional loss in decibels caused by the standing waves.

perfectly matched. The vertical axis gives the *additional* attenuation. For example, if the loss in a certain line is 1 dB when perfectly matched, a VSWR of 3 on that same line will cause an additional loss of approximately 0.5 dB. The total loss on the poorly matched line is therefore  $1 + 0.5 = 1.5$  dB. If the VSWR were 10 instead of 3, the additional loss would be 2.5 dB, and the total loss  $1 + 2.5 = 3.5$  dB.

It is important to note that the curves in Fig. 23 that represent VSWR are the values that exist *at the load*. In most cases of amateur operation, this will be at the antenna end of a length of transmission line. The VSWR as measured at the input or transmitter end of the line will be less, depending on the line attenuation. It is not always convenient to measure VSWR directly at the antenna. By using the graph shown in Fig. 24, however, you can obtain the VSWR at the load by measuring it at the input to the transmission line and using the known (or estimated) loss of the transmission line. For example, if the VSWR at the transmitter end of a line is measured as 3 to 1 and the line is known to have a total attenuation (under matched con-

Fig. 24 — VSWR at input end of transmission line vs. VSWR at load end for various values of matched-line loss.

ditions) of 1 dB, the VSWR at the load end of the line will be 4.4 to 1. From Fig. 23, the additional loss is nearly 1 dB because of the presence of the VSWR. The total line loss in this case is 2 dB.

# Antenna Fundamentals

An antenna system is comprised of all the components used between the transmitter or receiver and the actual radiator. Therefore, such items as the antenna proper, transmission line, matching transformers, baluns and Transmatch qualify as parts of an antenna system.

In a well designed system, only the antenna does the radiating. It is noteworthy that any type of feed line can be utilized with a given antenna, provided the following conditions are met. A suitable matching device must be used to ensure a low standing-wave ratio (SWR) between the feed line and the antenna, and another between the feed line and the transmitter (or receiver).

Some antennas possess an input impedance at the feed point close to that of certain transmission lines. For example, a half-wavelength, center-fed dipole, placed at a correct height above ground, will have a feed-point impedance of approximately 75 ohms. In such a case it is practical to use a 75-ohm coaxial or balanced line to feed the antenna. But few amateur half-wavelength dipoles actually exhibit a 75-ohm impedance. This is because at the lower end of the high-frequency spectrum the typical height above ground is rarely more than  $\frac{1}{4}$  wavelength. The 75-ohm characteristic is most likely to be realized in a practical installation when the horizontal dipole is approximately one-half, three-quarters or one wavelength above ground. At lower heights the approximate feed-point resistance may be obtained from Fig. 1, but values may vary at different locations because of differences in ground conductivity.

Fig. 1 shows the difference between the effects of perfect ground and real earth at low antenna heights. The effect on the resistance of a horizontal half-wave antenna is negligible only as long as the height of the antenna is greater than 0.2 wavelength. Below this height, while decreasing rapidly to zero over perfectly conducting ground, the resistance decreases less rapidly with height over actual ground. At lower heights the resistance stops decreasing at around 0.15 wavelength, and thereafter increases as height decreases further. The reason for the increasing resistance is that more and more of the induction field of the antenna is absorbed by

Fig. 1 — Curves showing the radiation resistance of vertical and horizontal half-wavelength dipoles at various heights above ground. The broken-line portion of the curve for a horizontal dipole shows the resistance over real earth, the solid line for perfectly conducting ground.

the lossy ground as the height drops below  $\frac{1}{4}$  wavelength.

For a half-wave vertical antenna, the center of which is  $\frac{1}{4}$  wavelength or more above the surface, differences between the effects of perfect ground and real earth on the impedance is negligible. The resistance of a vertical dipole at various heights above real and perfectly conducting ground is shown in Fig. 1.

## The Antenna Choice

The amount of available space should be high on the list of factors to consider when selecting an antenna. Those who live in urban areas often must accept a compromise type of antenna for the HF bands because the city lot won't accommodate full-size wire dipoles, end-fed systems or high supporting structures. Other constrictions are imposed by the amount of money available for an antenna system (including supporting hardware), the number of amateur bands to be worked and local zoning ordinances.

Finally, the operation objective comes into play; to dedicate one's self to DXing, or to settle for a general type of operation that will yield short- and long-haul QSOs during periods of good propagation.

Because of these influences, it is impos-

sible to suggest one type of antenna system over another. A rule of thumb might be to erect the biggest and best collection of antennas that space and finances will allow. If a modest system is the order of the day, then use whatever is practical and accept less than optimum performance. Practically any radiator will enable the operator to make good contacts under some conditions of propagation, assuming the radiator is able to accept power and radiate it at some useful angle respective to earth.

In general, the height of the antenna above ground is the most critical factor at the higher end of the HF spectrum — 14 through 30 MHz. This is because the antenna should be clear of conductive objects such as power lines, phone wires, gutters and the like, plus high enough to have a low radiation angle. This is not nearly as important at 2 to 10 MHz, but lower frequency antennas still should be well away from conductive objects and as high above ground as possible in the interest of good performance. The exception is a ground-mounted vertical antenna. Ground-plane verticals, however, should be installed as high above ground as possible so their performance will not be degraded by conductive objects.

## Antenna Polarization

Most HF-band antennas are either vertically or horizontally polarized, although circular polarization is possible, just as it is at VHF and UHF. The polarization is determined by the position of the radiating element or wire with respect to earth. Thus, a radiator that is parallel to the earth radiates horizontally, while an antenna at a right angle to the earth (vertical) radiates a vertical wave. If a wire antenna is slanted above earth, it radiates waves that are between vertical and horizontal in nature.

During line-of-sight communications, maximum signals will exist when the antennas at both ends of the circuit have the same polarity; cross polarization results in many decibels of signal reduction. During propagation via the ionosphere (sky wave), however, it is not essential to have the same polarization as the station at the opposite end of the circuit. This is because the radiated wave is bent and it tumbles considerably during its travel through the atmospheric layer from which it is refracted. At the far end of the communications path

the wave may be horizontal, vertical or somewhere in between at a given instant. On multihop transmissions, in which the signal is refracted more than once from the atmosphere, and similarly reflected from the earth's surface during its travel, considerable polarization shift will occur. Therefore, the main consideration for a good DX antenna is a low angle of radiation rather than the polarization. It should be said, however, that most DX antennas for HF work are horizontally polarized. The major exception is the ground-plane vertical and phased vertical arrays.

### Impedance

The impedance at a given point in the antenna is determined by the ratio of the voltage to the current at that point. For example, if there were 100 RF volts and 1.4 amperes of current at a specified point in an antenna and if they were in phase, the impedance would be approximately 71 ohms.

The impedance is significant with regard to matching the feeder to the feed point: Maximum power transfer takes place under a perfectly matched condition. As the mismatch increases, so does the reflected power. If the feed line is not too lossy or long, good performance can be had at HF when the standing-wave ratio (SWR) is 3:1 or less. When the feeder loss is very low — as with open-wire transmission line — much higher SWR is not detrimental to performance if the transmitter is able to work into the mismatched condition satisfactorily. In this regard, a Transmatch (matching network between the transmitter and the feed line) is often employed to compensate for the mismatch condition, enabling the operator to load the transmitter to its full rated power.

Antenna impedance can be either resistive or complex (containing resistance and reactance). This will depend on whether or not the antenna is resonant at the operating frequency. Many operators mistakenly believe that a mismatch, however small, is a serious matter, and that their signals won't be heard well even if the SWR is as low as 1.3:1. This unfortunate fallacy has cost much wasted time and money among some amateur groups as individuals attempted to obtain a perfect match. A perfect match, however ideal the concept may be, is not necessary. The significance of a perfect match becomes more pronounced only at VHF and higher, where feed-line losses are a major problem.

### Antenna Bandwidth

The bandwidth of an antenna refers generally to the range of frequencies over which the antenna can be used to obtain good performance. The bandwidth is usually referenced to some SWR value, such as, "The 2:1 SWR bandwidth is 3.5 to 3.8 MHz." Some more specific bandwidth terms are used also, such as the gain bandwidth and the front-to-back ratio

Fig. 2 — Effect of ground on the radiation of horizontal antennas at vertical angles for four antenna heights. These data are based on perfectly conducting ground.

bandwidth. The gain bandwidth is significant because the higher the antenna gain, the narrower the gain bandwidth will be for a given gain-bandwidth product.

For the most part, the lower the operating frequency of a given antenna design, the narrower the bandwidth. This follows the rule that the bandwidth of a resonant circuit doubles as the frequency of operation is increased by one octave (or doubled), assuming the Q is the same for each case. Therefore, it is often difficult to obtain sufficient bandwidth to cover all of the 160- to 80-meter bands with a dipole antenna cut for each of those bands. The situation can be aided by applying broadbanding techniques, such as fanning the far ends of a dipole to simulate a conical type of dipole.

### Radiation Angle

The vertical angle of maximum radiation is of primary importance, especially at the higher frequencies. It is advantageous, therefore, to erect the antenna at a height that will take advantage of ground reflection so as to reinforce the space radiation at the most desirable angle. Since low angles usually are most effective, this generally means that the antenna should be high. The height should be at least one-half

wavelength at 14 MHz, and preferably three-quarters or one wavelength. At 28 MHz the height should be at least one wavelength, and preferably higher.

The physical height required for a given height in wavelengths decreases as the frequency is increased, so that acceptable heights are not impractical; a half wavelength at 14 MHz is only 35 feet, while the same height represents a full wavelength at 28 MHz. At 10 MHz and lower, the higher radiation angles are effective, so a useful antenna height is not difficult to attain. But greater height is important at 10 MHz and below when it is desired to work DX consistently. Heights between 35 and 70 feet are suitable for the upper bands, the higher figures being preferable. It is well to remember that most simple horizontally polarized antennas do not exhibit the directivity they are capable of unless they are one-half wavelength or more above ground. Therefore, with dipole-type antennas it is not important to choose a favored broadside direction unless the antenna is at least one-half wavelength above ground.

### Imperfect Ground

Fig. 2 is based on ground having perfect conductivity, whereas the earth is not a perfect conductor. The principal effect of

actual ground is to make the curves inaccurate at the lowest angles; appreciable high-frequency radiation at angles smaller than a few degrees is practically impossible to obtain over horizontal ground. Above 15 degrees, however, the curves are accurate enough for all practical purposes, and may be taken as indicative of the result to be expected at angles between 5 and 15 degrees.

The effective ground plane — that is, the plane from which ground reflections can be considered to take place — seldom is the actual surface of the ground. Instead, it is several inches to a few feet below it, depending on the characteristics of the soil.

### Current and Voltage Distribution

When power is fed to an antenna, the current and voltage vary along its length. The current is maximum (loop) at the center and nearly zero (node) at the ends. The opposite is true of the RF voltage. The current does not actually reach zero at the current nodes, because of the end effect. Similarly, the voltage is not zero at its node because of the resistance of the antenna, which consists of both the RF resistance of the wire (ohmic resistance) and the radiation resistance. The radiation resistance is the equivalent resistance that would dissipate the power the antenna radiates, with a current flowing in it equal to the antenna current at a current loop (maximum). The ohmic resistance of a half-wavelength antenna is ordinarily small enough, compared with the radiation resistance, to be neglected for all practical purposes.

### Conductor Size

The impedance of the antenna also depends on the diameter of the conductor in relation to the wavelength, as indicated in Fig. 3. If the diameter of the conductor is increased, the capacitance per unit length increases and the inductance per unit length decreases. Since the radiation resistance is affected relatively little, the decreased L/C ratio causes the Q of the antenna to decrease so that the resonance curve becomes less sharp. Hence, the antenna is capable of working over a wide frequency range. This effect is greater as the diameter is increased, and is a property of some importance at the very high frequencies where the wavelength is small.

### THE HALF-WAVELENGTH ANTENNA

A fundamental form of antenna is a single wire whose length is approximately equal to half the transmitting wavelength. It is the unit from which many more complex forms of antennas are constructed and is known as a dipole antenna.

The length of a half-wave in free space is

$$\text{Length (ft)} = \frac{492}{f \text{ (MHz)}} \quad (\text{Eq. 1})$$

The actual length of a resonant half-

wavelength antenna will not be exactly equal to the half wavelength in space, but depends on the thickness of the conductor in relation to the wavelength. The relationship is shown in Fig. 3, where K is a factor that must be multiplied by the half wavelength in free space to obtain the resonant antenna length. An additional shortening effect occurs with wire antennas supported by insulators at the ends because of the capacitance added to the system by the insulators (end effect). The following formula is sufficiently accurate for wire antennas for frequencies up to 30 MHz.

Length of half-wave antenna (ft) =

$$\frac{492 \times 0.95}{f \text{ (MHz)}} = \frac{468}{f \text{ (MHz)}} \quad (\text{Eq. 2})$$

Example: A half-wave antenna for 7150 kHz (7.15 MHz) is  $468/7.15 = 65.45$  ft, or 65 ft 5 in.

Above 30 MHz the following formulas should be used, particularly for antennas constructed from rod or tubing. K is taken from Fig. 3.

Length of half-wave antenna (ft) =

$$\frac{492 \times K}{f \text{ (MHz)}} \quad (\text{Eq. 3})$$

$$\text{Length (in)} = \frac{5904 \times K}{f \text{ (MHz)}} \quad (\text{Eq. 4})$$

Example: Find the length of a half-wavelength antenna at 28.7 MHz, if the antenna is made of 1/2-inch-diameter tubing. At 28.7 MHz, a half wavelength in space is

$$\frac{492}{28.7} = 17.14 \text{ ft}$$

from Eq. 1. The ratio of half wavelength to conductor diameter (changing wavelength to inches) is

$$\frac{(17.14 \times 12)}{0.5 \text{ in.}} = 411$$

From Fig. 3, K = 0.97 for this ratio. The length of the antenna, from Eq. 3 is

$$\frac{492 \times 0.97}{28.7} = 16.63 \text{ ft}$$

or 16 feet 7 1/2 inches. The answer is obtained directly in inches by substitution in Eq. 4

$$\frac{5904 \times 0.97}{28.7} = 199.5 \text{ inches}$$

The length of a half wavelength antenna is affected also by the proximity of the dipole ends to nearby conductive and semi-conductive objects. In practice, it is often necessary after cutting the antenna to the computed length to do some experimental "pruning" of the wire, lengthening or shortening it in increments to obtain a low

Fig. 3 — Effect of antenna diameter on length for half-wavelength resonance, shown as a multiplying factor, K, to be applied to the free-space, half-wavelength equation (Eq. 1 of text). The effect of conductor diameter on the center feed-point impedance is shown here also.

Fig. 4 — Response of a dipole antenna in free space, looking at the plane of the conductor, solid line. If the currents in the halves of the dipole are not in phase, some distortion of the pattern will occur, broken line. (Pattern calculation courtesy of "Annie.")

SWR. This can be done by applying RF power through an SWR indicator and observing the reflected-power reading. When the lowest SWR is obtained for the desired part of an amateur band, the antenna is resonant at that frequency. The value of the SWR indicates the quality of the match between the antenna and the feed line. With feed-line impedances of 50 or 75 ohms, the SWR at resonance should fall between 1.1:1 and 1.7:1 for antennas of average height that are clear of nearby conductive objects. If the lowest SWR obtainable is too high for use with solid-state rigs, a Transmatch or line-input matching network may be used, as described in Chapter 16.

### Radiation Characteristics

The classic radiation pattern of a dipole antenna is most intense perpendicular to the wire. A figure-8 pattern (Fig. 4) can be

\*Annie, a commercially available program for plotting antenna patterns on the Apple II series of computers, is available from Sonnet Software, Dept. QH, 4397 Luna Course, Liverpool, NY 13088.

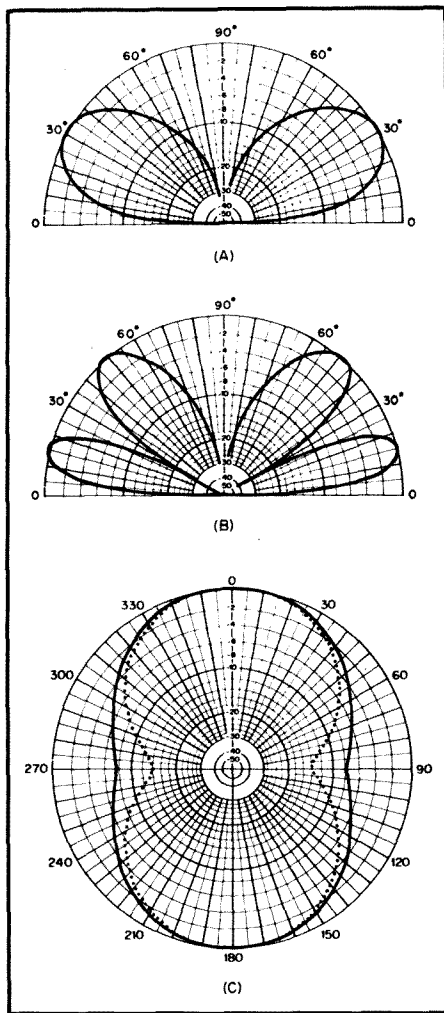

Fig. 5 — At A, elevation-plane response of a dipole antenna placed  $\frac{1}{2}$  wavelength above a perfectly conducting ground, and B, the pattern for the same antenna when it is raised to one wavelength height. C shows the azimuth patterns of the dipole for the two heights at the most favored elevation angle, the solid-line plot for the  $\frac{1}{2}$ - $\lambda$  height at an elevation angle of 30 degrees, and the broken-line plot for the  $1$ - $\lambda$  height at an elevation angle of 15 degrees. (Pattern calculation courtesy of "Annie.")

assumed off the broad side of the antenna (bidirectional pattern) if the dipole is  $\frac{1}{2}$  wavelength or greater above earth and is not degraded by nearby conductive objects. This assumption is based also on a symmetrical feed system. In practice, a coaxial feed line may distort this pattern slightly, as shown in Fig. 4. Minimum horizontal radiation occurs off the ends of the dipole. This discussion applies to a half-wavelength antenna that is parallel to the earth. If the dipole is erected vertically, however, uniform radiation in all compass directions will result in a doughnut pattern if it could be viewed from above the antenna.

Many beginners assume that a dipole antenna will exhibit a broadside pattern at any height above ground. In fact, as the antenna is brought closer to ground, the radiation pattern deteriorates until the antenna is, for the most part, an omnidirec-

Fig. 6 — Method for affixing the feed line to the center of a dipole antenna. A plastic block is used as a center insulator. The coaxial cable is held in place by means of a metal clamp.

Fig. 7 — Construction details for a folded-dipole antenna. TV ribbon line is used as the dipole and feed line. Two pieces of plastic form an insulator/sandwich at the center to hold the conductor junction secure. When ribbon line is used for the flat top, the two conductors should be shorted at about 82% of the distance from the feed point to the ends.

tional radiator of high-angle waves. Many are tempted to use any convenient height, such as 20 or 30 feet above ground, for an 80-meter dipole, only to learn that the system is effective in all directions over a relatively short distance (out to 500 or 1000 miles under good conditions).

It can be seen from this that height above ground is important for a host of reasons. Fig. 5 illustrates clearly the advantage gained from antenna height. The radiation angle of Fig. 5A is 30 degrees, whereas at a height of one wavelength (Fig. 5B) the lobes split and the lower ones provide a good DX-communications angle of 15 degrees. The directivity of the antenna at the two heights is shown in Fig. 5C. The solid line shows the azimuth pattern at a radiation angle of 30 degrees for a  $\frac{1}{2}$ - $\lambda$  dipole height, and corresponds to the plot in Fig. 5A. The broken line shows the pattern for a radiation angle of 15 degrees and a  $1$ - $\lambda$  height, corresponding to the plot of Fig. 5B. Fig. 5C illustrates that there is significant radiation off the ends of a low horizontal dipole, even at the most favored elevation angle. For the  $\frac{1}{2}$ - $\lambda$  height (solid line), the radiation off the ends is only 7.6 dB lower than that in the broadside direction.

The higher angle lobes of the pattern of Fig. 5B (50 degrees) are useful for short-haul communications and compare favorably in practice with the lobe angle

shown in Fig. 5A. At heights appreciably lower than  $\frac{1}{2}$  wavelength, the lobe angle becomes higher. Eventually the two lobes converge to create the discrete "ball of radiation" which has a very high-angle nature (poor for long-distance communications).

## Feed Methods

Most amateur single-wire dipole antennas (half wavelength) have a feed-point impedance between 50 and 75 ohms, depending on the installation. Therefore, standard coaxial cable is suitable for most installations. The smaller types of cable (RG-58 and RG-59) are satisfactory for power levels up to a few hundred watts if the SWR of the system is low. For high-power stations (RG-8 or RG-11) larger cables should be used.

These cables can be connected at the center of the antenna, as shown in Fig. 6. A plastic insulating block is used as central reinforcement for the cable and the dipole wires. The coax shield braid is connected to one leg of the dipole and the center conductor is soldered to the remaining leg. The exposed end of the cable should be sealed against dirt and moisture to prevent degradation of the transmission line.

Symmetrical feed can be obtained by inserting a 1:1 balun transformer at the dipole feed point. If one is not used, it is unlikely that the slight pattern skew resulting from nonsymmetrical feed will be noticed. The effects of unbalanced feed are most significant in beam antennas at VHF and higher. The narrower the beam pattern, the more annoying the condition will be.

The characteristic impedance of a dipole antenna can be increased by using a two-wire or folded dipole of the type shown in Fig. 7. This antenna offers a good match to 300-ohm TV ribbon. Alternatively, two pieces of wire can be used to form the equivalent of the TV-line dipole. If this is done it will be necessary to locate insulating spacers every few feet along the length of the dipole to keep the wires spaced apart uniformly and to prevent short circuiting. Open-wire TV ladder line is excellent for use in a 300-ohm folded dipole antenna, both for the radiator and the feed line. Feeder losses with this type of construction will be very low as opposed to molded TV twin-lead.

A dipole antenna can be used as an all-band radiator by using tuned open wire feed line. This principle is shown in Fig. 8A. In this example the dipole is cut to a half wavelength for the lowest desired amateur band. It is operated on its harmonics when used for the other chosen amateur bands. A typical antenna of this type might be utilized from 80 through 10 meters. This style of radiator is known by some amateurs as the center-fed Zepp. An end-fed version (end-fed Zepp) is shown in Fig. 8 at B. This version is not quite as

Fig. 8 — Center fed Zepp antenna (A) and an end-fed Zepp at B.

desirable as the center-fed version because the feed system is not symmetrical. This can cause feeder radiation and a distortion of the antenna radiation pattern.

Both types of Zepp antenna require a matching network (Transmatch) at the transmitter end of the line to convert the feeder impedance to 50 ohms, and to change the balanced condition to an unbalanced one. Although the feed line may be anything from 200 ohms up to 600 ohms (not critical), losses will be insignificant when open-wire line is used. This is true despite the variations in antenna feed-point impedance from band to band. The feed-point impedance for the dipole will be high at even harmonics and will be low at the lowest operating frequency and at odd harmonics thereof. For example, if the dipole is cut for 40 meters, the feed-point impedance will be low on 40 and 15 meters, but it will be high at 20 and 10 meters.

With a dipole antenna the feed line should be routed away from the antenna at a right angle for as great a distance as possible. This will help prevent current imbalance in the line caused by RF pickup from the dipole. A right-angle departure of  $\frac{1}{4}$  wavelength or greater is suggested.

Under some circumstances it may be necessary to experiment with the length of the open-wire feeders when using an all-band Zepp. This is because at some operating frequencies the line may present an "awkward" impedance to the Transmatch, making it impossible to obtain a suitable load condition for the transmitter. This will depend on the capability of the Transmatch being used.

#### Dipole Variations

The physical application of dipoles can be varied to obtain radiation properties that differ from those of the more conventional

Fig. 9 — Example of a sloping half-wavelength dipole. On the lower HF bands over poor to average earth, maximum radiation is off the sides and in the "forward direction" indicated here, if a nonconductive support is used. A metal support will alter this pattern by acting as a parasitic element, depending on its electrical height.

horizontal dipole. Furthermore, the nature and amount of property at the site will often dictate departures from the conventional means of erecting a dipole.

A sloping dipole can be useful for DX work on the lower HF bands because of its low angle of radiation. A sloping dipole is shown in Fig. 9. Excellent results can be had when the ground end of the antenna is only a few feet above the earth. When the antenna is supported with a nonconducting mast over poor to average earth, the radiation pattern tends to be cardioid shaped, but without a sharp null at the back. Maximum response is off the sides and in the "forward direction" as indicated in Fig. 9. The front-to-back ratio of the sloping dipole depends on the frequency and the conductivity of the earth, as well as the amount of slope and the vertical elevation angle of concern. Surprisingly, the sloping dipole becomes an omnidirectional radiator over a perfectly conducting earth.

If a metal mast or tower is used, it will alter the shape of the radiation pattern by acting as a parasitic element. Best results as a reflector seem to be obtained when the support is grounded and is approximately a quarter wave in physical height, supporting rotary beam or other antennas at the top. Some amateurs install four slopers for a given amateur band, spaced equidistantly around the tower. A feed-line switching system is used to obtain directivity in the chosen direction.

#### Drooping Dipole (Inverted V)

Another popular type of dipole antenna is the so-called inverted V, or drooping dipole. Because it has no characteristics of a true V antenna, the name inverted V is misleading. A drooping dipole is shown in Fig. 10. Newcomers to Amateur Radio are

Fig. 10 — At A, details for a drooping dipole which can be used for multiband HF operation. A Transmatch is shown at B, suitable for matching the antenna to the transmitter over a wide frequency range.

frequently led to regard this antenna as a panacea, but there is nothing magical or superior about a drooping dipole. In fact, its performance is inferior to that of a horizontal dipole at the same height as the apex. The main attribute is that it requires only one supporting structure. As with a horizontal dipole, it can be used for single or multiband operation.

Contrary to popular belief, the radiation off the ends of the drooping dipole is essentially no greater than that of a horizontal dipole at the same height as the apex. This myth probably arises because the drooping dipole is not an efficient radiator in the broadside direction, so it merely seems by comparison to its broadside performance that it is a good radiator off the ends. As is true of a horizontal dipole, the higher the drooping dipole is mounted above the ground, the better it will perform relative to low-angle, long-distance communications.

Best results are obtained when the enclosed angle of the drooping dipole is 90° or more. At angles less than 90°, considerable cancellation takes place, and reduced antenna performance results. At angles greater than 120° the antenna begins to function as a horizontal dipole.

When the ends of the drooping dipole are relatively close to the earth, pruning of the dipole legs may be necessary to compensate for the capacitive effect to ground.

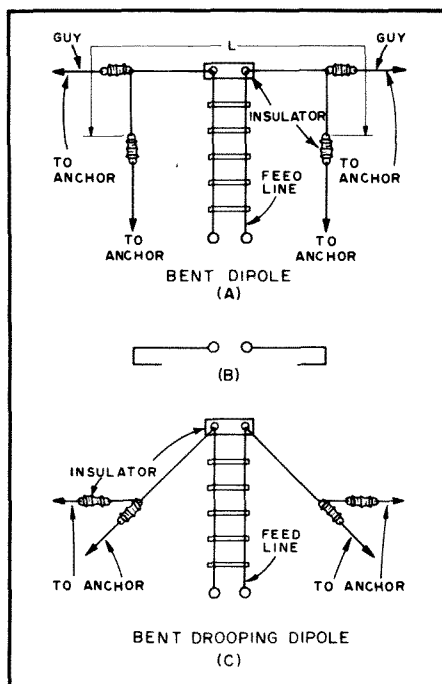

Fig. 11 — When limited space is available for a dipole antenna the ends can be bent downward as at A, or back on the radiator as shown at B. The drooping dipole at C can be erected with the ends bent parallel with the ground when the available supporting structure is not high enough to permit an enclosed angle of approximately 90°.

Thus, if the dipole is cut to length by means of the standard half-wavelength equation, it may be too long as a drooping dipole. Incremental trimming of each end of the dipole can be done while using an SWR indicator. This will show when the lowest SWR is obtained. A 50-ohm feed line offers a good match for drooping dipoles when single-band operation is desired. For multiband use, the antenna can be fed with open-wire line and matched to the transmitter with a Transmatch.

The most ideal supporting structure for a drooping dipole is a wooden or other nonconductive one. This type of support will have the least effect on the antenna pattern and performance.

Drooping dipoles are effective when used for a single band, the one for which it has been cut. Good results can also be had for two-band operation. An 80-meter dipole can be fed with open-wire line and used also on 40 meters as two half waves in phase. On 40 meters its performance at low radiation angles off the ends will be slightly superior to that of a 40-meter half-wave horizontal dipole at the same height as the apex.

#### Bent Dipoles and Trap Dipoles

When there is insufficient real estate to permit the erection of a full-size horizontal or drooping dipole, certain compromises are possible in the interest of getting an antenna installed. The voltage ends (far ends) of a dipole can be bent downward

Fig. 12 — Example of a trap dipole antenna. L1 and C1 can be tuned to the desired frequency by means of a dip meter before they are installed in the antenna.

toward earth to effect resonance, and the performance will not be reduced markedly. Fig. 11 illustrates the technique under discussion. At A the dipole ends are bent downward and secured to anchors by means of guy line. Some pattern distortion will result from bending the ends. The dipole ends can also be bent back over the wire halves of the antenna, as shown at B in Fig. 11. This causes some signal cancellation (more severe than with the system of Fig. 11A), so it is not a preferred technique.

Fig. 11C demonstrates a bending technique for drooping dipoles when the available supporting mast or tree is too short to permit normal installation. The ends of the dipole are guyed off by means of insulators and wires, as shown. Alternatively, but not preferred, is the fold-back method at B in Fig. 11.

All of the shortening systems highlighted in Fig. 11 will have an effect on the overall length of the dipole. Therefore, some cutting and testing will be necessary to ensure a low SWR in the favored part of the amateur band for which the antenna is built. If open-wire feeders and a Transmatch are used, the dipole length will not be critical, provided it is close to the length required for a fully extended half-wavelength dipole. Pruning will be required if single-band operation with coaxial feed line is planned.

Trap dipoles offer one solution to multiband operation with a shortened radiator. The concept is shown in Fig. 12. In this example the dipole is structured for two-band use. Assuming that the antenna is made for operation on 80 and 40 meters, the overall radiator (including the traps) must be resonant at the center of the chosen section of the 80-meter band. The traps add loading to the dipole, so the length from the feed point to the far end of each leg will be somewhat shorter than normal. During 40-meter operation the traps present a high impedance to the signal and divorce the wires beyond the traps. Therefore, the wire length from the feed point to each trap is approximately what it would be if the dipole were cut for just 40 meters, with no traps in the line.

This principle can be extended for additional bands, using a new set of traps for each band. Since there is considerable interaction between the various segments of a multiband trap dipole, considerable experimentation with the wire lengths between the traps and beyond will be necessary.

Fig. 13 — A helically wound dipole is illustrated at A. As shown, the radiation resistance will be very low and will require a broadband matching transformer. The coupling method shown at B is more satisfactory for providing a matched condition.

The trap capacitors (C1) should be high-voltage and high-current units. Transmitting mica capacitors offer good performance. Transmitting ceramic capacitors are usable, but change value with extreme changes of temperature. Therefore, they are more suitable for use in regions where the climate is fairly constant throughout the year. The coils (L1) should be reasonably heavy wire gauge to minimize  $I^2R$  losses. The  $X_L$  and  $X_C$  values in traps are not critical. Generally the reactance can be on the order of 100 to 300 ohms. The traps should be checked for resonance before they are installed in the antenna system. This can be done with a dip meter and a calibrated receiver. Weatherproofing should be added to the traps as a measure against detuning and damage from ice, snow and dirt.

#### Helically Wound Dipoles

The overall length of a half-wavelength dipole can be reduced considerably by using helically wound elements. Fig. 13A shows the general form taken with this type of antenna. A length of insulating rod or tubing (fiberglass or phenolic) is used to contain the wire turns of the dipole. The material should be of high dielectric quality. Varnished bamboo has been used successfully by some in lieu of the more expensive materials. A hardwood pole from

a lumber yard can be used after being coated one or more times with exterior spar varnish.

To minimize losses, the wire used should be of the largest diameter practical. The turns can be close-wound or spaced apart, with little difference in performance. The ends of the helical dipole should contain capacitance hats (disks or wire spokes preferred) of the largest size practical. The hats will lower the Q of the antenna and broaden its response. If no disks are used, extremely high RF voltage can appear at the ends of the antenna. At medium power levels and higher the insulating material can burn when no hats are used. The voltage effect is similar to that of a Tesla coil.

The feed-point impedance of helical dipoles or verticals is quite low. Therefore, it may be necessary to use some form of matching network to interface the antenna with 50-ohm coaxial cable. A broadband, variable-impedance transformer is convenient for determining the turns ratio of the final transformer used. The feed method shown at B of Fig. 13 can be used to obtain a matched condition. L2 is wound over L1, or between the two halves of L1, as illustrated. C1 is adjusted for an SWR of 1 at the center of the desired operating range. The bandwidth of this type of antenna is quite narrow. A 40-meter version with an 18-foot overall length exhibited a 2:1 SWR bandwidth of 50 kHz. The capacitance hats on that model were merely 18-inch lengths (whiskers) of no. 8 Copperweld wire. Greater bandwidth would result with larger capacitance hats.

To obtain half-wavelength performance it is necessary to wind approximately one wavelength of wire on the tubing. Final pruning can be done while observing an SWR indicator placed in the transmission line. Proximity to nearby conductive objects and the earth will have a significant effect on the resonance of the antenna. Ideally, final adjustments should be made with the antenna situated where it will be during use. Marine spar varnish should be painted on the elements after all tuning is finished. This will protect the antenna from the weather and will lock the turns in place so that detuning will not occur later.

A reasonably linear current and voltage distribution will result when using a helically wound dipole or vertical. The same is not true of center-, mid- or end-loaded (lumped inductance) dipoles. The efficiency of the helically wound antenna will be somewhat less than a full-size dipole. The performance will suffer as the helices are made shorter. Despite the gain-length trade-off, this antenna is capable of good performance when there is no room for a full-size dipole.

#### LONG-WIRE ANTENNAS

An antenna will be resonant so long as an integral number of standing waves of current and voltage can exist along its length; in other words, so long as its length

Fig. 14 — Standing-wave current and voltage distribution along an antenna when it is operated at various harmonics of its fundamental resonant frequency.

is some integral multiple of a half wavelength. When the antenna is more than one wavelength long it usually is called a long-wire antenna, or a harmonic antenna.

#### Current and Voltage Distribution

Fig. 14 shows the current and voltage distribution along a wire operating at its fundamental frequency (where its length is equal to a half wavelength) and at its second, third and fourth harmonics. For example, if the fundamental frequency of the antenna is 7 MHz, the current and voltage distribution will be as shown at A. The same antenna excited at 14 MHz would have current and voltage distribution as shown at B. At 21 MHz, the third harmonic of 7 MHz, the current and voltage distribution would be as in C; and at 28 MHz, the fourth harmonic, as in D. The number of the harmonic is the number of half waves contained in the antenna at the particular operating frequency.

The polarity of current or voltage in each standing wave is opposite to that in the adjacent standing waves. This is shown in the figure by drawing the current and voltage curves successively above and below the antenna (taken as a zero reference line), to indicate that the polarity reverses when the current or voltage goes through zero. Currents flowing in the same direction are in phase; in opposite directions, out of phase.

It is evident that one antenna may be used for harmonically related frequencies, such as the various amateur bands. The long-wire or harmonic antenna is the basis of multiband operation with one antenna.

#### Physical Length

The length of a long-wire antenna is not

Fig. 15 — Curve A shows the variation in radiation resistance with antenna length when the antenna is fed at a current maximum. Curve B shows power in the lobes of maximum radiation for long-wire antennas as a ratio to the maximum radiation for a half-wave antenna.

an exact multiple of that of a half-wave antenna because the end effects operate only on the end sections of the antenna; in other parts of the wire these effects are absent, and the wire length is approximately that of an equivalent portion of the wave in space. The formula for the length of a long-wire antenna, therefore is

$$\text{Length (feet)} = \frac{492 (N - 0.05)}{f \text{ (MHz)}}$$

where N is the number of half waves on the antenna.

Example: An antenna 4 half waves long at 14.2 MHz would be

$$\frac{492 (4 - 0.05)}{14.2} = \frac{492 (3.95)}{14.2} \\ = 136.9 \text{ feet, or } 136 \text{ feet } 10 \text{ inches.}$$

It is apparent that an antenna cut as a halfwave for a given frequency will be slightly off resonance at exactly twice that frequency (the second harmonic), because of the decreased influence of the end effects when the antenna is more than one-half wavelength long. The effect is not important, except for a possible unbalance in the feeder system and consequent radiation from the feed line. If the antenna is fed in the exact center, no unbalance will occur at any frequency, but end-fed systems will show an unbalance on all but one frequency in each harmonic range.

#### Impedance and Power Gain

The radiation resistance as measured at a current loop becomes higher as the antenna length is increased. Also, a long-wire antenna radiates more power in its most favorable direction than does a half-wave antenna in its most favorable direction.

Fig. 16 — Horizontal patterns of radiation from a full-wave antenna. The solid line shows the pattern for a vertical angle of 15°; broken lines show deviation from the 15° pattern at 9° and 30°. All three patterns are drawn to the same relative scale; actual amplitudes will depend on the height of the antenna.

Fig. 17 — Horizontal patterns of radiation from an antenna three half-waves long. The solid line shows the pattern for a vertical angle of 15°; broken lines show deviation from the 15° pattern at 9° and 30°. Minor lobes coincide for all three angles.

Fig. 18 — Horizontal patterns of radiation from an antenna 2 wavelengths long. The solid line shows the pattern for a vertical angle of 15°; broken lines show deviation from the 15° pattern at 9° and 30°. The minor lobes nearly coincide for all three angles.

This power gain is obtained at the expense of radiation in other directions. Fig. 15 shows how the radiation resistance and the power in the lobe of maximum radiation vary with the antenna length.

### Directional Characteristics

As the wire is made longer in terms of the number of half wavelengths, the directional effects change. Instead of the doughnut pattern of the half-wave antenna, the directional characteristic splits up into lobes which make various angles with the wire. In general, as the length of the wire is increased the direction in which maximum radiation occurs tends to approach the line of the antenna itself.

Directional characteristics for antennas  $1\lambda$ ,  $1\frac{1}{2}\lambda$ , and  $2\lambda$  are given in Figs. 16, 17 and 18 for three vertical angles of radiation. Note that, as the wire length increases, the radiation along the line of the antenna becomes more pronounced. Still longer antennas can be considered to have practically end-on directional characteristics, even at the lower radiation angles.

When a long-wire antenna is fed at one end or at the current loop closest to that end, the radiation is most pronounced from the long section. This unidirectional pattern can be accentuated by terminating the far end in a load resistance to ground. The load resistor will dissipate energy that would ordinarily be radiated toward the feed point. Depending on the pattern symmetry of the unterminated antenna, this resistor must handle up to half the power delivered to the feed point. The exact resistance must be determined empirically, but the voltage-to-current ratio at a current node is a good starting value. A quarter-wavelength wire beyond the resistor can serve as a pseudo ground for the system. Low-angle radiation from a long wire can be enhanced by sloping the wire down toward the favored direction.

### Methods of Feeding

In a long-wire antenna, the currents in adjacent half-wave sections must be out of phase, as shown in Fig. 14. The feeder system must not upset this phase relationship. This is satisfied by feeding the antenna at either end or at any current loop. A two-wire feeder cannot be inserted at a current node, however, because this invariably brings the currents in two adjacent half-wave sections in phase. A long-wire antenna is usually made a half wavelength at the lowest frequency and fed at the end.

### Long-Wire Directive Arrays

Two long wires can be combined in the form of a horizontal V, in the form of a horizontal rhombus, or in parallel, to provide a long-wire directive array. In the V and rhombic antennas the main lobes reinforce along a line bisecting the acute angle between the wires; in the parallel antenna the reinforcement is along the line of the lobe. This reinforcement provides both

gain and directivity along the line, since the lobes in other directions tend to cancel. When the proper configuration for a given length and height above ground is used, the power gain depends on the length (in wavelengths) of the wires.

Rhombic and V antennas are normally bidirectional along the bisector line mentioned above. They can be made unidirectional by terminating the ends of the wires away from the feed point in the proper value of resistance. When properly terminated, V and rhombic antennas of sufficient length work well over a three-to-one or four-to-one frequency range and hence are useful for multiband operation.

Antenna gains of the order of 10 to 15 dB can be obtained with properly constructed long-wire arrays. The pattern is rather sharp with gains of this order, however, and rhombic and V beams are not used by amateurs as commonly as they once were, having been displaced by the rotatable multielement Yagi beam. Further information on these antennas can be found in *The ARRL Antenna Book*.

### BEAMS WITH DRIVEN ELEMENTS

By combining individual half-wave antennas into an array with suitable spacing between the antennas (called elements) and feeding power to them simultaneously, it is possible to make the radiation from the elements add up along a single direction and form a beam. In other directions the radiation tends to cancel, so a power gain is obtained in one direction at the expense of radiation in other directions.

There are several methods of arranging the elements. If they are strung end to end, so that all lie on the same straight line, the elements are said to be collinear. If they are parallel and all lying in the same plane, the elements are said to be broadside when the phase of the current is the same in all, and end-fire when the currents are not in phase.

### Collinear Arrays

Simple forms of collinear arrays, with current distribution, are shown in Fig. 19. The two-element array at A is popularly known as a Franklin array, two half-waves in phase or a double Zepp antenna. It will be recognized as simply a center-fed dipole operated at its second harmonic.

By extending the antenna, as at B, the additional gain of an extended double Zepp antenna can be obtained. Carrying the length beyond that shown will result in an X-shaped pattern that no longer has the maximum radiation at right angles to the wire.

Collinear arrays may be mounted either horizontally or vertically. Horizontal mounting gives increased azimuthal directivity, while the vertical directivity remains the same as for a single element at the same height. Vertical mounting gives the same horizontal pattern as a single element, but improves the low-angle radiation.

Fig. 19 — Collinear antennas in phase. The system at A is known as two half waves in phase and has a gain of 1.8 dB over a half-wave antenna. By lengthening the antenna slightly, as in B, the gain can be increased to 3 dB. Maximum radiation is at right angles to the antenna. The antenna at A is sometimes called a double Zepp antenna, and that of B is known as an extended double Zepp.

Fig. 20 — Simple broadside array using horizontal elements. By making the spacing S equal to  $3/8$  wavelength, the antenna at A can be used at the corresponding frequency and up to twice that frequency. Thus when designed for 14 MHz it can also be used on 18, 21, 25 and 28 MHz. The antenna at B can be used on only the design band. This array is bidirectional, with maximum radiation broadside or perpendicular to the antenna plane (perpendicularly through this page). Gain varies with the spacing S, running from  $2\frac{1}{2}$  to almost 5 dB. (See Fig. 22.)

Fig. 21 — Top view of a horizontal end-fire array. The system is fed with an open-wire line at X and Y; the line can be of any length. Feed points X and Y are equidistant from the two insulators, and the feed line should drop down vertically from the antenna. The gain of the system will vary with the spacing, as shown in Fig. 22, and is a maximum at  $1/8$  wavelength. By using a length of 33 feet and a spacing of 8 feet, the antenna will work on 20, 17, 15, 12 and 10 meters.

Fig. 22 — Gain vs. spacing for two parallel half-wave elements combined as either broadside or end-fire arrays.

### Broadside Arrays

Parallel antenna elements with currents in phase may be combined as shown in Fig. 20 to form a broadside array, so named because the direction of maximum radiation is broadside to the plane containing the antennas. The gain and directivity depend on the spacing of the elements.

Broadside arrays may be suspended either with the elements all vertical or with them horizontal and one above the other (stacked). In the case of vertical elements, the horizontal pattern becomes quite sharp, while the vertical pattern is the same as that of one element alone. If the array is suspended horizontally, the horizontal pattern is equivalent to that of one element while the vertical pattern is sharpened, giving low-angle radiation.

Broadside arrays may be fed either by tuned open-wire lines or through quarter-wave matching sections and flat lines. In Fig. 20B, note the crossing over of the phasing section, which is necessary to bring the elements into proper phase relationship.

### End-Fire Arrays

Fig. 21 shows a pair of parallel half-wave elements with currents out of phase. This is known as an end-fire array because it radiates best along the plane of the antennas, as shown. The end-fire principle was first demonstrated by John Kraus, W8JK, and 2-element arrays of this type are often called "8JK" antennas.

The end-fire array may be used either vertically or horizontally (elements at the same height), and is well adapted to amateur work because it gives maximum gain with relatively close element spacing. Fig. 22 shows how the gain varies with spacing. End-fire elements may be combined with additional collinear and broadside elements to give a further increase in gain and directivity.

Either tuned or untuned lines may be used with this type of array. Untuned lines preferably are matched to the antenna through a quarter-wave matching section or phasing stub.

Fig. 23 — Unidirectional two-element end-fire array and method of obtaining 90° phasing.

### Unidirectional End-Fire Arrays

Two parallel elements spaced  $\frac{1}{4}$  wavelength apart and fed equal currents 90° out of phase will have a directional pattern in the plane of the array at right angles to the elements. The maximum radiation is in the direction from the element in which the current lags. In the opposite direction the fields from the two elements cancel.

One way in which the 90° phase difference can be obtained is shown in Fig. 23. Each element must be matched to its transmission line, the two lines being of the same type except that one is an electrical quarter wavelength longer than the other. The length  $L$  can be any convenient value. Open quarter-wave matching sections could be used instead. The two transmission lines are connected in parallel at the transmitter coupling circuit.

When the currents in the elements are neither in phase nor 180° out of phase the radiation resistances of the elements are not equal. This complicates the problem of feeding equal currents to the elements. If the currents are not equal, one or more minor lobes will appear in the pattern and decrease the front-to-back ratio. The adjustment process is likely to be tedious and requires field-strength measurements in order to get the best performance.

More than two elements can be used in unidirectional end-fire arrays. The requirement for unidirectivity is that there must be a progressive phase shift in the element currents. The shift must equal the spacing between the elements in electrical degrees, and the current amplitudes also must be properly related. This requires binominal current distribution — i.e., the ratios of the currents in the elements must be proportional to the coefficients of the binominal series. In the case of three elements, this requires that the current in the center element be twice that in the two outside elements, for 90° (quarter-wave spacing and element current phasing. This antenna has an overall length of  $\frac{1}{2}$  wavelength.

### Combined Arrays

Broadside, collinear and end-fire arrays

Fig. 24 — A four-element combination broadside collinear array, popularly known as the lazy-H antenna. A closed quarter-wave stub may be used at the feed point to match into an untuned transmission line, or tuned feeders may be attached at the point indicated. The gain over a half-wave antenna is 5 to 6 dB.

may be combined to give both horizontal and vertical directivity, as well as additional gain. The lower angle of radiation resulting from stacking elements in the vertical plane is desirable at the higher frequencies. In general, doubling the number of elements in an array by stacking will raise the gain from 2 to 4 dB, depending on the spacing.

Although arrays can be fed at one end as in Fig. 20B, it is not especially desirable in the case of large arrays. Better distribution of energy between elements, and hence better overall performance, will result when the feeders are attached as nearly as possible to the center of the array.

A 4-element array, known as the lazy-H antenna, is a popular configuration. This arrangement is shown with the feed point indicated, in Fig. 24. (Compare with Fig. 20B.) For best results, the bottom section should be at least a half wavelength above ground.

It will usually suffice to make the length of each element equal to that given by the dipole formula. The phasing line between the parallel elements should be of open-wire construction and its length can be calculated from:

Length of half-wave line (feet)

$$= \frac{480}{f \text{ (MHz)}}$$

Example: A half-wavelength phasing line for 28.8 MHz would be

$$\frac{480}{28.8} = 16.67 \text{ feet} = 16 \text{ feet } 8 \text{ inches}$$

The spacing between elements can be made equal to the length of the phasing line. No special adjustments of line or element length or spacing are needed, provided the formulas are followed closely.

### THE VERTICAL ANTENNA

One of the more popular amateur antennas is the vertical type. With this style of antenna it is possible to obtain low-angle radiation for ground-wave and DX work.

Fig. 25 — Radiation resistance (solid curve) and reactance (dotted curve) of vertical antennas as a function of physical height.
